After the last collar, the extendibility test asks for an extension of the common exterior coarse field over the main box in the component problem. If this passes, the Haar refresh uses the box coins and keeps the old variables for the prepared datum. The same component frame fixes both trees and the entrance root, so the tree gauge gives the same shell variables. The main fluctuation test reads the resulting field in the prepared shells, and the last-shell test reads the innermost stored field with its prescribed identity data. The localized reference law has the same exterior, frame, tree slice and cutoff in the two runs. Its denominator is the integral of that same density on the same slice, so the draw and any denominator failure agree. The test of $\chi_j(X^{\sim -6})$ is made on the newly drawn field in the inset test cubes. Its full local test neighbourhoods stay in X. Thus the healing decision agrees. The subsequent deletions or inert declarations, the rotation on the healed branch and the label update are functions of the common record and the component coins. Every bond in the final deep region either meets one of these common components or is unchanged. The common surviving labels specify which lower slots remain. This is the induction output at level j.

For the induction on the actual run we must verify that any alternative stage or main-step chart still reads the same incident rows and masks just identified. This is the local-read input to the witness construction below. A sharp test centred on a global determining set of earlier outcomes requires a separate comparison.

If there is a trigger, take its first level J. The preceding survival record is common. At J use the first kind of trigger if it occurs, since the truncated bad components are already common. Otherwise the split comparison gives the common second kind of trigger. Along a cluster path starting at its outer end, mark the first cells reaching successive index radii $3(c_{\mathrm{adj}}(J)+1)(i-1)$, $1 \le i \le m(J)$. From the initial cell one of the diameter endpoints is farther than $m_0(J)/2$. Take a path to it. Its bounded steps give a pattern of $m(J)$ cells, mutually separated by at least $2c_{\mathrm{adj}}(J)+3$. Choose the cluster and the path by a fixed order of cells in the tile. The choice uses only the common data at the first trigger. For a marked cell e, a bad domain or a failed full test puts a cell of Z_J in e^{+2}. The remaining hot kind is warm whenever e^{+2} contains no Z_J-cell. Thus the pattern event is that each mark has a cell of Z_J within two cells or is isolated and warm. For a deep cell z whose lineage survives from n to k, every completion of the tile data has the same survival decisions below J and the marked alternative at J. The status of an individual mark as isolated may vary with the exterior. With no trigger, the decisions agree through k by the same induction on the verified local

reads. These assertions use the split windows only for the original run. Under the local-read input the two types of events give witness sets in the sense of §5.20.2.4. Apply the no-window bound eq. 5.cdxxi, then take the union over witnesses in each tile and use eq. 5.cdxxii for the resulting products.

Keep the tiles whose indices relative to the original tile are even in all four coordinates. The marks in their e^{+2} neighbourhoods are disjoint. In each replica classify each marked cell as isolated and warm, or choose a cell of Z_J within two cells of it. The warm-cell bound can be peeled relative to the event for these chosen cells and the survival columns. The remaining event reads the regions and lineages unchanged by varying the free variables of an isolated box. Every warm mark thus pays $q_a^{r_J}$.

Classify the chosen cells and the column, if $J > n$, by fate. Group objects absorbed by the same healed component and specify its healing level $h \geq J$. Index the component by the level-h parent of its first object. Its lineage at J must contain exactly the level-J cells of that group among the chosen objects. For a group carrying the column, also require its lineage to contain every prescribed column cell at levels $n, \dots, J-1$. These restrictions allow the relative healing bound to be applied once per distinct component. A group with d chosen marks pays $r_J d$ units of the exponent. It has a cell at each level in $(J, h]$, which pays a further $h - J$ units. A column pays one unit per level in $[n, J-1]$. The column's top is used to specify its fate and is not charged as a second mark if it is already a chosen cell. No healed component serves different replicas. Even after moving to nearby chosen cells and projecting to the healing grid, their separation across an intervening tile is at least $\ell_\square - 6s_k > n_{\mathrm{sm}} s_k$. Apply eq. 5.cdxviii once to the surviving marks and columns in all replicas, so there is a single volume factor. Each replica has at most $m+1$ objects. The choices of nearby cells and the group labels cost at most $(C(m+1))^{m+1}$; summing the healing times costs at most $(1-q_a)^{-(m+1)}$. The cost per replica is at most

$$v_{J,\mathbf{e}} = \big(C(m+1)(1-q_a)^{-1}\big)^{m+1} q_a^{(J-n)_+ + r_J m}.$$

This includes the sum over absorption times. The pure-survival alternative has cost $v_{\mathrm{I}} = q_a^{\sum_{j=n}^{k} r_j}$. The whole replicated probability carries only the single factor $e^{B(x_k)V_k}$.

The tile grid has even side count in each coordinate. In the chessboard dissemination, the copies in the even-index class are pure translates, since two face reflections restore the orientation in that coordinate. Integrate the independent coins before dissemination. On the kept tiles, restore the coin integral using eq. 5.cdxxii. By translation covariance of the run, each witness cylinder forces its translated event almost surely. Dropping the other copies, which lie in $[0,1]$, therefore bounds the product by the probability of the replicated events. The chessboard root is of order $|\mathcal{T}|$ and the even-index class has $|\mathcal{T}|/16$ tiles. Consequently the chessboard norm of a witness is at most

$$e^{B(x_k)\ell_\square^4} v_{\mathfrak{w}}^{1/16}.$$

There are at most $\ell_\square^4 L^{4(k-J)}(m_0(J)+1)^{4(m-1)}$ patterns at level J. To bound the pattern count, put $u = x_k + k - J + C_*$ with C_* fixed. The flow gives $N_J = \check{R}_J \leq C(\log u)^r$. The inverse coupling at any level in the range defining $\bar{p}_J$ is at most $C(u + (\log u)^r) \leq C'u$, so $\log \bar{p}_J \leq C(1 + \log\log u)$. Also $\log \ell_\square \leq C(1+\log\log u)$. The displayed formula for D_J now gives $D_J \leq C(1+k-J+(\log u)^r)$. Using $f_J \leq C(1+D_J)$, we obtain

$$m_0(J) \leq C(1+k-J)(1+k-J+(\log u)^r) \leq Cu^2.$$

The lower flow bound gives $r_J \geq cM^4(\log u)^{5r}$ after choosing the coupling ceiling. Apart from the starting position factor $\ell_\square^4 L^{4(k-J)}$, the logarithms of the enumeration and absorption factors are at most $Cm(J)\log u$. Half the surplus $(r_J - 1)m$ pays this pattern count and its absorption prefactor. The remaining half supplies the factor $\widehat{q}^{(r_k-1)/2}$. Also

$$(J-n)_+ + m \geq (k-n+1) + (k-J).$$

Choose $c_a \geq 16\log(2L^4)$. Then $\sum_{J\leq k}(L^4\widehat{q})^{k-J} \leq 2$. Finally $r \geq 2$ gives $5r > 4r+1$, so, by taking the ceiling small, the single-level surplus pays $\ell_\square^8 e^{B(x_k)\ell_\square^4}$, C_{win}, and any fixed requested extra factor ϵ. The witness sum is therefore at most $\ell_\square^{-4}\widehat{q}^{\,k-n+1}$; the sum for an additional tile's deep level-k live cell is at most ϵ. Their product proves the two bounds of Lem. 5.72.

For the first bound the anchor can be anywhere in the torus. When the tiling exists, shift it by level-k cells so the level-k parent of the anchor lies in the central cell of its tile. The tile side and cell side are powers of the odd integer L, so the central cell is well defined and the shift is allowed. The side of the stopped lattice is twice a power of L, so whenever it is at least $2\ell_\square$, the tile count per side is even. If the torus is too small to contain this tiling, then $V_k \leq (2\ell_\square)^4$. On survival, $\Theta_k \geq 2c_a r_k(k-n+1)$. The same surplus comparison gives

$$B(x_k)V_k \leq c_a r_k, \qquad e^{B(x_k)V_k - 2c_a r_k(k-n+1)} \leq \ell_\square^{-4}\widehat{q}^{\,k-n+1}.$$

Thus the first bound follows directly from the stopped moment on every admitted prefix, without a tiling. Only the joint-tile statement requires actual tiles. The argument concerns survival and hence lineage age; it does not assign an age penalty to a seed that was healed before the lineage began.

Proof of Prop. 5.71. Anchor: choose any cell $\mathfrak{z}$ of the lineage region $\mathsf{Z}_n(C)$ at the first level $n = j_0 = k-a$ of the lineage. The lineage regions are nested and contained in the live regions. Hence $\mathfrak{z}$ stays live throughout the levels $n,\dots,k$, so that the event $\mathcal{E}_{\mathfrak{z}}^{(n)}(k)$ occurs, and the cell belongs to the component of $\mathfrak{c}$. This is the point at which the age of the lineage enters: a region healed in the meantime provides no such cell. *Sum over anchors:* a box of side $\mathsf{l}_\square$ contains at most $\mathsf{l}_\square^4 L^{4(k-n)}$ anchors, and each costs $\mathsf{l}_\square^{-4} q_a^{c(k-n+1)}$. For an anchor at a distance of $i \geq i_0$ boxes, the live component is connected and therefore passes through a chain of at least i distinct adjacent boxes, each of which contains a live cell. These cells need not be deep. Consider the 2^4 tilings whose face planes are displaced by $\pm\lfloor n_\square/4\rfloor$ cells from a corner of the level-k cell containing $\mathfrak{z}$, where $n_\square \geq 16$ is the number of level-k cells along a side of a tile. Every level-k cell is deep in a tile of one of these tilings, and $\mathfrak{z}$ is deep in all of them. By the pigeonhole principle a single tiling serves at least $i/16$ of the cells. These cells lie in at least $i/16^2$ distinct tiles, since a tile meets at most 2^4 boxes, and at least i/i_0 of these tiles, where $i_0 = 2\cdot 16^2$, are different from the tile of $\mathfrak{z}$. For a fixed reference chain, the choice of a shift, the subset of its indices served by that shift and the choice of one of at most 2^4 shifted tiles per index cost at most $16\cdot 2^i\cdot 2^{4i}$ choices. The chain itself has at most 3^{4i} choices. The second bound of the lemma sums the deep-cell positions inside the selected tiles. Hence with $C_{\mathrm{ent}} = 2^5 3^4$ and $\epsilon = (2C_{\mathrm{ent}})^{-i_0}$, the additional factor for such an anchor is at most $16\,C_{\mathrm{ent}}^i \epsilon^{i/i_0} = 16\cdot 2^{-i}$, which is summable against the $(2i+3)^4$ boxes of a shell. Finally $L^4 q_a^c \leq (2L^b)^{-2}$, and this is exactly the floor $c_a \geq C(b)\log L$ imposed in the statement of the proposition. Therefore $\tilde{\nu}(\mathfrak{lb}_k^{=a}(\mathfrak{c})) \leq C(2L^b)^{-2a}$. The geometric mean of this bound and that of Prop. 5.70 is the first bound. Summing it gives the age series

$$\sum_{a\geq 0} L^{ba}\,\tilde{\nu}(\mathfrak{lb}_k^{\geq a}(\mathfrak{c})) \leq Ce^{-cp_0(g_k)},$$

which two later parts use. In §6.1.1.2 the series is needed with rate $b \geq 8$, because for two points a live component of age a carries a weight of up to L^{8a}; there the series underlies the two-point law, Thm. A (c)(3), (c)(4). In Thm. A(c)(5) the series enters with rate $b > 16$, on each torus, since a weight L^{16a} arises for four points; this concerns clause (c)(5). The expansions of §6.1.1.2 and Thm. A(c)(5) require the age up to which a live component stores fields. This is the age read in the label. For a component holding an island, the block of which retains the fields of its core §4.17.1.3, it is at most the age of the lineage. Here, as in Thm. A(c)(5), the series is formulated with the age of the lineage, and this age is never smaller. The series therefore covers what these expansions require:

$$\{\mathfrak{c} \subset C,\, \mathrm{age}^{\mathrm{lab}}(C) \geq a\} \subset \mathfrak{lw}_k^{\geq a}(\mathfrak{c}).$$

For the second bound, each old live cell is carried into its whole parent cell at the next scale until its component is healed. A merge retains its lineage through that level. Thus if $\mathfrak{c}$ has lineage age a at level k and survives through K, its parent at level K has lineage age at least $a + K - k$. Sum the first bound at K over these terminal ages.

The two-term age bound. The prepaid trace bounds give a second age estimate on the tori without using the tiles and windows of Lem. 5.72. Decompose the event according to whether the lineage is healed at some level $j > k$ or stays live to the last level K' of the run or its prolongation. Fix $c_a > 0$ and choose the coupling ceiling small enough for the estimates below.

The event is empty if $k - a < 1$. For $j \geq k$ write $\mathfrak{c}^{(j)}$ for the cell at level j containing $\mathfrak{c}$. For a top X at level j, let $\mathscr{G}_X$ be the traces with first level $1 \leq j_0 \leq k - a$. If the component at $\mathfrak{c}$ is carried into X, its lineage up to level k lies in the lineage of X. On $\mathfrak{lw}_k^{\geq a}(\mathfrak{c})$ this puts the trace of X in $\mathscr{G}_X$. Every level from j_0 through j contributes a cell to the lineage. At $\mathsf{w} = 0$ the mark is therefore at least $\bar{c}_a(a + j - k + 1)$, where $\bar{c}_a = 2c_a M^4$. The prepaid trace bound in the proof of Prop. 5.70 gives

$$\sum_{\mathfrak{l} \in \mathscr{G}_X} \mathrm{wt}(\mathfrak{l}) \leq e^{-\bar{c}_a(a+j-k+1)} e^{-c_{\mathrm{cell}}|X|_j} e^{-2\min_{1 \leq i \leq k-a} p_0(g_i)}.$$

We fix c_{cell} before choosing the coupling ceiling.

Survival to the terminal level. For each history in the survival event distinguish the unique terminal component containing the cell $\mathfrak{c}^{(K')}$. Group the histories by their terminal traces. Positivity and the mass bound at fixed traces bound the unnormalized mass, after removing $e^{E_{(K')}}$, by

$$e^{C|\mathbb{T}^{(K')}|} \left[\sum_{X \ni \mathfrak{c}^{(K')}} \sum_{\mathfrak{l} \in \mathscr{G}_X} \mathrm{wt}(\mathfrak{l}) \right] \left[\sum_{\mathscr{C}} \prod_{Y \in \mathscr{C}} \sum_{\mathfrak{l}:\, \mathrm{top} = Y} \mathrm{wt}(\mathfrak{l}) \right].$$

Here X ranges over connected terminal cell unions, and $\mathscr{C}$ over collections of distinct such unions. For the second bracket we drop the exclusion with the distinguished component. Choose c_{cell} so that the sum of $e^{-c_{\mathrm{cell}}|X|_{K'}}$ over connected sets containing a given cell is at most one. The first bracket is then at most $e^{2 - 2p_0(g_k) - \bar{c}_a(a + K' - k + 1)}$, by the drift $p_0(g_i) \geq p_0(g_k) - 1$ for $i \leq k$. For the second bracket the unrestricted trace bound gives total activity at most one per cell. The product bound $1 + z \leq e^z$ then gives at most $e^{|\mathbb{T}^{(K')}|}$, since the number of cells is bounded by the number of sites. Divide once by the partition function floor at K', using $\mathsf{B}(x_{K'})$ to absorb both volume charges and the floor. For a prolongation by p levels on the same bare lattice, the number of terminal sites is $(\ell L^{-p})^4$, and the history law through level k is the same. A Markov bound on the global end mark alone would lose the factor $e^{-2p_0(g_k)}$.

Healing at level $j > k$. Use the outer-operation domination of the relative healing comparison above. Inside the bracket, deletion of the healed member with top X costs at most its restricted trace sum times $e^{C_I \check{R}_j^4 + C}$. A healed top is an aligned box of at most n_{sm} cells per side, so at most $(\sum_{n=1}^{n_{\mathrm{sm}}} n)^4$ such boxes contain $\mathfrak{c}^{(j)}$. Discard the rooted size charge and split the oldest creation payment using the drift to g_k and g_j. For $0 < c_{\mathrm{r}} < 1/2$ the exponents allocated to these scales are $c_{\mathrm{r}} p_0(g_k)$ and $(2 - c_{\mathrm{r}}) p_0(g_j)$, up to an additive constant. The ceiling gives $C_I \check{R}_j^4 \leq (1/2 - c_{\mathrm{r}}) p_0(g_j)$. The probability at this healing level is bounded by

$$C e^{-\bar{c}_a(a+j-k)} e^{-c_{\mathrm{r}} p_0(g_k)} e^{-3p_0(g_j)/2}.$$

The flow lower bound gives a bounded number of visits to any x_j-interval of length $\lambda_\sharp$, and the ceiling gives $e^{-3p_0(g_j)/2} \leq x_j^{-3}$. Thus the last factor is summable in j, uniformly in the run. This yields the first term of the bound without using the terminal partition function floor.

In particular, for each level-k cell $\mathfrak{c}$ and $a \geq 0$,

$$\tilde{\nu}\big(\mathfrak{lv}_k^{\geq a}(\mathfrak{c})\big) \leq Ce^{-\bar{c}_a a}\, e^{-cp_0(g_k)} + C\exp\Big[\mathsf{B}(x_{K'})\,|\mathbb{T}^{(K')}| - 2p_0(g_k) - \bar{c}_a\,(a + K' - k + 1)\Big],$$

where $K' \geq K$ is the last level of an arbitrary prolongation of the run § 5.2.4, the run itself counting as one of its prolongations. The first term contains no volume, and no condition ties k, a, K and ℓ together. The consequences of the bound follow from its second term, case by case; none of the cases is a hypothesis of any statement. (1) There is a side $\ell_V(g)$, tending to infinity as $g \to 0$, with the following property. For every torus with $\ell \leq \ell_V(g)$, the prolongation of (iv) terminates in the alternative where the torus is reduced to polylogarithmic size. In that case the gain $2p_0(g_k)$, of degree $\mathfrak{p}_0$ in the logarithm, dominates the volume term, of degree $4r + 1$. The bound is then $Ce^{-\bar{c}_a a}e^{-cp_0(g_k)}$ at every level. (2) The last lattice of the reference torus $T_{\ell_\star(g)}$ of Prop. 6.3 has polylogarithmic size even without prolongation. Hence that torus satisfies the same bound at all levels. (3) If $\ell > \ell_V(g)$, the torus satisfies the same bound at those levels at which $\bar{c}_a(K' - k + 1) \geq \mathsf{B}(x_{K'})|\mathbb{T}^{(K')}|$. This is a floor on the depth that depends on the torus; once it is met at one level, it is met at every lower level. At all of these levels, if $\bar{c}_a \geq b\log L + \log 2$, summing the bound gives the age series at the rate b. Thus this road alone supplies what §6.1.1.2 uses, namely the age series at the rate $b \geq 8$, at all levels of the reference torus, as used in Thm. A (c)(3), (c)(4). For Thm. A(c)(5) it supplies the series at $b > 16$ on each torus. On the tori of (1) it holds at all levels; on the tori of (3) it holds at the levels below one that depends on ℓ. The additional four-point hypothesis in the short-distance statement has exactly this quantifier structure: $\mathsf{d} \leq \mathsf{d}_4$ if $\ell \leq \ell_4(g)$, and $\mathsf{d} \leq \mathsf{d}_4(\ell)$ otherwise, where $\ell_4(g) := \max\{\ell_V(g), \ell_\star(g)\}$. The contribution of Lem. 5.72, through its tiles, windows and triggers, is decay at all levels and on all tori, with constants independent of ℓ. This is uniformity as $\ell \to \infty$. The same age threshold therefore works on every torus. Passing a four-point estimate to limits on $\mathbb{R}^4$ additionally requires the actual normalized interacting comparison and its $o(g^8)$ remainder, with the prescribed test factors, uniformly along the volume and cutoff limits; see eq. 6.ccxxxiii. These further inputs are not deduced here. The torus and additional-hypothesis restrictions in Thm. A(c)(5) remain in force.

The age constant. In §4.17.1.45 two roles of c_a are described; the one at work here is role (A), the dial of the mark. Its effect on the law of the histories is $C(2L^b)^{-a-(K-k)}$. Role (B), the age rate q_a of the aged load Σ_k, concerns the pairs of lists belonging to a class of the kind given there §4.17.1.45, and it is used in appendices A.8 and A.9. The floors on c_a listed in §4.17.1.45 concern histories, rotations and age-resolved rarity. Prop. 5.71 imposes the third of these.

Cutoffs beyond first passage. The dilation identity of § 5.2.4 gives

$$S^T_{n;K,\ell,\beta}(f_1,\dots,f_n) = S^T_{n;K-q,\,L^q\ell,\,\beta}(f_1^{[q]},\dots,f_n^{[q]}),$$
$$\|f^{[q]}\|_\sharp \le \|f\|_\sharp,$$

since $\mathcal{O}$ carries no power of the spacing. The same relation holds between $\mathbb{L}_K$ and $\mathbb{L}_{K-q}$. Let $\beta \ge g^{-2} + B_\sharp$ and $q \ge 0$, and suppose that $K - q = K(\beta, g)$. The bounds of Prop. 5.64 are then valid at the cutoff K, with $(L^q\mathsf{d}; L^qR; L^q\ell)$ in place of $(\mathsf{d}; R; \ell)$.

5.21. **Stability from a normalized history sum.** This is a conditional deduction of upper stability and the unsourced partition floor. It isolates the estimates a renormalization construction must supply. In particular it does not replace those estimates by a polymer convergence theorem. A representation with a sum over large-field labels and label-dependent integral operations need not be a single coarse Wilson integral multiplied by one uniformly small polymer gas.

Let the final four-dimensional periodic lattice have N sites and $4N$ independently oriented bonds. Haar measure on each SU(2) bond is normalized. Let w range over a specified ordinary complex source neighborhood containing zero. Assume there are complex measures $\tau_S(w)$, indexed by a finite set of labels, such that

$$Z(w) = \sum_S \tau_S(w)(\mathcal{V}), \qquad \tau_S(0) \ge 0. \tag{5.cdxxiii}$$

Assume all normalizers and scalar quantities below are well defined; E is the real vacuum constant of the unsourced all-small-field label. Put

$$\mathcal{E}(w) = \sum_{j,X} e_j(X; w), \qquad \mathcal{E}(0) = 0, \qquad \widetilde{Z}(w) = e^{-E-\mathcal{E}(w)} Z(w).$$

At each finite cutoff the sums are finite. The argument requires their locality and uniform estimates; it uses no sum over cutoffs.

A total-variation criterion for upper stability. Let $\mathcal{E}_S(w)$ denote the vacuum constant in the exponent of the term carrying label S. Suppose there are nonnegative weights W_S and real label costs $q(S)$ satisfying

$$\|e^{\mathcal{E}_S(w)}\tau_S(w)\|_{\mathrm{TV}} \le W_S, \qquad \mathrm{Re}[-E - \mathcal{E}(w) - \mathcal{E}_S(w)] \le C_0 N + q(S), \tag{5.cdxxiv}$$

and the weighted label bound

$$\sum_S e^{q(S)} W_S \le e^{C_1 N}. \tag{5.cdxxv}$$

The constants are independent of cutoff, volume and w in the specified source neighborhood. Then

$$|\widetilde{Z}(w)| \le e^{(C_0+C_1)N}. \tag{5.cdxxvi}$$

Indeed multiply each measure in eq. 5.cdxxiii by the common normalization, insert and remove its own $e^{\mathcal{E}_S(w)}$, take total variations, apply eq. 5.cdxxiv, and sum by eq. 5.cdxxv. This proof takes no logarithm of $Z(w)$ and asserts no absence of its complex zeros.

In a history construction, W_S is obtained by bounding the unsourced integrations after inserting a reserve factor such as $e^{cv(\omega)}$ on every local history. The ordinary source changes an island exponent by an extensive amount, $|\Psi_\omega(w)| \le C_r\, n(\omega)$, where sites are counted in their own scales. A sufficient reserve is $cv(\omega) \ge C_r n(\omega)$, uniformly in the history and the exterior arguments. This is an ordinary mass reserve for one presentation, and is distinct from estimates comparing marked or weighted derivatives of two different presentations.

It is essential that the majorant used for each component be a function of its own integration variables. A bound on its integral at each fixed exterior field is insufficient in a coupled product. For example, let both component factors be $f_1(x,y) = f_2(x,y) = \mathbf{1}_{|x-y|<\epsilon}$ on $[0,T]^2$. Each integral

of a factor in its own variable is at most 2ϵ, whereas the double integral of their product has order ϵT, not ϵ^2. A bound with the supremum over the admissible exterior pair *inside* the local integral supplies a component majorant; Tonelli then permits multiplication when the integration-variable groups are disjoint. The construction must also specify which Wilson factors are allotted to those majorants. An operation with no Wilson factor of its own has no independent plaquette-tail gain.

Neither eq. 5.cdxxiv nor eq. 5.cdxxv is a consequence of the last triangle inequality. They encode ordinary renormalization estimates: suppression of creation events, control of their genealogies, the allocation of Wilson and Gaussian factors without reuse, and payment of the missing vacuum normalizers of every large-field label. In particular, estimates with the volume of each fine lattice cannot simply be summed to obtain a bound with the volume N of the final lattice.

The floor from one positive label. Let $x \geq 1$ be the last inverse coupling and set $r = cx^{-1/2}$ with a fixed $0 < c \leq 1$. Write

$$\mathcal{B}_r = \{V : \|V_b - 1\|_{\mathrm{op}} < r \text{ for every bond } b\}.$$

Suppose the all-small-field label S_0 has a density with respect to final product Haar measure satisfying

$$d\tau_{S_0}(0)(V) \geq e^E \chi(V) \exp[-x\mathcal{A}(V) - C_I N]\, dV, \quad \chi = 1 \text{ on } \mathcal{B}_r, \quad \mathcal{A}(V) \leq C_A r^2 N \text{ on } \mathcal{B}_r. \tag{5.cdxxvii}$$

Here $\mathcal{A}$ may be the action of a minimizing background. If so, inclusion in the characteristic set and the displayed action bound are background estimates which must be verified; they do not follow merely by renaming $\mathcal{A}$ as a coarse action.

For normalized Haar measure there is an absolute $c_H > 0$ such that the operator-norm ball of radius $r \leq 1$ about the identity has measure at least $c_H r^3$. To prove this write $U = \cos\theta\, 1 + i \sin\theta\, n \cdot \sigma$, so $\|U - 1\|_{\mathrm{op}} = 2\sin(\theta/2)$ and normalized Haar measure is $(2\pi^2)^{-1} \sin^2\theta\, d\theta\, d\Omega(n)$. The interval $0 \leq \theta \leq r$ lies in this ball. Since $\sin\theta \geq 2\theta/\pi$ on $[0, 1]$, its measure is at least $8r^3/(3\pi^3)$. Decreasing the constant handles the irrelevant choice of an open instead of a closed ball.

Positivity in eq. 5.cdxxiii permits restriction to S_0, then to $\mathcal{B}_r$. Independence of the $4N$ Haar bonds gives

$$\begin{aligned} e^{-E} Z(0) &\geq e^{-(C_I + C_A c^2)N} (c_H c^3 x^{-3/2})^{4N} \\ &\geq \exp[-(C + 6\log x)N]. \end{aligned} \tag{5.cdxxviii}$$

Since $\mathcal{E}(0) = 0$, this is the required floor for $\widetilde{Z}(0)$. The constant depends on the fixed choices and on C_I, C_A, but not on cutoff or volume.

5.21.0.1. The terminal tests on a product of link balls. For the all-small-field label at the terminal level $n = K$ the determining sequence on the torus is constant. Its only data are the final bonds V. Its final label has no standing regions. The invariant form of the step gives the density

$$\chi_n(T_\ell)\, \exp\{E - x_n A(U_n(V)) + F_n(U_n(V))\}\, dV.$$

The equality of E with minus the empty label's vacuum sum holds at this depth. The pointed regular estimate on the all-small-field label has only one layer, at level n. For the level-j family let $h = n - j$. The tents at all its base points sum to one. Subtract its vacuum value and the corresponding tent-action term. The constant-strength cancellation gives a bound per base point of $CE_0[(1+h)L^{-\beta_{\mathrm{T}} h} + L^{-h}]L^{-4h}$. There are $L^{4h} N_n$ base points. Thus these terms sum to at most CN_n.

The vacuum-subtracted remainder has bound $C(1+h)L^{-4h}\theta_j^{-\kappa_0/2}$ in the rooted sum at a level-j site. Use the second-order estimate on the near liftable domains, and the norm tail for the other domains, including wrapping ones. The same site conversion gives $C(1+h)\theta_j^{-\kappa_0/2} N_n$. The lower flow bound and comparison of the frame with the flow make the sum over h bounded, since $\kappa_0/2 > 2$. On this empty standing label, the remainders include the terms left by healed histories and there

is no boundary term. The resulting $F_n \geq -C_I N_n$ and positivity justify keeping just this label in the lower bound.

We verify the remaining assertions of eq. 5.cdxxvii for this density. Write $\eta_n = L^{-n}$ in level-n units, and assume that $|V(b)-\mathbf{1}| < r$ on every level-n bond. Telescoping the unitary products gives $|\partial V - \mathbf{1}| < 4r$. For a density cube $\square$ take its actual test tower in $A = \square^{\sim 4}$. Its determining datum is obtained by lifting V from the top. To see the size of this datum, give a finer link the identity within a top block and the corresponding oriented $V(c)$ across a top block face. Each elementary plaquette of this lift is either trivial or has the holonomy of the corresponding top plaquette. The one-step average of this lift is its coarser lift: the two endpoint contours are trivial within each block, and every joining segment has the same single face value, or the identity if it crosses no top face. This verifies the same description on the averaged rows of the tower.

All determining plaquette holonomies, including those made using averages across the interfaces, are holonomies of the face lift. Thus the datum has radius $4r$. Apply the linear regularity theorem on the prescribed separated density tower, with its tied radii and with $4r$ below the datum ceiling. The tested plaquettes lie in $\square^{\sim}$, inside the top member of the tower by the test-cube geometry. Their defects are therefore at most $4B_3 r\eta_n^2$. The constant-sequence background of V satisfies the same bound on the whole torus. Take $r = c_0 x_n^{-1/2}$. On the real tube x_n and θ_n are comparable, and $\varepsilon_n\sqrt{\theta_n}$ is bounded below. A fixed c_0 therefore makes $4B_3 r < \varepsilon_n$ and places the datum and background below their respective regularity ceilings. Every factor of the terminal density test is one on the product of balls. The earlier fluctuation tests are accounted for in the integrated density and its regular and remainder totals.

There are $6N_0$ bare plaquettes and $N_0 = L^{4n}N_n$. Using the Wilson normalization gives

$$A(U_n(V)) \leq \tfrac{1}{2}(4B_3 r)^2 \eta_n^4\, 6N_0 = 48 B_3^2 r^2 N_n.$$

The action cost $x_n A(U_n(V))$ per final site is bounded. The four Haar balls per site give the $6\log x_n$ term in eq. 5.cdxxviii. At $n = 0$ the same conclusion follows directly by telescoping the bare plaquette products, with no background construction.

Local energy bounds and the first-passage window. Suppose the source families are actual functions of the source values in a fixed-layer enlargement X^+, holomorphic in its finite-dimensional source parameters and real at real arguments. Suppose their differences at the trivial field obey

$$|\Delta E_j(X,z;w)| \leq C_E e^{-\kappa d_j(X)}, \qquad |\Delta R_j(X;w)| \leq C_R e^{-\kappa d_j(X)}.$$

These are source-minus-unsourced differences: assume explicitly $\Delta E_j(X,z;0) = \Delta R_j(X;0) = 0$. Let the number of possible base points $z \in X$ be at most $C_M(d_j(X)+1)$, as follows for domains covered by the vertices of a cubical spanning tree. For $e_j(X;w) = \sum_{z\in X} \Delta E_j(X,z;w) + \Delta R_j(X;w)$,

$$|e_j(X;w)| \leq C_\delta e^{-(\kappa-\delta)d_j(X)} \qquad (\delta > 0). \tag{5.cdxxix}$$

This uses only $(m+1)e^{-\delta m} \leq C_\delta$. If the rooted entropy rate is $\kappa_D < \kappa$, choose $0 < \delta < \kappa - \kappa_D$. The resulting energy decay still exceeds entropy. Locality, holomorphy, realness and vanishing at zero pass through the finite base-point sum. Dependence on the source function itself is a structural hypothesis here; it is not implied by a bound on a chosen list of source coefficients.

If a first-passage argument supplies $g^{-2} < x \leq g^{-2} + B_\sharp$, then the constants in eq. 5.cdxxvi and eq. 5.cdxxviii, when bounded by $C(1+\log x)$, are uniform over the cutoff data at this fixed g. This is the final elementary step producing constants of the form C_g. It supplies no proof that an admissible run reaches that window.

What a pointwise polymer criterion would supply. There is a different sufficient mechanism when a construction actually has a pointwise hard-core gas. Let its polymers be nonempty subsets of a

set of N sites. Suppose, uniformly in a real coarse field V, its real activities obey

$$\sum_{\gamma' \not\sim \gamma} |z_{\gamma'}(V)| e^{a(\gamma')} \le a(\gamma), \qquad \sup_x \sum_{\gamma \ni x} |z_\gamma(V)| e^{a(\gamma)} \le b. \tag{5.cdxxx}$$

These inequalities remain valid after multiplication of all activities by any $t \in [0,1]$. The convergent cluster expansion makes its partition function $\Xi_V(t)$ nonzero and continuous on this interval. It is real there and $\Xi_V(0) = 1$; hence $\Xi_V(1) > 0$. The absolute cluster theorem bounds its logarithm by $\sum_\gamma |z_\gamma| e^{a(\gamma)} \le bN$: sum the rooted cluster bound and then use the nonempty site supports in eq. 5.cdxxx. The branch is the one continued from $t = 0$. It is real on the interpolation, and therefore gives

$$e^{-bN} \le \Xi_V(1) \le e^{bN}.$$

For complex source activities, the corresponding uniform criterion gives $|\Xi_V(w)| \le e^{bN}$. With a verified common Haar/Wilson integral representation and its action estimates, these facts could be used to prove stability and a floor.

Applying this lemma to a label/history representation requires an identity with that integral. Local polymer exponentiations on small-field regions, or exponentiation of the sum over healed components, do not by themselves provide a pointwise gas over all final coarse fields. For the history representation the concrete sufficient conditions are eq. 5.cdxxiv, eq. 5.cdxxv, and eq. 5.cdxxvii; verification of those ordinary conditions remains necessary for the construction.

5.22. **Source bounds for periodic Wilson states.** Reflection positivity transfers ordinary complex source bounds from finite Wilson tori to arbitrary periodic states through their DLR equations. The argument requires neither geometric forgetting for derivatives of inherited activities nor moment bounds for Gibbs states of a perturbed interaction.

Fix an odd integer $L \ge 3$, $a = L^{-K} \le 1$, a coupling $\beta > 0$, and $\mathcal{O}_a(f) = \sum_p f(x(p)) a_p$. All sums defining this observable are finite when f has compact support. Although its supremum norm may grow as a^{-4}, it is bounded at each fixed spacing. Every periodic Wilson DLR state is invariant under all lattice isometries and positive at all lattice mirrors by Prop. A.11.

5.22.1. *An exact domination lemma, before source estimates.* Use a cubic board of cells of side $l = L^j \ge a$, whose face planes cut links in half. Take cubic tori of side $\ell = 2L^m$ with $m \ge \max(0, j)$, having an even number of cells in every direction. Every sequence of sides tending to infinity in this family eventually accommodates any fixed coarser board of allowed side. All sequences in this section are taken in this family. When localization cubes have side Ma_s with the construction convention $M = L^{m_0}$, restrict to the cofinal subfamily $m \ge m_0$. Then $\ell/(Ma_s) = 2L^{m-m_0+s}$ is an even integer at every scale, and all localization partitions are retained. The cell algebra consists of bounded functions of bonds lying wholly inside the open cell; crossing bonds belong to no cell algebra. Reflected copies are conjugated when the reflecting isometry has negative determinant. For a cell function F define

$$p_{l,\ell}(F) = \left\langle \prod_C F^{[C]} \right\rangle_{a,\ell,\beta}^{1/N},$$
$$N = (\ell/l)^4. \tag{5.cdxxxi}$$

The number inside the root is nonnegative. To see this, split the board at one face and the opposite face. The disseminated product is $\Theta\Phi\,\Phi$ for the product of its copies in one half. Finite-torus reflection positivity applies.

We will use, including for complex functions,

$$\left|\left\langle \prod_C F_C \right\rangle\right| \le \prod_C p_{l,\ell}(F_C),$$
$$p(F+G) \le p(F) + p(G),$$
$$p(\bar{F}) = p(F),$$
$$p(1) = 1. \tag{5.cdxxxii}$$

Here are details extending the finite chessboard argument to this form. In one direction transport all slab profiles to one reference slab, using conjugated reflection for odd copies. For an arbitrary filling of the n slabs, n even, reflection Cauchy–Schwarz bounds the squared absolute partition integral by the two integrals obtained by retaining either half and reflecting it. Normalize label j by $(Z_j^{\mathrm{dis}} + \epsilon)^{1/n}$, where $Z_j^{\mathrm{dis}} \ge 0$ is its fully disseminated integral and $\epsilon > 0$. The normalized filling of maximum absolute value exists. Both reflected fillings also maximize whenever that maximum is positive: each is nonnegative, bounded by the same maximum, and their product bounds its square. A constant run in a maximizing filling can be doubled by retaining the half starting at that run. Once its length reaches $n/2$, a constant filling results. Every constant normalized filling is at most one. Thus the maximum is at most one; the zero maximum is trivial. Letting $\epsilon \downarrow 0$ proves the one-direction bound even when some disseminated integral is zero. Applying this argument successively to the four coordinate directions proves the first inequality in eq. 5.cdxxxii: coordinate reflections commute, and each successive dissemination copies the preceding pattern literally in the other coordinates. The resulting exponent for each original cell is $1/N$.

Expanding the disseminated product for $F + G$ and applying the first inequality term by term bounds it by $\sum_{k=0}^{N} \binom{N}{k} p(F)^k p(G)^{N-k}$. Its nonnegative Nth root proves the triangle inequality. Exactly half the copies are conjugated, giving $p(zF) = |z|p(F)$; conjugating the entire nonnegative disseminated integral proves $p(\bar{F}) = p(F)$. In particular $p(\mathrm{Re}(e^{-i\phi}F)) \le p(F)$.

5.22.1.1. Domination. For any periodic Wilson DLR state ρ, any finite collection of occupied cells, and any sequence of compatible tori $\ell_k \to \infty$,

$$\left|\rho\left(\prod_C F_C\right)\right| \le \liminf_{k\to\infty} \prod_C p_{l,\ell_k}(F_C). \tag{5.cdxxxiii}$$

Only finitely many factors differ from 1.

First consider a bounded real function H of one cell. Sum its mirror copies over a cube of side ℓ. Reflection invariance of ρ makes the expectation of the sum equal to $N\rho(H)$. Conditional Jensen bounds that expectation by the supremum, over exterior configurations, of the logarithm of its conditional exponential moment. Replace the exterior condition by periodic bonds. After adjoining dummy independent Haar variables if necessary, the two integrals use the same variables. Only boundary plaquettes change; each changes the Hamiltonian by at most 2β, and there are $O((\ell/a)^3)$ such plaquettes. Source factors do not cross the outer cell faces and therefore agree in the two integrals. It follows that

$$\rho(H) \le \log p_{l,\ell}(e^H) + C\beta l^4 a^{-3} \ell^{-1}. \tag{5.cdxxxiv}$$

This estimate is uniform in the exterior configuration, not in a; the volume limit is taken with a fixed.

For bounded real G, put $H = \log(1 + tG)$ with $0 < t < (2\|G\|_\infty)^{-1}$. The elementary inequalities $\log(1 + tG) \ge tG - Ct^2\|G\|_\infty^2$ and $\log p(1 + tG) \le tp(G)$ turn eq. 5.cdxxxiv, first as $\ell_k \to \infty$ and then as $t \downarrow 0$, into $\rho(G) \le \liminf_k p_{l,\ell_k}(G)$. For complex F choose ϕ so that $\rho(\mathrm{Re}(e^{-i\phi}F)) = |\rho(F)|$ and use the last consequence of eq. 5.cdxxxii.

Finally enclose the finitely many occupied fine cells strictly inside one larger coarse board cell. The one-cell inequality applies to $G = \prod_C F_C$. On every compatible torus the fine-board chessboard inequality gives $p_{\mathrm{coarse},\ell}(G) \le \prod_C p_{l,\ell}(F_C)$: disseminate the coarse cell, apply eq. 5.cdxxxii on the fine board, and take the coarse root. Choose the larger cell as a sufficiently large allowed integral power of the fine side, so that both boards are compatible along the chosen torus sequence. This proves eq. 5.cdxxxiii. The lower limit along *any* sequence is essential below.

The perturbation $\log(1 + tG)$ in this proof is arbitrary and need not be an admissible linear source. No renormalization-group bound was applied to it or to its Gibbs states. It enters only an exact Jensen and boundary-comparison argument and the elementary seminorm inequality.

The precise ordinary torus hypothesis. Here is one sufficient source hypothesis, stated to expose the actual input to the transfer. Fix constants $r, A, C_\pm > 0$, an entropy rate κ_0, and $\kappa > \kappa_0$, uniformly over the selected cutoff–coupling data (a, β) and allowed tori. Let $\|f\|_\sharp = \max(\|f\|_\infty, c_M\|\nabla f\|_\infty)$. For every finite family of real Lipschitz torus functions require the ordinary complex source bound, on $\sum_i |z_i|\|f_i\|_\sharp < 2r$,

$$|Z_{a,\ell}(W)| \le \exp\left[V_{a,\ell} + \operatorname{Re} U_{a,\ell}(W) + \operatorname{Re}\sum_{s=0}^{K}\sum_{D} e_{a,\ell,s,D}(W) + C_+\ell^4\right],$$
$$Z_{a,\ell}(0) \ge e^{V_{a,\ell} - C_-\ell^4}. \tag{5.cdxxxv}$$

The terms in this expression have the following meaning and bounds. The source-independent vacuum number $V_{a,\ell}$ is real.

The point counterterm is $U_{a,\ell}(W) = \sum_p u_{a,\ell,p}(W(x(p)))$, where each u is holomorphic and zero at zero. For each fixed cutoff its norm on smaller discs is bounded uniformly in p and ℓ; this bound may depend on the cutoff. The domain term $e_{a,\ell,s,D}$ is holomorphic in the ordinary source variables, is zero at zero, depends only on $W|_{D^+}$, and satisfies $|e_{a,\ell,s,D}| \le Ae^{-\kappa m(D)}$. Put $a_s = L^{-s}$ and require $\operatorname{diam} D^+ \le C_0 a_s(m(D) + 1)$. The domain entropy bound, in a convenient localized form, is

$$\sum_{D:\, D^+\cap B\neq\varnothing,\, m(D)\ge t} e^{-\kappa m(D)} \le C(R+1)^4 a_s^{-4} e^{-ct} \tag{5.cdxxxvi}$$

for every radius-R ball B and $t \ge 0$, uniformly in its position. A count per unit cube bounded by $e^{\kappa_0 m}$ implies this form after absorbing a fixed polynomial in m into a smaller entropy gap. All domain sums used are normally convergent on smaller source balls. Source representation independence is required: local terms depend on the source function on their indicated region, not on the particular list representing that function.

The condition in eq. 5.cdxxxv is an upper bound and a floor, not a claim that $Z(W)$ is zero-free on the whole source ball. Its ordinary source class includes the global real Lipschitz profiles constructed by mirror periodization. This last inclusion matters. For $w = \sum_i z_i f_i$ in one cell, the periodized source is

$$W^{\mathrm{ch}} = \sum_i z_i H_i^+ + \sum_i \bar{z}_i H_i^-. \tag{5.cdxxxvii}$$

The even and odd copy profiles $H_i^\pm$ are real. If each support is at distance $b > a$ from the faces, the profiles vanish near the faces and their Lipschitz norms are at most $\|f_i\|_\sharp$. Hence $\|W^{\mathrm{ch}}\|_\flat \le 2\sum_i |z_i|\|f_i\|_\sharp$, independently of the number of cells. The ordinary radius $2r$ in eq. 5.cdxxxv therefore supplies the radius r used below. One first regards the two lists of coefficients as independent

complex variables; evaluating one at the conjugate of the other does not require a new analytic extension.

Holomorphic cell normalizers from the ordinary hypothesis. Suppose m radius-R support balls lie at distance at least a fixed $b > 1$ from the faces of a cell C of side l. For each torus form a normalizer $E_{C,\ell}(z)$ as follows. Retain in $U + \sum e$ only the point terms and domains whose complete dependence region lies in one open board cell. Evaluate each retained term at the source copy in that cell, conjugate its value if that cell has odd parity, sum over cells, and divide by N. The result is holomorphic in z, even though eq. 5.cdxxxvii itself involves $\bar{z}$: on an odd cell the retained term has the form $g(\bar{z})$, and $\overline{g(\bar{z})}$ is holomorphic. Its real part is unchanged by this outer conjugation. Also $E_{C,\ell}(0) = 0$.

Any discarded source-dependent domain meets a support ball and reaches a cell face. Its diameter is at least b, so $m(D) \geq b/(C_0 a_s) - 1$. Counting once per ball, eq. 5.cdxxxvi shows that the discarded contribution divided by N is at most

$$B_{\mathrm{face}}(m, R, b) \leq CAm(R+1)^4 \sum_{s \geq 0} a_s^{-4} e^{-c'b/a_s} < \infty. \tag{5.cdxxxviii}$$

The sum is independent of the cutoff. Overcounting domains meeting several balls only enlarges this upper bound. Point counterterms whose source is nonzero lie strictly inside cells, so none are discarded. Combining eq. 5.cdxxxi, eq. 5.cdxxxv and eq. 5.cdxxxviii proves

$$\begin{aligned} p_{l,\ell}(e^{\mathcal{O}_a(w)}) &\leq \exp[\mathrm{Re}\, E_{C,\ell}(z) + B_C], \\ B_C &= (C_+ + C_-) l^4 + B_{\mathrm{face}}(m, R, b). \end{aligned} \tag{5.cdxxxix}$$

At a fixed cutoff the normalizers are locally bounded uniformly in ℓ. For the point terms this follows from their fixed-cutoff bound and $O(l^4 a^{-4})$ plaquettes per cell. For the domain terms use eq. 5.cdxxxvi with $t = 0$ and the finite sum of a_s^{-4} over $s \leq K$. These bounds may grow with K, which is harmless for the next step. Montel's theorem therefore gives a subsequence on which $E_{C,\ell}$ converges locally uniformly to a holomorphic E_C. Explicitly, Cauchy estimates on smaller source balls give equicontinuity there; Arzela–Ascoli and a diagonal selection over a countable compact exhaustion give the subsequence, and Cauchy's formula proves holomorphy of its limit. For finitely many occupied cells take one common subsequence. It is chosen from the torus normalizers alone, independently of every infinite-volume state.

There is a second uniform bound that does not grow with K. If $n \geq 2$ sources in the same cell have pairwise support distance at least d, a point counterterm has zero mixed derivative, because a point cannot belong to two of the supports. A contributing domain must meet all supports; in particular its diameter is at least d. Cauchy's formula and eq. 5.cdxxxvi, with the first support ball as anchor, give

$$\begin{aligned} |\partial_1 \cdots \partial_n E_C(0)| &\leq D_n(d; R) \prod_i \|f_i\|_\sharp, \\ D_n(d; R) &= CA(R+1)^4 \max(1, d^{-4})(n/r)^n. \end{aligned} \tag{5.cdxl}$$

Indeed the remaining scale sum is $\sum_s a_s^{-4} e^{-c'd/a_s} \leq C \max(1, d^{-4})$. This follows by splitting at $a_s \approx d$; the tail becomes a convergent sum $Cd^{-4} \sum_{j \geq 0} L^{4j} e^{-c'' L^j}$. The same estimate holds before the Montel limit, and hence after it.

All-state generating functions, cumulants and mean differences.

Proposition 5.75 (Ordinary torus source estimates imply all-state bounds)**.** Assume the ordinary torus source hypothesis in eq. 5.cdxxxv–eq. 5.cdxxxvi, including the stated locality, point counterterms and uniformity, and the proved lattice symmetries. Then eq. 5.cdxliii, eq. 5.cdxliv and eq. 5.cdxlv hold for every periodic Wilson DLR state, uniformly in the cutoff, the states and the support positions. Their constants depend only on the displayed source constants, the number of entries, the support radius and, for higher cumulants, the support separation. ■

Let $f_1, \dots, f_n$ have radius-R supports at arbitrary positions. A zero test makes every corresponding multilinear assertion trivial, so such tests may be omitted. Choose an allowed side $l \le C_L n(R+b+1)$ and a board offset that puts each support ball at distance at least b from every face. For each coordinate, the forbidden offsets occupy at most $2n(R+b+a)$ of a period; choosing l larger than a fixed multiple of this number leaves an allowed link-plane offset. Thus at most n cells are occupied. Put $w_C = \sum_{i:\,\mathrm{supp}\, f_i \subset C} z_i f_i$. Apply eq. 5.cdxxxiii to $F_C = e^{\mathcal{O}_a(w_C)}$ along the common Montel subsequence in eq. 5.cdxxxix. For every periodic DLR state ρ this gives

$$\begin{aligned} \left| e^{-E(z)} \rho\left(e^{\sum_i z_i \mathcal{O}_a(f_i)} \right) \right| &\le Q, \\ E &= \sum_C E_C, \\ Q &= e^{\sum_C B_C}, \\ \sum_i |z_i| \|f_i\|_\sharp &< r. \end{aligned} \tag{5.cdxli}$$

The same E and Q serve all states at the datum. The number Q depends on n, R and the fixed source constants, but not on the cutoff, state, or support positions. This conclusion uses the lower limit along the selected sequence, rather than an upper limit over all tori.

Write the normalized holomorphic function in eq. 5.cdxli as h_ρ. It has $h_\rho(0) = 1$ and $|h_\rho| \le Q$. A logarithm is needed only near zero, where it exists by continuity. For any nonempty subset $B \subset \{1, \dots, n\}$, Cauchy's formula, with all other variables zero, gives

$$|\partial_B h_\rho(0)| \le Q(|B|/r)^{|B|} \prod_{i \in B} \|f_i\|_\sharp.$$

The finite derivative identity for a logarithm now implies

$$|\partial_1 \cdots \partial_n \log h_\rho(0)| \le r^{-n} \sum_\pi (|\pi| - 1)! Q^{|\pi|} \prod_{B \in \pi} |B|^{|B|} \prod_i \|f_i\|_\sharp. \tag{5.cdxlii}$$

The sum is over set partitions. No uniform zero-free polydisc is needed for this identity at zero.

For $n \ge 2$, the cumulant is the sum of the mixed derivatives of E and $\log h_\rho$. If more than one cell is occupied, the mixed derivative of $E = \sum_C E_C$ is zero because every summand lacks a variable. If one cell is occupied, use eq. 5.cdxl. eq. 5.cdxl–eq. 5.cdxlii prove the all-state separated cumulant bound

$$|\kappa_n^\rho(\mathcal{O}_a(f_1), \dots, \mathcal{O}_a(f_n))| \le C_n(d; R) \prod_i \|f_i\|_\sharp. \tag{5.cdxliii}$$

Here C_n is explicit as eq. 5.cdxlii, with the uniform choice of Q above, plus D_n. This proves a finite constant for each n; no factorial growth assertion beyond these formulas is being made.

For one radius-R test choose one cell with $l \le C_L(R+b+1)$ and the corresponding common normalizer E_f. Cauchy directly gives

$$|\rho(\mathcal{O}_a(f)) - E_f'(0)| = |h_\rho'(0)| \le (Q_R/r)\|f\|_\sharp.$$

Consequently, for every pair of periodic states at the same datum,

$$|\rho(\mathcal{O}_a(f)) - \nu(\mathcal{O}_a(f))| \le (2Q_R/r)\|f\|_\sharp. \tag{5.cdxliv}$$

The common derivative $E_f'(0)$ may diverge with the cutoff. The estimate controls its differences from the means and hence differences between the means. The argument also covers separated reflected copies: their support radii, distances and test norms are unchanged.

If desired the one-point constant can be chosen to grow only as $(R+1)^4$. Choose a fixed smooth partition of unity by translates of compactly supported functions of uniformly bounded derivative. Its members have supports in balls of a fixed radius R_0, only $C(R+1)^4$ meet a radius-R support, and $\|f\psi_j\|_\sharp \le C\|f\|_\sharp$. Apply eq. 5.cdxliv to these pieces with the fixed constant Q_{R_0} and add. Such a partition is obtained by dividing a nonnegative compact bump, positive on a unit cube, by the positive periodic sum of its integer translates.

5.22.1.2. Short-distance differences between states. At a common first-passage datum let D_n be the difference of the connected n-point functions of two periodic states. For tests in a common unit ball, eq. 5.cdxli uses the same energy E in both states. The source bound admits overlapping supports. Thus the mixed derivative of E cancels, and eq. 5.cdxlii gives

$$|D_n(F_1,\dots,F_n)| \le C_n \prod_i \|F_i\|_\sharp.$$

Take $a_K \le \mathsf{d}$ and put the supports of the f_i in a ball of radius $5\mathsf{d}$. For small enough d, pack $N \ge c\mathsf{d}^{-4}$ disjoint lattice translates of this ball inside a unit ball, with gaps between the copies. For each argument $i < n$ use an independent family of uniform signs ϵ_v^i on the translates. In the last argument use $\epsilon_v^n = \prod_{i<n}\epsilon_v^i$. Write $F_i = \sum_v \epsilon_v^i \tau_v f_i$. Since every summand vanishes at the boundary of its own ball, both the supremum and Lipschitz bounds of f_i hold for F_i. In the multilinear expansion the sign average keeps exactly the terms whose translations all coincide. Translation invariance makes that average $ND_n(f_1,\dots,f_n)$. For $n=1$ take the ordinary sum with all signs one. Therefore

$$|D_n(f_1,\dots,f_n)| \le C_n\mathsf{d}^4 \prod_i \|f_i\|_\sharp \le C_{n,\vartheta}\mathsf{d}^{4-n}\prod_i \|f_i\|_\infty,$$

where the last bound uses $\mathrm{Lip}\, f_i \le \|f_i\|_\infty/(\vartheta\mathsf{d})$.

Finally put $b_1 = C_1(R)$ and $b_m = C_m(d;R)$ for $m \ge 2$. The moment–cumulant formula and invariance of higher cumulants under constant shifts give

$$\left|\rho\prod_{i=1}^k[\mathcal{O}_a(f_i) - \nu(\mathcal{O}_a(f_i))]\right| \le \left(\sum_{\pi\in\mathrm{Part}\{1,\dots,k\}}\prod_{B\in\pi} b_{|B|}\right)\prod_i \|f_i\|_\sharp. \tag{5.cdxlv}$$

Singleton blocks use eq. 5.cdxliv; the other blocks use eq. 5.cdxliii. This is the centered moment estimate required when a component is centered at a different state or mixture, with the same uniformity in both states.

Thus eq. 5.cdxxxv–eq. 5.cdxxxvi, source locality, the stated ordinary holomorphy, and the proved lattice symmetries imply the bounds used under G4. The transfer requires no weighted analytic extension. The analytic construction must still prove the actual ordinary source bound, entropy gap, upper stability and floor. A torus statement controlling only separated mixed derivatives of a logarithm does not state the cell estimate in eq. 5.cdxxxix or a common one-point normalizer. Those concrete conditions must be retained when replacing an all-state input by the transfer theorem.

5.23. **Factorial moment bounds from rooted domains.** We strengthen the spatial counting used in the ordinary-source transfer. The resulting estimates have factorial growth in the number of entries and a separation singularity of order proportional to that number. Only the ordinary finite-torus source estimates are used. In particular, neither weighted forgetting nor source bounds for perturbed Gibbs states are added.

Retain the ordinary source upper bound and floor in eq. 5.cdxxxv, the point-local counterterms, and the proved chessboard domination in eq. 5.cdxxxiii. Let $L \geq 3$ be odd, $a = L^{-K}$, and $a_s = L^{-s}$, $0 \leq s \leq K$. All constants below are uniform over the chosen cutoff–coupling data and all large allowed tori. The physical source norm is $\|f\|_\sharp = \max(\|f\|_\infty, c_M\|\nabla f\|_\infty)$.

The stronger count and its geometric origin. The localization parameter obeys $M = L^{m_0}$ for a fixed integer $m_0 \geq 0$. Use the cofinal family of original tori $\ell = 2L^m$, $m \geq m_0$. At every actual scale, $\ell/(Ma_s) = 2L^{m-m_0+s}$ is an even integer, so all localization partitions tile the torus; no scale terms are omitted. Every fixed power-of-L board also tiles all sufficiently large tori in this family, with even cell counts. At scale s use a cubical partition of side $\rho_s = Ma_s$. A localization domain X is a union of these cubes. It admits a finite connected cubical edge tree meeting every cube of X, and $m(X)$ is the minimum number of edges of such a tree. The source dependence region is contained in a fixed number of neighbouring cube layers around X. This includes source values at plaquette barycentres whose plaquette has a corner in a one-layer enlargement of X, because a bare plaquette has diameter $O(a) \leq O(a_s)$.

For a fixed cube Q the elementary rooted entropy estimate is

$$\#\{X : Q \subset X,\, m(X) = m\} \leq Ce^{\kappa_D m}. \tag{5.cdxlvi}$$

Here is a proof for the stated domain indexing. A minimizing tree with m edges has at most $m+1$ vertices. Every cube meeting an edge of the cubical grid contains an endpoint of that edge; hence every cube of X contains a tree vertex. Choose a tree vertex at a corner of Q in at most 16 ways. Traversing each tree edge twice gives a closed walk of length $2m$ from that corner. There are at most 8^{2m} such walks. At most $16(m+1)$ cubes contain a vertex of the walk, and a subset of these specifies X. Thus

$$\# \leq 16\, 8^{2m} 2^{16(m+1)}.$$

This covers all admissible domains; restricting the domain class can only reduce the count. The same upper bound applies on the finite cubical quotient.

Suppose $|e_{s,X}(w)| \leq Ae^{-\kappa m(X)}$, where $\kappa > \kappa_D$. Summing eq. 5.cdxlvi gives a positive entropy gap $c > 0$. If the dependence region sees a radius-u ball, some cube of X lies within $C\rho_s$ of that ball. There are at most $C(1 + u/a_s)^4$ choices of this root cube. Consequently

$$\sum_{X:\, X^+ \text{ sees } B,\, m(X)\geq t} e^{-\kappa m(X)} \leq C(1 + u/a_s)^4 e^{-ct}. \tag{5.cdxlvii}$$

There is no factor a_s^{-4} when $u \ll a_s$. This improvement uses the fixed-layer dependence geometry and rooted indexing; a bound only by $C(u+1)^4 a_s^{-4}$ would not suffice for the argument below. Also, summing over every possible root cube, with harmless overcounting, gives the global estimate

$$\sum_X e^{-\kappa m(X)} \leq C\ell^4 a_s^{-4}. \tag{5.cdxlviii}$$

The tree representation implies $\operatorname{diam} X^+ \leq Ca_s(m(X) + 1)$, as needed in these estimates.

A polynomial bound for one finely supported cell source. Let a board have side $\eta \le 1$ and one real test v supported in a ball of radius $\delta \le \eta$, lying at distance at least δ from the faces. Assume $\delta \ge 16a$. Periodize zv by reflected copies, conjugating odd copies. Its ordinary source norm is at most $2|z|\|v\|_\sharp$. Thus ordinary source radius $2r$ allows $|z| < r/\|v\|_\sharp$, independently of the number of cells.

Construct the interior-cell holomorphic normalizer $E_{v,\ell}(z)$ as in eq. 5.cdxxxix. The discarded terms are the source-dependent domains whose full dependence region is not contained in one cell. Such a domain sees a copy of the support ball and reaches a face, so $m(X) \ge c_0\delta/a_s - C_0$. Let $N = (\ell/\eta)^4$. The discarded sum divided by N has three scale ranges.

For $a_s \ge \eta$, discard even the source restriction and use eq. 5.cdxlviii. The cost is at most $CA(\eta/a_s)^4$ per scale and per cell; its sum is bounded by a geometric series. For $\delta \le a_s < \eta$, eq. 5.cdxlvii gives a bounded cost per scale, and there are at most $C(1+\log(\eta/\delta))$ such scales. For $a_s < \delta$, eq. 5.cdxlvii and the forced domain size give a cost at most

$$CA(1+\delta/a_s)^4 e^{-c'\delta/a_s}.$$

The sum is bounded uniformly in δ by comparison with $\sum_{j\ge 0}(1+L^j)^4 e^{-c''L^j}$. All ranges may be truncated at the actual cutoff, which only decreases the bounds. The point-local counterterms are retained: their nonzero sources are strictly inside cells. Their possibly large first derivatives cause no face error.

The stability and floor cost per cell is $(C_+ + C_-)\eta^4 \le C_+ + C_-$. We obtain

$$p_{\eta,\ell}(e^{z\mathcal{O}_a(v)}) \le \exp[\mathrm{Re}\, E_{v,\ell}(z)]\, Q_0(\eta/\delta)^p \tag{5.cdxlix}$$

for constants $Q_0 \ge 1$, $p \ge 0$ independent of a, η, δ and the support position. Fixed-cutoff local boundedness and Montel selection supply a limiting holomorphic univariate normalizer E_v. For any finite list of pieces use one common subsequence. It is chosen from the torus data and is independent of the infinite-volume states.

Board offsets and a genuine product source polydisc. Consider n tests supported in radius-R balls, with distinct supports at distance at least $d > 0$. Put $\bar{d} = \min(d, 1)$, and choose an allowed board side, a power of L, such that

$$\frac{\bar{d}}{16L} < \eta \le \frac{\bar{d}}{16},$$
$$\delta = \frac{\eta}{64n}. \tag{5.cdl}$$

First suppose $a \le \delta/16$; thus this board side is a multiple of the mesh. A fixed smooth partition of unity at mesh proportional to δ splits each f_i into pieces $v_{i,k}$ with

$$\#\{k : v_{i,k} \ne 0\} \le C(1+R/\delta)^4,$$
$$\mathrm{supp}\, v_{i,k} \subset B_{i,k}(\delta),$$
$$\|v_{i,k}\|_\sharp \le C\delta^{-1}\|f_i\|_\sharp. \tag{5.cdli}$$

For example, scale a smooth compact partition obtained from translates of a bump divided by their positive periodic sum. Scaling its bounded first derivatives gives the last inequality. A zero piece contributes nothing and is omitted.

Choose one piece from each original test. In any coordinate the offsets for which one enclosing radius-δ ball comes within δ of a face occupy an interval of length at most 4δ modulo η. On the

discrete link-plane offsets, one such interval contains at most $4\delta/a+2$ candidates. The n intervals exclude at most $n(4\delta/a+2)<\eta/a$ candidates by eq. 5.cdl and the fine-mesh assumption. There is an allowed offset in each coordinate. Hence all chosen balls have the required margin. Different original tests occupy different cells: a four-dimensional side-η cube has Euclidean diameter $2\eta<d$, whereas their nonempty supports are d apart.

Write these chosen pieces as $v_1,\dots,v_n$ and their different cells as $C_1,\dots,C_n$. By eq. 5.cdxlix each has a univariate normalizer E_i and a bound

$$\begin{aligned} Q_i &\le Cn^p, \\ r_i &= r/\|v_i\|_\sharp. \end{aligned} \tag{5.cdlii}$$

Product domination in eq. 5.cdxxxiii is applied to the separate cell factors. It therefore gives, for every subset S and every periodic state ρ,

$$\left|\exp\left[-\sum_{i\in S}E_i(z_i)\right]\rho\left(e^{\sum_{i\in S}z_i\mathcal{O}_a(v_i)}\right)\right|\le\prod_{i\in S}Q_i \qquad (|z_i|<r_i, i\in S). \tag{5.cdliii}$$

This is a product polydisc; no bound on its combined source norm is needed. Each chessboard factor in eq. 5.cdxxxiii uses only one periodized piece and its own ordinary source disc. Inactive factors are exactly 1, with $p(1)=1$, so eq. 5.cdliii contains the product over the active subset, not the product over all n indices. The same normalizers work for every state, including a second centering state ν.

Common centering and factorial order. Define $X_i=\mathcal{O}_a(v_i)-E_i'(0)$. Differentiating the normalized function in eq. 5.cdliii once in each active variable, and using product Cauchy, gives

$$|\rho\prod_{i\in S}X_i|\le\prod_{i\in S}(Q_i/r_i). \tag{5.cdliv}$$

Only the first derivative of each univariate E_i occurs; no bound on its higher derivatives is required. Applying the one-variable case to ν gives $|\nu(\mathcal{O}_a(v_i))-E_i'(0)|\le Q_i/r_i$. Expanding the product centered at ν over its active subsets and using eq. 5.cdliv therefore proves

$$\left|\rho\prod_{i=1}^n[\mathcal{O}_a(v_i)-\nu(\mathcal{O}_a(v_i))]\right|\le 2^n\prod_i(Q_i/r_i). \tag{5.cdlv}$$

This explains both the necessity of subset bounds in eq. 5.cdliii and the role of a common normalizer. Uniform moments for auxiliary perturbed Gibbs states are not being presumed.

The sum in eq. 5.cdlv over the piece choices from eq. 5.cdli, using linearity of centering. The board may depend on that finite piece choice; every constant is independent of that choice. Since $\delta\le 1$,

$$\begin{aligned} \left|\rho\prod_{i=1}^n[\mathcal{O}_a(f_i)-\nu(\mathcal{O}_a(f_i))]\right| &\le [C(R+1)^4n^p\delta^{-5}]^n\prod_i\|f_i\|_\sharp \\ &\le B_0(R)^n n^{(p+5)n}\bar{d}^{-5n}\prod_i\|f_i\|_\sharp. \end{aligned} \tag{5.cdlvi}$$

If $a>\delta/16$, dispense with the partition and the board. A radius-R ball contains at most $C(1+R/a)^4$ plaquette barycentres. Since $0\le a_p\le 2$,

$$\|\mathcal{O}_a(f)-\nu(\mathcal{O}_a(f))\|_\infty\le C(R+1)^4a^{-4}\|f\|_\sharp\le C(R+1)^4\delta^{-4}\|f\|_\sharp.$$

Its product bound is absorbed by eq. 5.cdlvi, because δ is comparable to $\bar{d}/n$, $p \geq 0$ and $\bar{d} \leq 1$. This handles every cutoff, including the case when the prospective side η is smaller than the mesh.

Choose the fixed integer $k = \lceil p \rceil + 5$. The elementary inequality $n! \geq (n/e)^n$, obtained by integrating $\log x$, converts eq. 5.cdlvi to

$$\left| \rho \prod_{i=1}^{n} [\mathcal{O}_a(f_i) - \nu(\mathcal{O}_a(f_i))] \right| \leq B(R)^n (n!)^k \max(1, d^{-5n}) \prod_i \|f_i\|_\sharp. \tag{5.cdlvii}$$

Proposition 5.76 (Graded moments and cumulants)**.** Under the ordinary torus source hypotheses and the rooted domain geometry stated above, eq. 5.cdlvii holds for every pair of periodic Wilson DLR states at the same datum. The same moment and cumulant bounds hold for finite Wilson tori in the compatible family above a fixed minimum side, with the integrating and centering state equal to that torus law. For $n \geq 2$ their cumulants satisfy

$$|\kappa_n^\rho(\mathcal{O}_a(f_1), \ldots, \mathcal{O}_a(f_n))| \leq [2B(R)]^n (n!)^k \max(1, d^{-5n}) \prod_i \|f_i\|_\sharp. \tag{5.cdlviii}$$

For the finite-torus assertion, use the univariate normalizers $E_{i,\ell}$ directly. The finite chessboard inequality gives eq. 5.cdliii with those normalizers and the same Q_i on the product polydisc. The remaining estimates use the torus distance for the support separation. They are finite and use no volume limit. The chosen sub-unit power-of-L board tiles every compatible torus above the fixed minimum side.

The constants are independent of the cutoff, the states and support positions. The exponent k is one fixed finite integer. One may take $B(R) = C(R+1)^4$ with a constant fixed by the source and domain parameters. ∎

To verify the cumulant assertion without an unnecessary extra factorial, center at ρ and apply the moment–cumulant formula. For a partition with block sizes $n_1, \ldots, n_m$, use eq. 5.cdlvii on each block and $\prod_j n_j! \leq n!$. The remaining combinatorial bound is

$$\sum_\pi (|\pi| - 1)! \prod_{D \in \pi} (|D|!)^k \leq (n!)^{k-1} \sum_\pi (|\pi| - 1)! \prod_{D \in \pi} |D|! \leq 2^{n-1} (n!)^k.$$

For exactly m blocks, the middle sum equals $\frac{n!}{m}\binom{n-1}{m-1}$: order the blocks, sum over positive compositions of n, and cancel their factorial denominators. Summing over m proves the inequality and eq. 5.cdlviii.

The separation singularity in this theorem is d^{-5n}, not a single d^{-5} prefactor independent of n. This is a factorial-growth estimate at each fixed separation, with diagonal order proportional to n. It is sufficient for extensions whose derivative order may grow linearly with the number of entries. A stronger separation law requires an additional argument. Likewise the theorem does not prove the ordinary analytic source and stability hypotheses themselves.

One may also recover a presentation with a separation prefactor independent of n, at the cost of one factorial power. Put $x = \max(1, d^{-5})$. The exponential series gives $x^n \le n!e^x$, so eq. 5.cdlvii implies

$$\left|\rho \prod_{i=1}^{n} [\mathcal{O}_a(f_i) - \nu(\mathcal{O}_a(f_i))]\right| \le e^{\max(1,d^{-5})} B(R)^n (n!)^{k+1} \prod_i \|f_i\|_\sharp. \tag{5.cdlix}$$

Thus $A(d;R) = e^{\max(1,d^{-5})}$ is one possible prefactor in that notation. Its separation behavior is much worse than a polynomial. The quantitative extension uses the sharper graded form in eq. 5.cdlvii, rather than attempting to infer diagonal order from this rewritten bound.

5.24. **Compactness of separated correlations.** A sequence of cutoff data with uniform source estimates has a subsequence whose separated correlations converge. We also prove existence of Wilson Gibbs states at each fixed datum. Constructing the cutoff data and their uniform estimates, comparing different cutoffs, tuning, and proving uniqueness of continuum limits require further arguments.

The fixed-cutoff Gibbs measure argument. Fix a spacing $a > 0$, a finite inverse coupling $\beta \ge 0$, and the compact group $G = \mathrm{SU}(2)$. Choose one orientation of each nearest neighbor bond of $a\mathbb{Z}^4$ and denote this countable set by E. A configuration is $U \in \mathcal{X} = G^E$; the opposite bond has matrix U_e^{-1}. The product topology is compact and metrizable. For example, enumerating the bonds gives a metric $\sum_{r\ge1} 2^{-r} \min(1, \|U_{e_r} - V_{e_r}\|)$. Continuous functions depending on finitely many bonds are uniformly dense in $C(\mathcal{X})$. Indeed, replacing all coordinates after the first N by a fixed configuration changes the metric by at most 2^{-N}, and uniform continuity proves this approximation.

Let $A_p(U) = 1 - \frac{1}{2}\operatorname{Re}\operatorname{Tr} U_p \in [0,2]$ be the Wilson plaquette action. For a finite bond window W, let $\mathcal{P}(W)$ be the plaquettes meeting W and let ∂W be their bonds outside W. Define

$$\gamma_W F(U) = \frac{\int_{G^W} F(VU) \exp[-\beta \sum_{p\in\mathcal{P}(W)} A_p(VU)]\, dV}{\int_{G^W} \exp[-\beta \sum_{p\in\mathcal{P}(W)} A_p(VU)]\, dV}. \tag{5.cdlx}$$

Here VU replaces the variables in W, and Haar measure is normalized. The denominator lies between $e^{-2\beta|\mathcal{P}(W)|}$ and one. The normalized density is therefore a continuous function of the finite variables $(V, U_{\partial W})$. If F is continuous local, $\gamma_W F$ is continuous local, depending only on the remaining variables of F and on ∂W. This proves the Feller property directly; integration of a uniformly continuous function over the compact finite product preserves continuity. By uniform approximation it also holds for $F \in C(\mathcal{X})$.

Take Wilson probability measures on periodic tori with integer periods $N \to \infty$, and lift them periodically to $\mathcal{X}$. The finite partition function is finite and strictly positive because the integrand is continuous and positive on a compact space. The lifted measures have a weakly convergent subsequence. One direct compactness argument is as follows. The space $C(\mathcal{X})$ is separable: on a compact metric space finite approximations by distance functions with rational coefficients form a countable uniformly dense family. Successively extract convergence of the integrals on this family. Uniform approximation then defines a bounded positive functional on all of $C(\mathcal{X})$, with value one at the constant one. Its Riesz probability measure is the weak limit. This argument simultaneously gives convergence against every continuous function, not merely the chosen countable family.

The lifted torus measure is not itself an infinite-volume DLR state: remote periodic copies can determine an inside variable. The identity needed for passage to the limit is a local one. Fix W

and a continuous local F. For all sufficiently large periods, the finite bonds involved in W, ∂W and F embed injectively into the torus, and the plaquettes meeting W are precisely their usual torus counterparts. Integrating the variables in that torus window first gives exactly

$$\widetilde{\mu}_N(\gamma_W F) = \widetilde{\mu}_N(F). \tag{5.cdlxi}$$

Both integrands are continuous local. Their weak limits satisfy $\mu(\gamma_W F) = \mu(F)$. Cylinder approximation and $\|\gamma_W F\|_\infty \le \|F\|_\infty$ extend this identity to all continuous F. Equivalently the Borel probability measures $\mu\gamma_W$ and μ agree. The identity consequently holds for every bounded Borel F.

It is also the conditional-law formulation of DLR. For bounded outside-measurable g, the kernel is proper and satisfies $\gamma_W(gF) = g\gamma_W F$. Hence $\mu(gF) = \mu(g\gamma_W F)$, and $\gamma_W F$ is outside measurable. Thus eq. 5.cdlx is the conditional expectation given the bonds outside W. This holds for every finite window.

The torus lifts are invariant under lattice translations and the hypercubic group. These transformations preserve Haar measure and the Wilson action, including when a chosen bond orientation is reversed. Weak convergence preserves their invariance, so μ is an invariant Wilson DLR state. In particular it is periodic, with the whole lattice as a period group. The same Feller argument makes the class of translation-invariant DLR states weakly closed, hence compact, and its defining identities make it convex. No compactness of the union over arbitrary period groups is being asserted.

If a source argument uses a prescribed compatible cofinal family of tori, take that family in this proof. No measure estimate beyond compactness is needed. Reflection positivity and the stronger symmetry theorems for every periodic DLR state are separate results; this measure argument proves neither their all-state estimates nor any uniformity as $a \downarrow 0$.

Recognition of limits on sufficiently large tori. Fix (K, β) and a finite bond window W. Use the same cofinal family of admissible tori for the periodic lifts and for their limit points in $\mathcal{G}^{\mathrm{tor}}_{K,\beta}$. Write h_W for the density in eq. 5.cdlx. If the torus is large enough for $W \cup \partial W$ to embed, the marginal on W of its periodic lift has Haar density

$$m_{\widetilde{\mu}_N}(V) = \int h_W(V \mid U_{\partial W})\, d\widetilde{\mu}_N(U).$$

Indeed, for functions of W the identity eq. 5.cdlxi needs only this embedding. The same formula gives the marginal m_μ of any fixed-cutoff torus limit point. All these densities are bounded below by $e^{-2\beta|\mathcal{P}(W)|}$. The functions $h_W(V \mid \cdot)$ of the exterior variables form a compact family in the uniform norm as V ranges over G^W. A finite uniform net and weak convergence thus show that the densities converge uniformly along any torus subsequence converging weakly to μ. The lower bound on the densities gives uniform convergence of their ratios to one. In particular

$$\inf_{\mu \in \mathcal{G}^{\mathrm{tor}}_{K,\beta}} \left\| m_\mu / m_{\widetilde{\mu}_N} - 1 \right\|_\infty \longrightarrow 0 \qquad (N \to \infty).$$

Otherwise a sequence of violating tori would have a weak limit point in this very class and the ratios along that subsequence would tend to one.

For each datum (K, β) take W to be the bond window of physical radius $K + 1$ in the max norm, centered at the origin, and choose a physical side threshold $\ell_\flat(K, \beta)$. Choose it so that every larger admissible torus contains the window without wrapping and the preceding infimum is at most e^{-1/a_K}. We may also take the threshold at least $2L^K$. Choose a limit state μ with ratio error $\epsilon \le 2e^{-1/a_K}$. This single state serves for all orders and all fixed compact supports eventually contained in the window. In fact, if $Y_i = \mathcal{O}_K(f_i)$ and the test supports lie in a box of radius R

within the window with a margin for their plaquettes, then

$$\left|\widetilde{\mu}_N\left(\prod_{i\in I} Y_i\right) - \mu\left(\prod_{i\in I} Y_i\right)\right| \le \epsilon \prod_{i\in I} C(1+R/a_K)^4 \|f_i\|_\infty.$$

The density ratio gives this inequality directly by integration. Expanding cumulants in moments gives an error at order n bounded by $C_n\epsilon(1+R/a_K)^{4n}\prod_i \|f_i\|_\infty$. Expansion over subsets gives the same estimate for the products centered in their respective states. Along first-passage data at fixed g with $K\to\infty$, these errors tend to zero for every fixed R and n. Thus each separated-correlation limit from tori above these thresholds has the same separated cumulants of order $n\ge 2$ and the same self-centered functional as a volume-first limit. Conversely, for a volume-first sequence, at each cutoff choose an arbitrarily large torus from the subsequence realizing the state at that cutoff so its density ratio satisfies the same tolerance. The same comparison realizes its continuum limit by tori above the thresholds.

5.24.0.1. The diagonal reflection form on these tori. Let $\Theta F = \overline{F\circ\theta^*}$ for a diagonal lattice reflection through the origin. The window W is invariant under θ. For a bounded Borel F of the bonds on its positive side, $\Theta F\cdot F$ is a function of W. The fixed-cutoff state μ is reflection positive by Prop. A.11. The same density ratio as above gives

$$\widetilde{\mu}_N(\Theta F\cdot F) \;\ge\; -\epsilon\,\widetilde{\mu}_N(|\Theta F|\,|F|) \;\ge\; -\epsilon\,\widetilde{\mu}_N(|F|^2).$$

The first expression is real by reflection invariance of the torus law. The second inequality uses Cauchy–Schwarz and that invariance. Thus the same side threshold controls the reflection form simultaneously for every such F. Along growing tori above the threshold, the error tends to zero for $F=F_K$ whenever $\epsilon\widetilde{\mu}_N(|F_K|^2)\to 0$. In particular this holds for fixed polynomials in finitely many compactly supported lattice observables, centered in the torus law if desired, by the plaquette count above.

The continuum hypothesis. Fix an odd $L\ge 3$ and a sequence $a_j = L^{-K_j}\downarrow 0$. At the same datum (a_j,β_j) let ρ_j,ν_j be periodic Wilson DLR states. The all-mirror lattice theorem supplies the following properties used here: both states are invariant under unit lattice translations and the hypercubic group, and ρ_j is reflection positive at coordinate and diagonal lattice mirrors. The centering state ν_j is invariant at those mirrors as well. These properties are lattice inputs to the compactness argument.

The infinite-lattice case includes volume-first limits when the states are torus limit points. Direct growing-torus limits are treated below with the finite-torus bounds. The density comparison above identifies limits from tori with sides at least $\ell_\flat(K,\beta)$ with volume-first limits. For general growing tori and for removal of volume after a fixed-torus continuum limit, diagonal reflection positivity requires a separate argument. Tuned fixed-torus limits, when obtained by matched-cutoff estimates, remain separate from the subsequence theorem.

For $f\in C_c^1(\mathbb{R}^4)$ write

$$\mathcal{O}_j(f) = \sum_p f(x_p)A_p, \qquad X_j(f) = \mathcal{O}_j(f) - \nu_j(\mathcal{O}_j(f)), \qquad m_{j,n}(\mathbf{f}) = \rho_j\prod_{i=1}^n X_j(f_i). \tag{5.cdlxii}$$

There is one plaquette for each coordinate plane and lattice site, so six orientations are counted once each; x_p is its barycenter. There is no power of a_j in the observable. At a fixed cutoff these are bounded continuous random variables with finite bond dependence. Set $m_{j,0}=1$ and complexify multilinearly.

Let $\mathfrak{S}_n$ be the tuples of compact C^1 tests with pairwise disjoint supports. A zero entry gives value zero and can be set aside. The separation is the minimum distance of the supports, not that of balls containing them. Every support may lie in its own radius-R ball; these balls may overlap.

Use the fixed physical norm

$$\|f\|_\sharp = \max(\|f\|_\infty, c_M\|\nabla f\|_\infty), \qquad c_M > 0 \text{ fixed.}$$

The ordinary source hypothesis is used only through the following proved implications of it. At each fixed order there is a bound

$$|m_{j,n}(\mathbf{f})| \le C_n(d;R)\prod_i \|f_i\|_\sharp \tag{5.cdlxiii}$$

when the supports have distance at least $d > 0$ and the stated radius bound. Bounds holding eventually on each fixed support neighborhood suffice for extraction. The one-point version is included: for different centering and integrating states it is a uniform bound on their mean difference, not on either unsubtracted mean.

For the quantitative conclusion assume the graded bound, with one finite integer $k \ge 1$ and $B(R) < \infty$ independent of j and the two states,

$$|m_{j,n}(\mathbf{f})| \le B(R)^n (n!)^k \max(1, d^{-5n}) \prod_i \|f_i\|_\sharp. \tag{5.cdlxiv}$$

For $n = 1$ take $d = 1$. A harmless change of B includes complex entries. These are all-state bounds at the indicated data and also apply to the pair (ρ_j, ρ_j) used for canonical recentering. The ordinary-source theorem obtains this bound from D1 and its actual rooted domain geometry, including the fixed-layer dependence and strict entropy gap. A weaker counting assertion alone does not supply this hypothesis. Those source hypotheses, and existence of the given sequence of cutoff data with common constants, are not proved by this section.

5.24.0.2. Compactness on growing tori. For a direct sequence of compatible tori of sides $\ell_j \to \infty$, use its Wilson law for both integration and centering. For any fixed finite collection of bounded support neighborhoods in $\mathbb{R}^4$, choose a box containing them and a fixed margin. Once its diameter is less than $\ell_j/4$, the quotient map to the torus is injective and preserves distances on the box. Periodize each test by summing its translates by the periods. The copies are disjoint, so the sup and Lipschitz norms are preserved. The torus distances between the projected supports are the original distances. The finite-torus part of Prop. 5.76 thus gives eq. 5.cdlxiii and eq. 5.cdlxiv eventually on each fixed support neighborhood.

The countable extraction below only uses eventual bounds on each such neighborhood, so the same diagonal sequence works for the tori. Each graded inequality passes to the limit on its fixed tuple. The extension to diagonal-flat Schwartz tests is then made on that limit functional. Translations, hypercubic symmetries and coordinate mirror positivity pass with the same fixed margins. For coordinate reflection positivity on a torus, the projected supports lie inside one half of the torus cut by the rounded mirror and its antipodal mirror for all large j. The limiting diagonal mirror is a separate case. The half-period is an integer number of lattice spacings, so the antipodal mirror has the same site or link type as the chosen mirror. The fixed support margin accommodates the full diameter of every sampled plaquette. Diagonal positivity uses the additional recognition or another diagonal reflection-positivity input.

A fixed admissible torus. For Thm. A(a)(ii), fix T_ℓ and take any sequence of first-passage data with $K_j \to \infty$. The first bound in Prop. 5.64 applies directly to the connected functions. On this torus the factor $e^{nc_V\ell^4}$ is fixed at each n. Use a countable basis of rational coordinate boxes on the torus. Every tuple of separated compact supports is contained in finite unions of such boxes whose closures remain separated. In each union choose the smooth cutoff exhaustion used below and multiply by rational real Fourier polynomials on T_ℓ. Smoothing and the C^1 convergence of the Fourier approximants give a countable dense family with support in that union. Diagonal extraction on this list of tuples and all $n \ge 2$ gives one subsequence. Telescoping with the torus bound on each product of the fixed support neighborhoods, as in eq. 5.cdlxvi, extends convergence to every separated C^1 tuple. Each canonically centered moment is the finite sum of products of

connected functions over partitions without singletons. The same subsequence therefore gives all the centered moments. The bound and permutation and hypercubic symmetries pass to the limit. Round a torus translation to the lattice modulo ℓ and use the same telescoping estimate on fixed neighborhoods of its translated supports. This gives all torus translations in the limit.

On a product of separated coordinate neighborhoods take smooth cutoffs χ_i supported there and equal to one near the support projections of a joint test F. For $k_i \in \mathbb{Z}^4$ write $e_{k_i}(x) = e^{2\pi i k_i \cdot x/\ell}$. Define the distribution of the connected limit there by

$$F \longmapsto \sum_{k \in \mathbb{Z}^{4n}} \widehat{F}(k) S_n(\chi_1 e_{k_1}, \dots, \chi_n e_{k_n}).$$

Each entry has $\|\chi_i e_{k_i}\|_\sharp \le C(1+|k_i|)$. The torus bound thus costs at most $C(1+|k|)^n$, and $5n+1$ derivatives of F give summable Fourier decay after this cost in dimension $4n$. The series agrees with S_n on separated smooth tensors. The same Fourier approximation with cutoffs gives density of these tensors on each product neighborhood. Thus the local definitions agree on overlaps and give a unique distribution of locally finite order off the diagonals. The same argument applies to the centered moments, using their finite partition formula. Coordinate mirror positivity passes to these limits by the moving-test argument below, using supports compactly contained in one of the two slabs between the rounded link mirror and its antipodal mirror.

If these fixed-torus limits are taken along $\ell_j \to \infty$ and then converge on separated tuples in $\mathbb{R}^4$, the resulting limit is also realized by one growing-torus cutoff sequence. List the countable separated tuples below, projecting them to T_{ℓ_j} once their support neighborhoods embed. At ℓ_j, choose one index from its defining cutoff sequence with $K \ge j$ and with error at most $1/j$ from the fixed-torus limit on the first j listed tuples whose neighborhoods embed. These are finitely many requirements on a convergent sequence. For any fixed separated tuple, choose an approximant from this list with the same separated neighborhoods. The per-ball bound in Prop. 5.64 holds eventually on this product with one constant for the finite cutoffs and the inner limits. Telescoping at both ends gives twice the approximation error plus $1/j$ between the selected finite-torus values and the inner limits. First let j tend to infinity, then let the approximation error tend to zero. The same indices give the centered moments by the finite partition formula. This argument uses the uniform per-ball bound on the growing family.

A countable support-adapted family. Let $\mathcal{U}$ be the bounded finite unions of open boxes with rational endpoints. This is countable. Every finite collection of separated compact sets K_i has neighborhoods $U_i \in \mathcal{U}$ such that $K_i \subset U_i$ and the closures $\overline{U}_i$ are pairwise separated. Cover each compact set by sufficiently small rational boxes inside a neighborhood of radius less than one fourth of its distance from the other sets, then take a finite subcover. The neighborhoods can also stay in any prescribed open support regions.

For each $U \in \mathcal{U}$ we now exhibit a countable family dense in $C^1_c(U)$ for the C^1 norm, with every approximant supported in U. Fix a nonnegative smooth unit-mass bump ϱ in the unit ball. For integers $m \ge 1$ let

$$\chi_{U,m} = \mathbf{1}_{\{x : \operatorname{dist}(x, U^c) > 1/(2m)\}} * \varrho_{1/(8m)}.$$

It is smooth, compactly supported in U, takes values in $[0,1]$, and equals one where $\operatorname{dist}(x, U^c) \ge 1/m$. Use finite rational linear combinations of

$$\chi_{U,m}(x)\cos(2\pi q \cdot x/N), \qquad \chi_{U,m}(x)\sin(2\pi q \cdot x/N), \quad q \in \mathbb{Z}^4,\ N \in \mathbb{N}, \tag{5.cdlxv}$$

and take their rational span over all indices. Call this real countable family D_U.

To verify density, fix $f \in C^1_c(U)$ and choose m such that $\chi_{U,m} = 1$ on a neighborhood of its support. Extend f by zero, smooth it on a sufficiently small scale, and view the resulting smooth compact function as periodic on a large integer-side box. Smoothing converges to f in C^1 because f and its gradient are uniformly continuous. The Fourier partial sums of this smooth periodic function converge with their first derivatives: repeated integration by parts makes the differentiated Fourier

series absolutely summable. Approximate their finitely many real sine and cosine coefficients by rationals and multiply by $\chi_{U,m}$. The multiplication is bounded in C^1, and $\chi_{U,m}f = f$. This produces the required approximants. Complexification gives the countable dense family $D_U + iD_U$ for complex tests.

List all tuples $(g_1, \dots, g_n)$, for every $n \geq 1$ and every ordered list of pairwise separated $\overline{U}_i$, with $g_i \in D_{U_i} + iD_{U_i}$. This is one countable list. By eq. 5.cdlxiii the values of each coordinate form a bounded sequence; finite initial values do not matter if a bound starts eventually. Extract an infinite subsequence for convergence of the first coordinate, then a subsequence of it for the second, and so on. If I_r is the rth nested infinite index set, choose increasing $j_r \in I_r$. For each fixed coordinate its values along (j_r) eventually lie in the convergent subsequence for that coordinate. All listed values therefore converge along this single subsequence.

Extension to every separated tuple. The following telescoping estimate explains why that one extraction is enough. If $\operatorname{supp} f_i \cup \operatorname{supp} g_i$ lies in $\overline{U}_i$, let $d_U > 0$ be a lower bound for their pairwise distances, taking $d_U = 1$ when $n = 1$, and choose a common finite radius bound R_U. Multilinearity and eq. 5.cdlxiii give, uniformly in the relevant tail,

$$|m_{j,n}(\mathbf{f}) - m_{j,n}(\mathbf{g})| \leq C_n(d_U; R_U) \sum_{i=1}^{n} \|f_i - g_i\|_\sharp \prod_{h \neq i} \max(\|f_h\|_\sharp, \|g_h\|_\sharp). \tag{5.cdlxvi}$$

Every mixed tuple in this telescoping sum is separated because the neighborhoods, rather than just the two endpoint tuples, carry the separation.

Given any $\mathbf{f} \in \mathfrak{S}_n$, choose such rational neighborhoods and approximate each entry in C^1 by the corresponding countable family. The right side of eq. 5.cdlxvi tends to zero uniformly in j. For a fixed approximating tuple its values converge along (j_r). Comparing two indices through this tuple shows that $m_{j_r,n}(\mathbf{f})$ is Cauchy. Define its limit by $\sigma_n(\mathbf{f})$. This definition is independent of all neighborhoods and approximants because it is the limit of the original sequence at that tuple. The subsequence has not been chosen again for $\mathbf{f}$; convergence now holds on every separated compact C^1 tuple simultaneously. Set $\sigma_0 = 1$.

Passing in eq. 5.cdlxvi proves the same local continuity estimate for σ_n. On compact subsets of each product of the fixed support spaces, convergence is uniform: choose a finite C^1 net in that compact set, apply pointwise convergence at its centers, and use eq. 5.cdlxvi at both ends. Its constants are uniform on a norm-bounded set.

Multilinearity passes whenever all tuples in the proposed identity are admissible. In particular the union of the alternative supports in a single entry must stay separated from the other entries. Permutation symmetry, conjugation and reality pass directly from their exact lattice identities. The bounds in eq. 5.cdlxiii and eq. 5.cdlxiv pass with their original constants at every fixed tuple, since absolute-value inequalities are closed under convergence. Their radius and separation parameters concern the original supports, not the larger neighborhoods used to construct the limit.

Moving arguments, real symmetries, and rounded mirrors. Suppose $f_{i,j} \to f_i$ in C^1 and all their supports lie in fixed pairwise separated compact neighborhoods. eq. 5.cdlxvi and fixed-tuple convergence give

$$m_{j_r,n}(f_{1,j_r}, \dots, f_{n,j_r}) \longrightarrow \sigma_n(f_1, \dots, f_n). \tag{5.cdlxvii}$$

This is also valid for every finite combination of tuples. For translations the needed C^1 convergence has the explicit modulus

$$\|\tau_v f - \tau_w f\|_\sharp \leq \max\{\|\nabla f\|_\infty |v - w|, c_M \omega_{\nabla f}(|v - w|)\} \longrightarrow 0, \tag{5.cdlxviii}$$

where $\omega_{\nabla f}$ is the uniform modulus of continuity of the compactly supported continuous gradient. No second derivative is required. The chain rule gives the corresponding convergence for a convergent sequence of Euclidean isometries.

For any fixed real translation v choose lattice vectors $v_j \in a_j\mathbb{Z}^4$ with $v_j \to v$. Both states are invariant under v_j, so $m_{j,n}(\tau_{v_j}\mathbf{f}) = m_{j,n}(\mathbf{f})$. The moving-test statement proves real translation invariance of σ_n. Hypercubic invariance is exact at every spacing and passes without rounding.

For clarity the reflection limit also works at arbitrary affine positions. A coordinate mirror $x_\mu = c$ can be approximated by link mirrors with $c_j \in a_j(\mathbb{Z} + 1/2)$ and $c_j \to c$. A diagonal mirror $x_\mu \pm x_\lambda = c$ is approximated by $c_j \in a_j\mathbb{Z}$. In unit-normal coordinates its offset grid is $a_j\mathbb{Z}/\sqrt{2}$. These are different conventions for the same diagonal mirror; no factor $\sqrt{2}$ is discarded. The reflected tests converge in C^1: the linear reflection part is fixed and the translation parts differ by $2(c_j - c)e_\mu$ in the coordinate case, and by $(c_j - c)(e_\mu \pm e_\lambda)$ in the diagonal case.

Let F be a finite complex combination of separated tuples whose entries lie strictly on one open side of the limiting mirror. Its compact support has positive distance from the mirror. For all fine cutoffs the barycenters sampled by those entries and all the bonds of their plaquettes lie on the same side of the rounded mirror: a plaquette has diameter $O(a_j)$, while that distance is fixed. Form its centered lattice polynomial F_j. Reflection invariance of ν_j makes centering commute with the lattice reflection. The moment identity gives

$$\rho_j(\overline{\theta_j F_j} F_j) = m_j(\theta_j \overline{F} \cdot F).$$

The left side is nonnegative where the lattice mirror has exact positivity. For a diagonal mirror through the origin on tori above the local density threshold, its negative part tends to zero by the diagonal reflection-form bound above. Every tuple on the right has a common positive support separation for large j: internal separations are fixed and the two sides are separated by the mirror gap. Apply eq. 5.cdlxvii to get

$$\sigma(\theta \overline{F} \cdot F) \geq 0. \tag{5.cdlxix}$$

Reflection invariance itself passes in the same way. The argument applies at coordinate mirrors for both lattice constructions and at diagonal mirrors for periodic states. For tori above the local density threshold, the diagonal conclusion at the origin extends to affine translates by translation invariance of the limit. A diagonal torus limit outside this threshold requires its own mirror estimate.

The one-point limit and the connected functions. The first moment is determined more precisely by the plaquette means. Unit translations and hypercubic symmetry make

$$\delta_j = \rho_j(A_p) - \nu_j(A_p)$$

independent of the plaquette position and its coordinate plane. Define

$$R_j(f) = \frac{a_j^4}{6} \sum_p f(x_p), \qquad c_j = 6a_j^{-4}\delta_j. \tag{5.cdlxx}$$

Then $m_{j,1}(f) = c_j R_j(f)$. Each orientation samples a translate of $a_j\mathbb{Z}^4$. Comparing its sample value to the integral on the corresponding side-a_j cube gives

$$R_j(f) \longrightarrow \int f, \qquad |R_j(f) - \textstyle\int f| \leq C_R a_j \|\nabla f\|_\infty \tag{5.cdlxxi}$$

for a test supported in a fixed radius-R ball. Indeed the sample and any point of its cube are at distance at most $2a_j$; only $C(R+1)^4 a_j^{-4}$ cubes can contribute. Average the six such estimates. The same bound is independent of the center of that ball.

Choose one real smooth compact bump f_* with $\int f_* = 1$. Its limiting moment exists by the preceding extraction, and $R_j(f_*) \to 1$. Consequently along the extracted subsequence

$$c_j = \frac{m_{j,1}(f_*)}{R_j(f_*)} \longrightarrow c \in \mathbb{R}, \qquad \sigma_1(f) = c \int f. \tag{5.cdlxxii}$$

In particular the coefficients are bounded on that tail. This bound is uniform over both states: $|c_j| \le 2B(R_*)\|f_*\|_\sharp$ once $R_j(f_*) \ge 1/2$, and $|c| \le B(R_*)\|f_*\|_\sharp$. This argument uses the uniform one-point comparison and the common plaquette means; it is not a deduction from formal continuum translation invariance alone. If $\rho_j = \nu_j$, then $c = 0$.

All connected limits are finite algebraic consequences, requiring no common disc of analyticity for an exponential. For a fixed n work in the algebra with $z_i^2 = 0$ and let

$$M_j(z) = 1 + \sum_{\varnothing \ne A \subset [n]} m_{j,|A|}(\mathbf{f}_A) \prod_{i \in A} z_i.$$

The logarithm is the finite series for $\log(1 + (M_j - 1))$. Its coefficient of $\prod_{i=1}^n z_i$ is

$$K_{j,n}(\mathbf{f}) = \sum_{\pi \in \mathrm{Part}[n]} (-1)^{|\pi|-1}(|\pi| - 1)! \prod_{A \in \pi} m_{j,|A|}(\mathbf{f}_A). \tag{5.cdlxxiii}$$

In fact the term of degree r in the logarithm counts the $r!$ orders of each partition with r blocks and divides by r, giving $(r-1)!$. Every subtuple is separated. Hence these finite polynomials converge to the same formula with σ in place of m_j; denote it by S_n. Conversely the finite exponential series gives $\sigma_n = \sum_\pi \prod_{A \in \pi} S_{|A|}$, since its factor $1/r!$ cancels the orders of the blocks.

Adding constants to the $X_j(f_i)$ multiplies M_j by $\exp(\sum_i b_i z_i)$, so changes its logarithm only in degree one. Thus for $n \ge 2$, $K_{j,n}$ is the usual cumulant of the raw variables $\mathcal{O}_j(f_i)$ under ρ_j, independent of the centering state. The graded cumulant bound passes as well:

$$|S_n(\mathbf{f})| \le [2B(R)]^n (n!)^k \max(1, d^{-5n}) \prod_i \|f_i\|_\sharp, \qquad n \ge 2. \tag{5.cdlxxiv}$$

One may obtain it either from the uniform lattice cumulant bound, or directly from eq. 5.cdlxxiii: if block sizes are n_h, $\prod_h n_h! \le n!$, and

$$\sum_\pi (|\pi| - 1)! \prod_{A \in \pi} (|A|!)^k \le (n!)^{k-1} \sum_\pi (|\pi| - 1)! \prod_{A \in \pi} |A|! \le 2^{n-1}(n!)^k.$$

For exactly r blocks the last unweighted sum is $\frac{n!}{r}\binom{n-1}{r-1}$, by ordered compositions of n.

There is a canonical centered functional distinct from the original two-state moments. Center at ρ_j instead of ν_j; expanding each product and using convergence of $m_{j,1}$ gives along the same subsequence

$$\sigma_n^0(\mathbf{f}) = \sum_{A \subset [n]} \sigma_{|A|}(\mathbf{f}_A) \prod_{i \notin A} (-c \textstyle\int f_i) = \sum_{\pi \in \mathrm{Part}_{\ge 2}[n]} \prod_{A \in \pi} S_{|A|}. \tag{5.cdlxxv}$$

It has empty value one, singleton zero, the same higher connected functions, and all the bounds and positivity properties above. For the bounds use the lattice pair (ρ_j, ρ_j) before passing to the limit, so no uncontrolled constant from recentering is introduced.

The quantitative flat extension and closed inequalities. For completeness the topology retained by this compactness statement is explicit. Let $\Delta_n = \bigcup_{i<h}\{x_i = x_h\}$ and let $\mathcal{S}_{\Delta,n}$ be the Schwartz functions whose every jet vanishes on Δ_n. Use

$$p_s(\Phi) = \max_{|\alpha| \le s} \sup_x (1 + |x|^2)^{s/2} |\partial^\alpha \Phi(x)|.$$

On unit-radius supports, eq. 5.cdlxiv and $\|f\|_\sharp \le \max(1, c_M)\max(\|f\|_\infty, \|\nabla f\|_\infty)$ give the quantitative flat-extension hypothesis with separation exponent five. For either limit the theorem gives a unique extension Σ_n with

$$|\Sigma_n(\Phi)| \le C^n (n!)^{k+32} p_{20n}(\Phi). \tag{5.cdlxxvi}$$

The same bound holds for the centered and connected extensions, after changing C. Separated smooth tensors are dense in $\mathcal{S}_{\Delta,n}$.

For the infinite-lattice inputs the same uniform estimate holds for the extensions $\Sigma_{j,n}$. In the direct torus construction the graded bound is eventual on each fixed compact tuple. Distant

supports can project onto the same part of a torus at finite j, so that argument gives the flat estimate on the limit through the fixed compact tuples.

For the infinite-lattice sequence, given Φ approximate it by a finite sum T of smooth separated tensors in p_{20n}. The common estimate controls both $\Sigma_{j,n}(\Phi - T)$ and $\Sigma_n(\Phi - T)$ uniformly in j. On T convergence has already been proved. Taking first the cutoff limit and then the approximation error to zero proves

$$\Sigma_{j_r,n}(\Phi) \longrightarrow \Sigma_n(\Phi). \tag{5.cdlxxvii}$$

The positive-time version of the density theorem uses tensors strictly above the mirror. Their reflected products are flat on all cross diagonals, including the time boundary. Thus the limit's symmetry, reality, real translations and reflection positivity extend by this density and the continuity of tensor products in Schwartz seminorms. For each mirror with the lattice positivity input, use its corresponding positive half-space. It follows by an orthogonal change of variables in the flat-space density construction; it does not assume invariance of the functional under that change of variables.

More generally any closed inequality involving finitely many fixed tuple evaluations and continuous functions of them passes to the limit. The statement allows moving tests as in eq. 5.cdlxvii, convergent scalar coefficients and eventual uniform bounds. Its proof is simply convergence of those finitely many numbers followed by continuity and closedness of the inequality. It does not turn strict inequalities into uniform strict bounds or provide estimates whose constants diverge with the cutoff.

The proposition records the infinite-lattice construction, including its diagonal mirror input. Direct growing tori give the compact-tuple convergence, limiting flat extension and coordinate reflection positivity by the preceding argument.

Proposition 5.77 (Subsequential continuum compactness)**.** For every input sequence satisfying the lattice properties and two-state uniform bounds above, there is one subsequence whose moments converge on every separated compact C^1 tuple. The limiting functional is admissibly multilinear, symmetric and real, invariant under real translations and the hypercubic group, and reflection positive at every coordinate and diagonal affine mirror. It retains the graded bound and its quantitative diagonal-flat extension. Its first moment is $c\int f$, its higher connected functions are the limits of the integrating states' cumulants, and eq. 5.cdlxxv is their canonical centered functional. Moving arguments and fixed-tuple closed inequalities pass as stated above. ■

The preceding sections prove every assertion. The fixed-cutoff measure argument ensures that invariant Wilson DLR states are available at each given datum. It supplies neither a sequence of admissible renormalization data with $K_j \to \infty$ nor D1's uniform source bounds. It also supplies no identification of two different extracted limits, no matched-cutoff convergence rate, and no claim of a full Yang–Mills observable theory.

5.25. **Extension to diagonal-flat Schwartz tests.** A graded bound for compact separated moments implies an extension to diagonal-flat Schwartz tests, with explicit dependence on the number of arguments. The graded bound for the gauge theory remains a hypothesis. We construct the local distributions by Fourier series on product boxes and track the constants as the number of variables grows.

5.25.1. *The hypothesis and the quantitative conclusion.* Use $\|f\|_1 = \max(\|f\|_\infty, \|\nabla f\|_\infty)$ on $C^1_c(\mathbb{R}^4;\mathbb{C})$. Suppose S_n, $n \geq 1$, are complex multilinear forms on tuples with pairwise separated compact supports. Multilinearity is required whenever the supports in the identity remain separated. Fix numbers $1 \leq b < \infty$, $\kappa \geq 0$ and $\alpha \geq 0$, independent of n, such that

$$|S_n(f_1,\dots,f_n)| \leq b^n (n!)^\kappa \max(1, d^{-\alpha n}) \prod_i \|f_i\|_1 \tag{5.cdlxxviii}$$

if every support lies in a ball of radius one, placed anywhere, and different supports have Euclidean distance at least $d > 0$. For $n = 1$ only the radius and norm conditions are imposed. A centered first moment equal to zero is included. Real forms may first be complexified, changing b by an absolute factor. Neither invariance nor positivity is needed for the extension.

Put $A = \lceil \alpha \rceil$, $k_* = A + 15$, and $\Delta_n = \bigcup_{i<j} \{x_i = x_j\}$. Let $\mathcal{S}_{\Delta,n}$ be the Schwartz functions on $\mathbb{R}^{4n}$ whose derivatives of every order vanish on Δ_n. For $n = 1$ this is the ordinary Schwartz space. Write

$$p_k(\varphi) = \max_{|\beta| \le k} \sup_x (1 + |x|^2)^{k/2} |\partial^\beta \varphi(x)|. \tag{5.cdlxxix}$$

Proposition 5.78 (Quantitative diagonal-flat extension)**.** There is $C < \infty$, depending on b, α and fixed numerical cutoff choices but not on n, and a unique continuous linear functional Σ_n on $\mathcal{S}_{\Delta,n}$ agreeing with S_n on smooth separated tensors. It satisfies

$$|\Sigma_n(\varphi)| \le C^n (n!)^{\kappa+32} p_{k_* n}(\varphi), \qquad n \ge 1. \tag{5.cdlxxx}$$

Finite sums of smooth compact separated tensors are dense in this diagonal-flat space in its Schwartz topology. In its positive-time subspace, the tensors may be chosen with supports compactly contained in $\{x_4 > 0\}$. These are constrained density assertions, not density in the unrestricted Schwartz space across the diagonals. ∎

The conclusion is an H1 growth estimate with linear derivative order and a fixed factorial exponent; its constants are intentionally not optimized. For example, $\alpha = 5$ gives the sufficient order $20n$. The probability-theory normalization $\Sigma_0(1) = 1$ may be added separately.

The radius-one formulation loses no information about a hypothesis stated as

$$B(R)^n (n!)^\kappa \max(1, d^{-\alpha n}),$$

with constants independent of support positions. Choose a fixed smooth unit-scale partition in each slot. A function supported in a radius-R ball is a sum of at most $C(1+R)^4$ supported pieces of radius at most one, each with C^1 norm at most $C\|f\|_1$. Supports of pieces from different slots retain the original separation. Multilinearity and eq. 5.cdlxxviii therefore imply the same bound with

$$B_{\mathrm{eff}}(R) \le Cb(1+R)^4. \tag{5.cdlxxxi}$$

Thus only $B(1)$ is used, even if the supplied large-radius upper bound was exponential. This assertion concerns a separate ball for each entry, not one ball enclosing the entire configuration.

5.25.2. *Cutoffs with controlled derivatives.* We fix all cutoffs once. They can be chosen in Gevrey class two, with

$$0 \le \eta \le 1, \qquad |\partial^\beta \eta| \le C^{|\beta|+1} (|\beta|!)^2. \tag{5.cdlxxxii}$$

Here is an explicit construction and a justification of this bound. Set $a(t) = e^{-1/t}$ for $t > 0$ and $a(t) = 0$ for $t \le 0$. On the complex circle $|z - t| = t/2$ one has $\mathrm{Re}(1/z) \ge 2/(9t)$. Cauchy's formula bounds $|a^{(m)}(t)|$ by $m!(2/t)^m e^{-2/(9t)}$. Maximizing $t^{-m} e^{-c/t}$ and using $(m/e)^m \le m!$ gives $C^{m+1}(m!)^2$. The step

$$s(t) = \frac{a(t)}{a(t) + a(1-t)}$$

is set equal to zero for $t \le 0$ and one for $t \ge 1$. Its denominator on $[0,1]$ is at least e^{-2}. The same derivative bound holds for its reciprocal and hence for s. For precision, differentiate $D(1/D) = 1$ inductively; after division by $(m!)^2$, the convolution coefficients are $1/\binom{m}{r} \le 1$. If $|D^{(r)}| \le C_D^{r+1}(r!)^2$, a derivative constant $C_D(1+2e^2C_D)$ for the reciprocal closes the resulting geometric sum. Products obey the same bound by Leibniz's formula. This proves eq. 5.cdlxxxii, including flatness at the join points.

Choose an even η_0 equal to one on $[-1,1]$, zero outside $[-2,2]$, and nonincreasing on $[0,\infty)$, using $s(2-|t|)$ in the transition. Put $\psi(t) = \eta_0(2t)$ and $D(t) = \sum_{z\in\mathbb{Z}} \psi(t-z)$. At most three summands occur locally and $D \ge 1$. Then $\chi_1 = \psi/D$ is supported in $[-1,1]$, has eq. 5.cdlxxxii, and $\sum_z \chi_1(t-z) = 1$. Define

$$\chi(u) = \prod_{a=1}^{4} \chi_1(u_a),$$

$$\chi^+(u) = \prod_{a=1}^{4} \eta_0(u_a),$$

$$\zeta(u) = 1 - \chi^+(u). \tag{5.cdlxxxiii}$$

Thus $\sum_{z\in\mathbb{Z}^4} \chi(u-z) = 1$, $\chi^+ = 1$ on the support of χ, and ζ is zero for $|u|_\infty \le 1$ and one for $|u|_\infty \ge 2$. All these functions lie between zero and one and have eq. 5.cdlxxxii, with an absolute constant. In particular, undifferentiated factors cost one.

We will repeatedly use the following elementary product estimate. For N factors of this kind at scale h, every derivative of order q is bounded by

$$(CN)^q (q!)^2 h^{-q}. \tag{5.cdlxxxiv}$$

An absolute prefactor is allowed at $q = 0$. Indeed, distribute the multiindex among the factors by Leibniz. The sum of the multinomial coefficients is N^q, and the product of the factorials of the assigned derivative orders is at most $q!$. Derivatives of pair differences $x_i - x_j$ introduce only signs. This argument produces no factor C^N when most factors are undifferentiated.

5.25.3. *An explicit local functional on a product box.* First, tensor relations cause no ambiguity. In a finite relation between separated tensors, let d be smaller than every separation. Localize all entries by one finite smooth partition on sets of diameter less than $d/8$. A product of slot sets with two sets closer than $d/2$ has a zero factor in every original tensor: otherwise two original supports would be closer than d. On every remaining product the slot sets are separated, and the form is an ordinary multilinear map on their supported function spaces. It factors through their algebraic tensor product. The latter embeds injectively in functions on the Cartesian product: for the finite-dimensional function spans in any relation, finitely many point evaluations give invertible matrices in each slot. A zero tensor therefore has zero value. Summing the localization proves independence of the tensor presentation.

Here is a quantitative local extension. Let $0 < h \le 1/16$, $\ell = h/64$, and let slot centers be $c_i \in \mathbb{R}^4$. Suppose the cubes $Q_i^+ = c_i + [-2\ell, 2\ell]^4$ have pairwise distance at least $h/2$. They lie in balls of radius one. For a smooth function u supported in $\prod_i (c_i + [-\ell,\ell]^4)$, take its Fourier series on the product of period-8ℓ cubes centered at these points. Write its coefficients as $c_{k_1,\dots,k_n}$, $k_i \in \mathbb{Z}^4$. Multiplying the series by $\prod_i \chi^+((x_i - c_i)/\ell)$ gives a series of separated tensors equal to u

everywhere. There is no boundary ambiguity: u vanishes near the boundaries of the period cubes. Explicitly, with $Q = \prod_i (c_i + [-4\ell, 4\ell]^4)$, the coefficients are

$$c_{k_1,\dots,k_n} = (8\ell)^{-4n} \int_Q u(x) \exp\left[-\frac{i\pi}{4\ell} \sum_i k_i \cdot (x_i - c_i)\right] dx.$$

In the scaled variables $y_i = (x_i - c_i)/(4\ell)$, apply $(1 - \pi^{-2}\Delta_i)^4$ in every four-dimensional slot. Integration by parts gives

$$|c_{k_1,\dots,k_n}| \le C^n J_{8n,\ell}(u) \prod_i (1 + |k_i|^2)^{-4},$$

$$J_{q,\ell}(u) = \max_{|\beta| \le q} \ell^{|\beta|} \|\partial^\beta u\|_\infty. \tag{5.cdlxxxv}$$

The sum of absolute coefficients in the product differential operator is at most C^n; no factor depending unspecifiedly on dimension is hidden here. The localized exponential in slot i has C^1 norm at most $C\ell^{-1}(1 + |k_i|)$. Since

$$\sum_{k \in \mathbb{Z}^4} (1 + |k|)(1 + |k|^2)^{-4} < \infty,$$

eq. 5.cdlxxviii makes the series of its moment values absolutely convergent and gives a local functional $T(u)$ with

$$|T(u)| \le (Cb)^n (n!)^\kappa h^{-(\alpha+1)n} J_{8n,\ell}(u). \tag{5.cdlxxxvi}$$

For a tensor supported in the inner cubes it agrees with S_n: its Fourier coefficients factor slot by slot, the partial sums converge in C^1, and eq. 5.cdlxxviii permits passage through the multilinear form.

These local extensions glue to a unique functional T on $C_c^\infty(\mathbb{R}^{4n} \setminus \Delta_n)$. To check this explicitly, in an overlap choose smaller product boxes enclosing the compact support under consideration. Fourier expansions with cutoffs inside the overlap converge with every fixed number of derivatives and consist of separated tensors. Two local functionals agreeing on those tensors therefore agree there, by their finite-order bounds in eq. 5.cdlxxxvi. A finite partition of unity on a compact off-diagonal set now defines T independently of the cover. For original separated tensors of larger radius, first partition each entry into sufficiently small pieces and use multilinearity. This also shows that the glued T agrees with the given form on all smooth compact separated tensors, not just on the boxes used in its construction. This gluing argument is used for consistency, not for the numerical bound: the latter uses only the fixed explicit grid and eq. 5.cdlxxxvi.

5.25.4. *Dyadic configuration layers and the factorial accounting.* Set $h_j = 2^{-j}/16$ and define

$$P_h(x) = \prod_{i<l} \zeta((x_i - x_l)/h),$$

$$D_0 = P_{h_0},$$

$$D_j = P_{h_j} - P_{h_{j-1}}$$

$$(j \ge 1). \tag{5.cdlxxxvii}$$

For $n = 1$ the empty product is one and $D_j = 0$ for $j \ge 1$. Off the diagonals $\sum_{j \ge 0} D_j = 1$. A fine layer has support

$$h_j \le \min_{i<l} |x_i - x_l|_\infty \le 4h_j. \tag{5.cdlxxxviii}$$

The statements about support also hold for its derivatives. Monotonicity of the one-variable cutoffs makes $0 \le D_j \le 1$, although positivity of these differences is not needed for the estimates.

At level j set $\ell_j = h_j/64$ and use the product grid partition

$$\chi_{j,z}(x) = \prod_{i=1}^{n} \chi(x_i/\ell_j - z_i),$$
$$z \in (\mathbb{Z}^4)^n. \tag{5.cdlxxxix}$$

Retain a box if $\chi_{j,z} D_j$ is not identically zero. At one point of that box every pair has distance greater than h_j; its centers therefore have pair distance at least $h_j - 2\ell_j$. The expanded cubes $\ell_j z_i + [-2\ell_j, 2\ell_j]^4$ have pair distance at least $h_j - 6\ell_j > h_j/2$. Thus eq. 5.cdlxxxvi applies to $u_{j,z} = \chi_{j,z} D_j \varphi$. A box with only boundary contact can be ignored if its smooth localized function is zero.

There are at most Cn^2 pair and grid factors in such a cutoff. Using eq. 5.cdlxxxiv, Leibniz's formula and $q = 8n$, we obtain the uniform scaled-derivative cost

$$(Cn^2)^{8n}((8n)!)^2 \le C^n (n!)^{32}. \tag{5.cdxc}$$

Here $n^{16n} \le e^{16n}(n!)^{16}$, while $(8n)! \le 8^{8n}(n!)^8$. This accounts for every dependence on the number of pair cutoffs; the $\binom{n}{2}$ undifferentiated factors do not create C^{n^2}.

On a fine layer choose a pair with $|x_i - x_l|_\infty \le 4h_j$ and replace x_i by x_l. The resulting point y lies on a diagonal and $|x - y| \le 8h_j$. Every derivative of φ vanishes there. Taylor's integral remainder along this segment gives, for $|\beta| \le 8n$ and any positive integer m,

$$|\partial^\beta \varphi(x)| \le \frac{(Ch_j)^m}{m!} C^{k_* n} (1 + |x|^2)^{-k_* n/2} p_{k_* n}(\varphi) \tag{5.cdxci}$$

when $8n + m \le k_* n$. The derivative of order m along a vector uses at most four coordinate directions; its multinomial sum is bounded by the m-th power of that vector's ℓ^1 norm. Also $|x - y| \le 1/2$, so the weight at every point of the segment is comparable with that at x, at cost $C^{k_* n}$. These are exponential, not factorial, costs in n.

Take

$$m = (A + 5)n + 2,$$
$$8n + m = (A + 13)n + 2 \le (A + 15)n. \tag{5.cdxcii}$$

In differentiating $u_{j,z}$, a derivative on a cutoff costs h_j^{-1}, which its scaled-derivative factor in J_{8n,ℓ_j} cancels. Derivatives remaining on φ are bounded by eq. 5.cdxci. Since $h_j \le 1$, unused positive powers of h_j can be discarded. eq. 5.cdlxxxiv, eq. 5.cdxc–eq. 5.cdxcii consequently imply

$$J_{8n,\ell_j}(u_{j,z}) \le C_A^n (n!)^{32} h_j^m p_{k_* n}(\varphi) \sup_{x \in \operatorname{supp} \chi_{j,z}} (1 + |x|^2)^{-k_* n/2}. \tag{5.cdxciii}$$

For $j = 0$ use the same estimate without h_j^m, by the ordinary Schwartz derivative bound; all powers of the fixed h_0 are absorbed in C_A^n.

The grid sum has exactly the needed size. Since $1 + \sum_i |x_i|^2 \ge \prod_i (1 + |x_i|^2)^{1/n}$, and grid points in one slot differ from its box by a fixed distance less than one,

$$\sum_z \sup_{x\in\operatorname{supp}\chi_{j,z}} (1+|x|^2)^{-k_*n/2} \le C_A^n \prod_{i=1}^n \sum_{z_i\in\mathbb{Z}^4} (1+|\ell_j z_i|^2)^{-k_*/2} \le C_A^n h_j^{-4n}. \tag{5.cdxciv}$$

The one-slot sum is bounded by $C_A\ell_j^{-4}$ by comparison with the integral of $(1+|u|^2)^{-k_*/2}$ on $\mathbb{R}^4$; it is finite because $k_*>4$. No number of configurations depending exponentially on n^2 is being counted.

Combine eq. 5.cdlxxxvi, eq. 5.cdxciii and eq. 5.cdxciv. Since $\alpha\le A$, the sum of absolute values at every fine level is at most

$$C^n(n!)^{\kappa+32}p_{k_*n}(\varphi)h_j^{m-(\alpha+5)n} \le C^n(n!)^{\kappa+32}p_{k_*n}(\varphi)h_j^2. \tag{5.cdxcv}$$

The coarse level has the same bound without h_j^2. The dyadic sum $\sum_j h_j^2$ is finite. We may therefore define

$$\Sigma_n(\varphi)=\sum_{j\ge0}\sum_z T(\chi_{j,z}D_j\varphi). \tag{5.cdxcvi}$$

This absolutely convergent sum proves eq. 5.cdlxxx and continuity in its stated seminorm. It agrees with T on compact off-diagonal tests, because there only finitely many layers and boxes occur and their partition sums to one. In particular it has the required tensor values.

5.25.5. *Density, the time boundary, and independence of choices.* We give the density details also needed for uniqueness. First cut off infinity by $Q_R(x)=\prod_i\chi^+(x_i/R)$. For a fixed Schwartz seminorm p_k, an extra L powers of decay give

$$p_k((1-Q_R)\varphi)\le C_{n,k,L}R^{-L}p_{k+L}(\varphi), \qquad R\ge1. \tag{5.cdxcvii}$$

This follows by Leibniz, since the nonzero terms have at least one $|x_i|\ge R$ and cutoff derivatives cost R^{-1}. Next cut out all pairwise diagonals with P_h. Where a derivative of $1-P_h$ can contribute, some pair is within $2h$. Applying the same Taylor argument with arbitrarily many extra derivatives gives

$$p_k((1-P_h)\varphi)\le C_{n,k,M}h^{M-k}p_{k+M}(\varphi). \tag{5.cdxcviii}$$

For each fixed n,k choose $M>k$. Thus compact tests supported away from every diagonal are dense in $\mathcal{S}_{\Delta,n}$. For example both displayed density constants may be bounded by $C^{k+M+L+1}(n^2+1)^k(k!)^2$, with unused parameters omitted. This follows from eq. 5.cdlxxxiv and the same directional Taylor remainder; these constants are not used in place of the uniform estimate in eq. 5.cdxcv. On each such compact set, use a finite product-box partition and the Fourier expansions of eq. 5.cdlxxxv. Their partial sums converge with every derivative and have a common compact support. They consequently converge in the Schwartz topology and are finite sums of separated smooth tensors. This proves the asserted constrained tensor density. Choosing the truncations and Fourier partial sums successively for the first $1,2,\dots$ seminorms gives a single convergent sequence.

For positive time define $\mathcal{S}_{\Delta,+,n}$ by requiring all derivatives to vanish outside $\{x_{1,4}>0,\dots,x_{n,4}>0\}\setminus\Delta_n$. In addition to the preceding cutoffs, set

$$B_h(x)=\prod_{i=1}^n s(x_{i,4}/h-1). \tag{5.cdxcix}$$

It is zero if some time is at most h and one if all are at least $2h$. Where $1 - B_h$ contributes to a positive-time test, a time is within $2h$ of zero. Taylor expansion to that forbidden hyperplane, where every jet vanishes, proves the analogue of eq. 5.cdxcviii. Hence $Q_R P_h B_h \varphi$ approximates every positive-time test in the full Schwartz topology. Product boxes for this approximation can be expanded while staying strictly above time zero. Their tensor approximants are therefore strictly positive-time separated tensors.

There is also a uniform quantitative version: replace P_h throughout eq. 5.cdlxxxvii by $P_h B_h$. A fine layer then has all pair distances and all times at least h, while one pair distance or one time is at most $4h$. The expanded grid boxes retain separation and positive time. There are still at most Cn^2 cutoff factors. Taylor to the nearest forbidden pair diagonal or time hyperplane supplies eq. 5.cdxci, so exactly the same k_* and factorial exponent apply. This verifies explicitly that the time-boundary constraint introduces no hidden growth in n.

Uniqueness now follows without a choice of a particular partition. Any two continuous extensions agreeing on separated tensors agree on a dense subspace and hence on all of $\mathcal{S}_{\Delta,n}$. Thus the Fourier boxes, cutoffs, dyadic grids and orders of their absolutely convergent sums do not change the resulting functional. The same statement holds on the positive-time subspace.

If the compact moments are symmetric, real or invariant under a specified Euclidean motion, their extensions inherit that identity by density and continuity of the test-function transformations. If the compact moments are reflection positive, take finite positive-time Schwartz sequences and approximate their components by the tensors just constructed. For a negative-time and positive-time factor, their tensor product is flat on all cross diagonals: away from the time boundary one factor already vanishes, and at time zero its jets vanish. Internal diagonals are handled by their own factors. The tensor product is continuous in Schwartz seminorms. Thus the reflected quadratic forms converge, and their nonnegativity passes to these full sequence domains. This proves the distribution-space implication once eq. 5.cdlxxviii is supplied; it is not a proof of the gauge-theory estimate in eq. 5.cdlxxviii.

5.25.5.1. The graded-source limit and phase consequence. Under Prop. 5.76, every pointwise limit on separated tuples of its two-state centered moments retains eq. 5.cdlvii: for each fixed tuple the inequality is closed and its constants are uniform in cutoff and in both states. The phase-interface theorem realizes each of its component forms by such sequences of pure lattice states, centered at the specified reference states. Therefore the same bound holds for those components, including their possibly nonzero first moments; their one-point shifts are covered by the all-state comparison bound. The fixed equivalence between $\|\cdot\|_\sharp$ and $\|\cdot\|_1$ is absorbed in the radius-one constant b. Thus eq. 5.cdlxxviii applies with $\alpha = 5$ and the graded factorial exponent k. These limits and components consequently have the unique diagonal-flat extensions with order $20n$ and factorial exponent $k+32$, uniformly over the stated phase realization. This uses that realization rather than assuming an unrelated component decomposition has the same bounds. It supplies neither contact terms across the diagonals nor full rotational covariance.

5.25.6. *Why the precise hypotheses matter.* Position uniformity cannot be replaced by unrestricted exponential growth in an enclosing radius. For example, $S_1(f) = \int e^{|x|^2} f(x)\,dx$ has finite bounds for compact tests in every fixed ball about the origin, with an exponential radius cost, but has no continuous extension to Schwartz space agreeing with those values. Translated nonnegative compact bumps, damped by $e^{-|x|^2/2}$, converge to zero in every Schwartz seminorm while their values diverge. Their supports can be chosen in successively more distant unit balls. This example violates the position-uniform radius-one hypothesis. Under that actual hypothesis in eq. 5.cdlxxxi rules out this obstruction.

Nor may a prefactor such as e^{cn^2} be silently called factorial growth of a fixed order. A lognormal random constant field has moments $S_n(f_1, \dots, f_n) = e^{n^2/2} \prod_i \int f_i$. It is translation invariant and reflection positive, but violates every estimate in eq. 5.cdlxxx with fixed linear seminorm order and

fixed factorial exponent. To see this, take unit-integral Gevrey-two bumps in n separated unit balls with centers at distance $O(n)$ from the origin. Their tensor is diagonal-flat. For every fixed k, its seminorm p_{kn} grows at most $C^n(n!)^{C_k}$, by eq. 5.cdlxxxii and the polynomial location weights. Its moment grows like $e^{n^2/2}$, which is larger than $C^n(n!)^q$ for every fixed q. Thus the graded, fixed-exponent assumption in eq. 5.cdlxxviii has mathematical content; reflection positivity alone does not supply it.

6. Short distances and Euclidean covariance

The short-distance calculation identifies the free-curvature coefficient after running the coupling to the separation scale. It requires a conditional interacting law, including the exterior configuration and the differentiated normalizer. We give these requirements explicitly before the comparison and insertion estimates. The angular arguments and the reflection-positive Hilbert-space construction provide the covariance needed in §7.

6.1. **The short-distance coefficient and nontriviality.** The short-distance conclusions below retain the interacting extraction and state-transfer inputs of Group F. In particular the exact conditional identities of § 6.3 require the actual complete-law identification, connected force and boundary estimates, a common reference for conditional means, and marked bad-event moments with rates relative to the g^4 signal. The classical Gaussian cutoff theorem supplies a reference estimate; the interacting inputs require separate proof. The assertions of Props. 6.1 and 6.3 are proof-outline conclusions conditional on that remaining package.

6.1.1. *Two-point short-distance asymptotics, torus four-point positivity, and universality.* At short distances, the connected two-point function behaves to leading order like that of N^2-1 free fields. On the tori the same holds for the connected four-point function, restricted to nearly collinear quadruples, which form the class $\mathfrak{T}^{(4)}$ introduced in Thm. A(c)(5). The strength of these free fields equals the running coupling evaluated at the observation scale; it is non-zero and tends to zero only logarithmically.

Objects. The test pairs are $(f,h)\in\mathfrak{T}_{\mathbb{E}}(\mathsf{d};\vartheta)$, that is, pairs of non-negative Lipschitz bumps, each supported in a ball of radius d, placed at a distance from one another that lies between d and $6\mathsf{d}$ (§6.1.1.1). The free kernel is $\mathcal{K}_{\mathrm{free}}(f,h)=\iint f(x)h(y)|x-y|^{-8}dx\,dy$. We take the coupling $g(\mathsf{d})=g_{K-s(\mathsf{d})}(\beta)$, as well as the normalisation $\zeta_K(\mathsf{d})=\zeta'_{K-s(\mathsf{d})}(\beta)$, at the level whose spacing is smaller than d by a power of $\log g(\mathsf{d})^{-2}$.

Proposition 6.1 (non-triviality; Thm. A(c)(3)-(5))**.** Assume $g\le\gamma_W(\vartheta)$. Then there exist an integer $n_0\ge 1$, a threshold $\mathsf{d}_0=\mathsf{d}_0(g,\vartheta)\in(0,1)$, a function $\bar\eta:(0,\mathsf{d}_0]\to[0,\frac13]$ that is non-decreasing with $\bar\eta(\mathsf{d})\to 0$ as $\mathsf{d}\to 0$, and, for each $\ell\in\mathfrak{L}(g)$, a function $\bar\varepsilon_\ell:(0,\mathsf{d}_0]\to[0,\frac12]$ that is non-decreasing with $\bar\varepsilon_\ell(\mathsf{d})\to 0$ as $\mathsf{d}\to 0$, with the following properties whenever $\mathsf{d}\le\mathsf{d}_0$. (i) Take any first-passage datum with $K-s(\mathsf{d})\ge n_0$, any $\ell\in\mathfrak{L}(g)$ and any pair in $\mathfrak{T}_{T_\ell}(\mathsf{d};\vartheta)$. Then

$$\langle\mathcal{O}(f);\mathcal{O}(h)\rangle_{K,\ell,\beta}=\zeta_K(\mathsf{d})^2\,\tfrac{3(N^2-1)}{\pi^4}\,g(\mathsf{d})^4\,\mathcal{K}_{\mathrm{free}}(f,h)\,(1+\varepsilon),$$
$$|\varepsilon|\le\tfrac12,$$

and moreover $|\varepsilon|\le\bar\varepsilon_\ell(\mathsf{d})$, the inequality $|\frac{11N^2}{12\pi^2}g(\mathsf{d})^2\ln(1/\mathsf{d})-1|\le\bar\eta(\mathsf{d})$ holds, and $|\zeta_K(\mathsf{d})-1|$ is bounded by the same right-hand side; all of these bounds are uniform in (K,β). The same identity is also valid in every periodic Gibbs state at β on $\mathbb{L}_K$, with the same $\zeta_K(\mathsf{d})$ and $g(\mathsf{d})$ and with an error satisfying $|\varepsilon|\le\frac12$ (§6.1.1.1). (ii) On pairs of class C^1, every continuum limit obtained from Thm. A(a)(ii) on the torus T_ℓ, as well as every one obtained from Thm. A(a)(iii) on $\mathbb{R}^4$, obeys

$$S_2(f,h) = \tfrac{3(N^2-1)}{\pi^4}\big(\tfrac{12\pi^2}{11N^2}\big)^2 \frac{\mathcal{K}_{\mathrm{free}}(f,h)}{(\ln(1/\mathsf{d}))^2}\,(1+\eta),$$
$$c \le 1+\eta \le C,$$

and on each T_ℓ one has $\eta \to 0$ as $\mathsf{d} \to 0$. (iii) On the tori, let $\vartheta \le \vartheta_\square$, the number from Thm. A(c)(5), which depends only on the fixed data. For the additional four-point clause, assume there exist an integer $n_4 \ge n_0$, a number $\mathsf{d}_4 \in (0, \mathsf{d}_0]$, a side $\ell_4(g) \in \mathfrak{L}(g)$, together with, for each $\ell \in \mathfrak{L}(g)$ with $\ell > \ell_4(g)$, a threshold $\mathsf{d}_4(\ell) \in (0, \mathsf{d}_4]$, with the following property. Suppose $K - s(\mathsf{d}) \ge n_4$. Suppose $\mathsf{d} \le \mathsf{d}_4$ when $\ell \le \ell_4(g)$, and $\mathsf{d} \le \mathsf{d}_4(\ell)$ otherwise. Then for every quadruple in $\mathfrak{T}^{(4)}_{T_\ell}(\mathsf{d};\vartheta)$ (Thm. A(c)(5)), the following bounds hold uniformly in (K,β). Here c, C are constants that are allowed to depend on g as well as on the shape ϑ.

$$c\,(N^2-1)\,g(\mathsf{d})^8 \prod_i \|f_i\|_\infty \le S^T_{4;K,\ell,\beta}(f_1,\dots,f_4) \le C\,(N^2-1)\,g(\mathsf{d})^8 \prod_i \|f_i\|_\infty.$$

Clause (iii) is a statement about the lattice functions on the tori. For four points, Thm. A asserts nothing about the limits, and nothing about $\mathbb{R}^4$. ■

Additional comparison estimates are required for four-point positivity on arbitrary shapes or continuum components and for rigidity of general short-distance germs.

6.1.1.1. The short-distance two-point law and its asymptotic-freedom normalisation. **Objects.** The class $\mathfrak{T}_{\mathbb{E}}(\mathsf{d};\vartheta)$ consists of the pairs of non-zero Lipschitz functions $f, h \ge 0$ satisfying

$$\operatorname{supp} f \subset B(x,\mathsf{d}),$$
$$\operatorname{supp} h \subset B(y,\mathsf{d}),$$
$$\mathsf{d} \le \operatorname{dist}(\operatorname{supp} f, \operatorname{supp} h) \le 6\mathsf{d},$$
$$\textstyle\int f \ge \vartheta \|f\|_\infty \mathsf{d}^4,$$
$$\operatorname{Lip} f \le \tfrac{\|f\|_\infty}{\vartheta \mathsf{d}},$$

where the final two conditions are required of h as well. It follows that $c\vartheta^2\|f\|_\infty\|h\|_\infty \le \mathcal{K}_{\mathrm{free}}(f,h) \le C\|f\|_\infty\|h\|_\infty$. On $\Lambda^2\mathbb{R}^4$ the free curvature propagator is given by

$$\mathbb{K}(u) = \pi^{-2}|u|^{-4}\,\Lambda^2 \mathsf{I}(\hat u),$$
$$\mathsf{I}(\hat u) = 1 - 2\hat u \hat u^{\mathsf{T}},$$
$$\hat u = u/|u|,$$

which is the two-point tensor of $\mathrm{d}A$ when A is a one-form with covariance $\delta_{\mu\nu}(4\pi^2|x|^2)^{-1}$. Since $\Lambda^2\mathsf{I}$ is an involution, $\operatorname{tr}\mathbb{K}(u)^2 = 6\pi^{-4}|u|^{-8}$. On $\Lambda_{K,\ell}$, let $F = \mathrm{d}A$ be the free lattice curvature, where d denotes the lattice coboundary; this curvature is the standard Gaussian on exact 2-cochains with a single colour and unit coupling, and $\mathbb{E}_{\mathrm{free}}$ denotes the expectation with respect to it. Its background part at depth s is $F_B := \mathbb{E}_{\mathrm{free}}[F \mid Q_{K-s}(\mathbf{1})A$ modulo closed forms], and we set

$$C^{\mathrm{free}}_K = C^{\mathrm{bg}}_{K,s} + C^{\mathrm{fl}}_{K,s},$$
$$C^{\mathrm{bg}}_{K,s}(p,q) = \mathbb{E}_{\mathrm{free}}\,F_B(p)F_B(q),$$

$$\mathcal{K}_{K,s}(f,h)=\sum_{p,q} f(x(p))h(x(q))\,C^{\mathrm{bg}}_{K,s}(p,q)^2.$$

Let Q^{pl}_j be the average of plaquettes, that is, of 2-cochains, over blocks of order j; it is the counterpart of the straight average of 1-forms. Because $\mathrm{d}\,Q_j(\mathbf{1})=\mathrm{d}\,Q^{\mathrm{st}}_j(\mathbf{1})=Q^{\mathrm{pl}}_j\mathrm{d}$, the conditioning above is conditioning on $Q^{\mathrm{pl}}_{K-s}F$. The $C^{\mathrm{bg}}_{K,K-j}$ are therefore kernels of orthogonal projections whose ranges are nested, and the slices

$$\mathcal{C}_{(j)}:=C^{\mathrm{bg}}_{K,K-j+1}-C^{\mathrm{bg}}_{K,K-j}$$
$$(C^{\mathrm{bg}}_{K,K}=C^{\mathrm{free}}_K),$$
$$C^{\mathrm{fl}}_{K,s}=\sum_{1\le j\le K-s}\mathcal{C}_{(j)},$$

are the covariances of mutually independent pieces of F. For the free field, the renormalisation group thus reduces to an orthogonal decomposition.

Statement. The error in Prop. 6.1(i) satisfies $|\varepsilon|\le\frac12$ and, in addition, $|\varepsilon|\le\bar\varepsilon_\ell(\mathsf{d})\to0$ on each torus of the family, uniformly in the cutoff, the bare coupling, the pair and its position. The same identity, with the same $\zeta_K(\mathsf{d})$ and $g(\mathsf{d})$ and with $|\varepsilon|\le\frac12$, holds for $\langle\mathcal{O}(f);\mathcal{O}(h)\rangle_\nu$ in every periodic Gibbs state ν at β on $\mathbb{L}_K$. The constant arises as follows: $a_p\approx\frac12|F(p)|^2$; for each colour, Gaussian half-squares have covariance $\frac12(\text{covariance})^2$; and $\frac{N^2-1}{2}\cdot\frac{6}{\pi^4}=\frac{3(N^2-1)}{\pi^4}$.

Two variants. (i) *The one-loop coupling.* Define $\mathsf{g}(\mathsf{d}):=\big(g^{-2}+\frac{11N^2}{12\pi^2}\ln\frac{1}{\mathsf{d}}\big)^{-1/2}$, which depends on d and g only. Lem. 6.2, together with $0\le s\log L-\ln\frac{1}{\mathsf{d}}-\ln C_W(s)<\log L$, gives

$$\big|g(\mathsf{d})^{-2}-\mathsf{g}(\mathsf{d})^{-2}\big|\le o(s)+C+\tfrac{c_0}{\log L}\ln C_W(s)=o(s(\mathsf{d})),$$

uniformly in (K,β). Hence $g(\mathsf{d})/\mathsf{g}(\mathsf{d})\to1$, and if $\mathsf{g}(\mathsf{d})$ is put in place of the running coupling $g(\mathsf{d})$ of the construction, the law still holds below a different threshold, with error functions that differ but are of the same type. (ii) *Cutoffs off first passage.* Let $K'=K(\beta,g)$, and let $b=K-K'$, which may be positive, zero or negative. The dilation identity of § 5.2.4 then takes the form

$$\langle\mathcal{O}(f);\mathcal{O}(h)\rangle_{K,\ell,\beta}=\langle\mathcal{O}(f^{[b]});\mathcal{O}(h^{[b]})\rangle_{K',L^b\ell,\beta},$$

and the map $f\mapsto f^{[b]}$ sends $\mathfrak{T}_{T_\ell}(\mathsf{d};\vartheta)$ into $\mathfrak{T}_{T_{L^b\ell}}(L^b\mathsf{d};\vartheta)$ and leaves $\mathcal{K}_{\mathrm{free}}$ invariant. Consequently, whenever $L^b\ell\in\mathfrak{L}(g)$, $L^b\mathsf{d}\le\mathsf{d}_0$ and $K'-s(L^b\mathsf{d})\ge n_0$, the law at $(K',L^b\ell,\beta)$ with separation $L^b\mathsf{d}$ determines the behaviour of $\mu_{K,\ell,\beta}$ at separation d. For K large and under the conditions of clause (d)(1), § 5.2.4 and § 5.2 and appendix A.8 give $|b|\le C(\varrho)$ for the tuned data and for each of their offsets $t\in\mathsf{J}$. When $b<0$, the identity is to be read in the direction from $(K',L^b\ell)$ to (K,ℓ).

Proof outline. (1) The local analysis is carried out on a single torus, the smallest one, $T_{\ell_\star(g)}$. On that torus the law holds by Prop. 6.3 of §6.1.1.2, and its kernel there is $\frac{N^2-1}{2}\mathcal{K}_{K,s}$. Reflection positivity then carries it from this torus to the remaining volumes and to the Gibbs states. For the Gibbs states this is the only route available, because the expansion deals with torus measures. The local analysis can also be carried out on the other tori. Thm. A(c)(5) does this, with four sources, on every torus of the family, but only below a threshold on d which may decrease with ℓ. The transfer, by contrast, yields a single threshold d_0 common to all of them. (2) Comparison of lattice and continuum. Let u be the shortest vector representing $x(p)-x(q)$ on T_ℓ, with $|u|\approx\mathsf{d}$, let $\sigma_{pq}:=a_K^4\pi^{-2}|u|^{-4}$, and let $\mathbb{K}(\cdot)_{pq}$ be the entry belonging to the planes of p,q. Then

$$|C_K^{\mathrm{free}}(p,q) - a_K^4\,\mathbb{K}(u)_{pq}| \le C\Big[\Big(\frac{a_K}{|u|}\Big)^{1/2} + \Big(\frac{|u|}{\ell}\Big)^4\Big]\sigma_{pq}$$

$$(10a_K \le |u| \le \tfrac{1}{10}\ell),$$

$$|C_{K,s}^{\mathrm{fl}}(p,q)| \le o(1)\,\sigma_{pq}.$$

The first estimate uses the exponent and range proved in appendix A.4. Its range is compatible with the witness requirements. The fixed room floor gives $C_W(s) \ge C_{W,0}A_0^2$ for the admitted small couplings. Increase n_0 so that $10L^{-n_0} \le C_{W,0}A_0^2$. Then

$$\frac{a_K}{\mathsf{d}} = \frac{L^{-(K-s)}}{L^s\mathsf{d}} \le \frac{L^{-n_0}}{C_W(s)} \le \frac{1}{10}.$$

For two supports in the stated shape class, every short difference has $\mathsf{d} \le |u| \le 10\mathsf{d}$: the upper bound is the minimum support distance plus the two support diameters. Decrease d_0 so that $\mathsf{d}_0 \le \ell_\star(g)/100$. Consequently $10a_K \le |u| \le \ell/10$ on every admitted torus. The increase of n_0 uses only constants fixed before g; the decrease of d_0 is made after g, as in the witness construction.

The first inequality compares second differences of the Green's function on the lattice torus with those of the continuum Green's function. Because $a_K/\mathsf{d} \le L^{-n_0}/C_W(s)$, the first term on its right is small by the choice of n_0, and it tends to 0 with d uniformly in K, since the room increases. On the reference torus the second term is at most $C(\mathsf{d}/\ell_\star)^4$, which is small with d_0 and tends to 0 with d. The second inequality is §6.1.1.2(c). Approximating by a Riemann sum, at a relative cost of $Ca_K/(\vartheta^3\mathsf{d})$, yields $\mathcal{K}_{K,s} = 6\pi^{-4}\mathcal{K}_{\mathrm{free}}(1+o(1))$. (3) The common-normalizer transfer estimate in eq. 6.vi, under its stated comparison hypotheses, transfers the law to every T_ℓ and every ν at a cost of $C_2\mathsf{d}^2\|f\|_\infty\|h\|_\infty$, in which $C_2 = C_2(g,\vartheta)$ denotes the constant of that lemma at $n=2$. Take $\mathsf{d} \le \mathsf{d}_0(g,\vartheta)$; there Lem. 6.2 gives $\frac{11N^2}{12\pi^2}g(\mathsf{d})^2\ln(1/\mathsf{d}) \ge \frac{2}{3}$. In this range the cost is a fraction of the main term. That fraction goes to 0 as d does, and so do the $o(1)$ of (2) and the R of Prop. 6.3. The threshold d_0 is chosen at the point where these three errors combined give $|\varepsilon| \le \frac{1}{2}$. The main term is $\ge c\vartheta^2(\ln(1/\mathsf{d}))^{-2}\|f\|_\infty\|h\|_\infty$. Consequently, on every torus, the error goes to 0 as d does.

The same convergence extends to periodic Gibbs states and to $\mathbb{R}^4$ provided the reference-comparison and common-normalizer hypotheses of eq. 6.vi hold uniformly along the defining sequence.

(4) The quantities $\zeta_K(\mathsf{d})$ and $g(\mathsf{d})$ are controlled by Lem. 6.2.

6.1.1.2. Isolating a single scale: coupling and normalisation at the scale d. **Objects.** We set $s = s(\mathsf{d})$ and $k_0 := K - s$, the witness level. We also write $x := x_{k_0}(\beta) = g(\mathsf{d})^{-2}$. The separation measured in level-k_0 units is $\hat{\mathsf{d}} := L^s\mathsf{d} \in [C_W(s), LC_W(s))$. This inclusion holds for $\mathsf{d} < 1$, in which case $s(\mathsf{d}) \ge 1$, and it follows from the minimality of $s(\mathsf{d})$ and the monotonicity of C_W. We write $\underline{x}_s := g^{-2} + \lambda_\sharp s - c_5$ and $\bar{x}_s := g^{-2} + B_\sharp(s+1)$ for the ends of the envelope of § 5.2.1; they do not depend on (K,β), and they are non-decreasing in s. The room $C_W(s) = C_{W,0}\,p_0(\bar{x}_s^{-1/2})^2$ contains a constant $C_{W,0}$, chosen large after L, M and ϑ and before g. The lower bounds placed on this constant are $\vartheta\,C_W(s) \ge CM$, which is used in the Strategy, and those required in (b) and (c) below. The room tends to infinity, but $\log C_W(s) = o(s)$.

Lemma 6.2 (coupling and normalisation)**.** Uniformly in (K,β), and with no torus entering § 5.2.2, one has

$$|x_{K-s} - x_K - c_0 s| \le o(s),$$

$$\zeta_k' = 1 + \sum_{j\le k} b_j'(0) \in [\tfrac{2}{3}, \tfrac{4}{3}],$$

$$|\zeta'_{K-s} - 1| \le C g_{K-s}\, p_0(g_{K-s}).$$ ■

The first bound is the flow statement of § 5.2.1. Because $s(\mathsf{d}) \log L / \ln(1/\mathsf{d}) \to 1$, it yields $g(\mathsf{d})^{-2}/\ln(1/\mathsf{d}) \to c_0/\log L = \frac{11N^2}{12\pi^2}$. For the other two bounds, note that a constant source $w \equiv \zeta$ acts as a shift of β in which every auxiliary choice is held frozen. The increment $b_{j+1}(\zeta)$ is holomorphic for $|\zeta| < 2\varrho$, and its slope is $\le C\big[g_j^3 (\log x_j)^{\mathfrak{p}_0} + \varrho^{-1} g_j^{\kappa_0 - 4}\big]$ §5.20.1.2. Since $x_j \ge x_k + \lambda_\sharp(k-j) - C$, the slopes summed over the levels $j < k$ are at most $C\big[g_k (\log x_k)^{\mathfrak{p}_0} + \varrho^{-1} g_k^{\kappa_0 - 6}\big]$. This bound is a function of x_k alone, it tends to 0, and for $\kappa_0 \ge 7$ it is $\le C g_k\, p_0(g_k)$.

Proposition 6.3 (the law on the reference torus)**.** Let $g \le \gamma_W(\vartheta)$, let (K, β) be a first-passage datum, and suppose that $\mathsf{d} \le \mathsf{d}_0$, $K - s(\mathsf{d}) \ge n_0$ and $(f, h) \in \mathfrak{T}_{T_{\ell_\star(g)}}(\mathsf{d}; \vartheta)$. Then on the torus $T_{\ell_\star(g)}$, uniformly in (K, β) and in the pair, one has

$$\langle \mathcal{O}(f); \mathcal{O}(h) \rangle = \zeta_{k_0}'^{\,2}\, \tfrac{N^2-1}{2}\, x^{-2}\, \mathcal{K}_{K,s}(f, h)\, (1 + R),$$
$$|R| \le \tfrac{1}{4},$$
$$R \to 0 \,(s \to \infty).$$ ■

Strategy. In this proof the pair (f, h) is also written (f_1, f_2). We set $k_1 := k_0 + \mathsf{n}$ with $\mathsf{n} := \lceil 2 \log_L \bar{x}_s \rceil$. Here g is fixed first. Then d_0 is chosen, small enough that $\mathsf{n} \le s(\mathsf{d})$ whenever $\mathsf{d} \le \mathsf{d}_0$. This gives $k_1 \le K$. Reduce d_0 further to fit the complete clean read boxes and their padded neighborhood into a single lattice patch on the reference torus. The geometry of the two localized readouts below bounds the physical diameter by

$$C(\mathsf{r} + L\mathsf{D} + M\check{R}_{k_0}) L^{-(s-\mathsf{n})}.$$

Here $L^{\mathsf{n}} \le L\bar{x}_s^2$, and $\bar{x}_s$ is affine in s at fixed g. The factors $\mathsf{r}, \mathsf{D}, \check{R}_{k_0}$ grow at most polynomially in $1 + s$, uniformly in the first-passage datum. Thus the displayed diameter tends uniformly to zero as $s \to \infty$. Taking it below $\ell_\star(g)/4$ gives the common lift used in the box comparisons. Moreover $x_j \approx x$ for $k_0 \le j \le k_1$, because $B_\sharp \mathsf{n} \ll x$. The sourced construction §5.20.1.1 is carried out up to a level $k \le k_1$, with the sources measured at depth $K - k$. At depth s one has $\|f\|_{\sharp,s} = \|f\|_\infty$, because $\vartheta\, C_W(s) \ge CM$ for $\mathsf{d} \le \mathsf{d}_0(g, \vartheta)$. Above the witness level, $\|f\|_{\sharp, K-k} \le L^{k-k_0} \|f\|_\infty$, so the disc in z becomes smaller. The identities for the derivatives at $z = 0$ remain valid, and in the bounds each derivative in a source costs a factor L^{k-k_0}. One then has $Z(z)/Z(0) = \mathbb{E}_{\mathsf{P}^{(k)}}\, e^{\Phi^{(k)}(z)}$. In what follows we write $\mathsf{P} = \mathsf{P}^{(k_0)}$, which is a law distinct from the law P_{k_0} of Prop. 5.66 that appears further on, and $\Phi = \Phi^{(k_0)}$. Everything stated about these two objects in this paragraph holds at each level $k \le k_1$, with k in place of k_0 and $K - k$ in place of s. P is a probability law on triples. Each triple consists of a class $[h]$ of histories of level k_0 sharing one standing part $h^\flat$ §4.17.1.1, a block field $V \in \mathcal{V}_{k_0}$, and the stored fields. The law is determined by the unsourced sums $\tau_{[h]} := \sum_{h' \in [h]} \tau_{h'}$. Here $\tau_{[h]}(dV)$ is an integral over the stored fields, which are the fields left unintegrated at level k_0. Its integrand is the exponential of the exponent of the sum, integrated against a positive measure composed of the gauge-fixing factors, the characteristic functions, the delta functions of the averaging constraints and Haar measures. Dividing this integrand by $Z(0)$ yields the law on triples. Φ is the difference between the sourced and the unsourced exponent of $\tau_{[h]}$. An exponent is attached to such a sum and not to an individual τ_h §4.17.1.1, §4.17.1.45. The marginal of P in $([h], V)$ equals $Z(0)^{-1} \tau_{[h]}(dV)$. Tested on gauge-invariant functions, this marginal agrees with the push-forward under $h \mapsto [h]$ of the (h, V)-marginal of P_{k_0}, the law on triples (bare field, history, block field) of Prop. 5.66 §5.20.1.1. Projected further onto $[h]$, the marginal is the image of $\tilde{\nu}$. Both laws therefore extend one and the same law of $[h]$ and of the gauge orbit of V, but they add different variables. P_{k_0} adds the bare field and h, the particular member of the class.

P adds the stored fields, on which the part of Φ attached to the live components depends. With the notation $\Phi_B^{(k)} := \prod_{i\in B} \partial_{z_i} \Phi^{(k)}|_{z=0}$ we have

$$\langle \mathcal{O}(f_1); \mathcal{O}(f_2)\rangle = \langle \Phi_1^{(k)}; \Phi_2^{(k)}\rangle_{\mathsf{P}^{(k)}} + \mathbb{E}_{\mathsf{P}^{(k)}} \Phi_{12}^{(k)}$$
$$(1 \le k \le k_1).$$

All of these are expressions for one and the same quantity. At $k = k_0$ the first term on the right is the main term and the second term is an error ((a), (b)). At $k = k_1$ the roles are exchanged, and the law is obtained at that level ((c)). Both $\Phi_i^{(k)}$ and $\Phi_{12}^{(k)}$ are derivatives with respect to the sources. The argument uses conservation of mass alone, $\sum_h \tau_h^w(\mathcal{V}_k) = Z(w)$. In other words, it uses exactness with the sources measured at depth $K-k$, which is the depth s when $k = k_0$ (Prop. 5.65 of §5.20.1.1, together with §5.20.1.2). This is what isolates the scale; no conclusion is drawn from P_{k_0}, the coupling with the bare field. The law of $\mathcal{M}^{k_0}U$ is not identified with the marginal of P in V, because inside what $\mathbf{R}$ heals it replaces the law of the block field. Under P_{k_0}, the equality $V = \mathcal{M}^{k_0}U$ is valid only on bonds at a large distance from the components that $\mathbf{R}$ has acted on. For this reason the sources are carried through the steps, and no observable is conditioned.

(a) *Locality.* The source enters the exponent in three ways. *Pointed pieces:* away from the live components, the coupling term is a sum of functions, each of which depends on a single value of w; this holds because the running shift at a plaquette is a finite sum of functions of this kind. As $f_1 f_2 = 0$, these pieces give no mixed derivative. *Regular local terms:* these are indexed by $j \le k_0$ and $X \in \mathcal{D}_j$, and they depend on w only on $X^\sim$ §5.20.1.2. Every domain that meets both supports satisfies $d_j(X) \ge c\,\hat{\mathsf{d}}/M$. By Cauchy bounds on the source disc, the contribution of these terms to Φ_{12} is bounded pointwise by $C\hat{\mathsf{d}}^4 e^{-c\kappa\hat{\mathsf{d}}/M} \prod \|f_i\|_\infty$. This is of order $e^{-c\,p_0^2}$, where, in this step, p_0 without an argument stands for $p_0(g_{k_0})$. It is therefore smaller than any power of $g(\mathsf{d})$. *The part attached to the live components:* only a cruder bound is used for this part. Consider a class $[h]$ in which a live component is in contact with a support, that is, lies within distance $c\,\mathsf{d}$ of it. The label is common to the class, and hence each live component, its lineage and the age of that lineage are common to the class as well; the members of the class differ only in healed components. Let $a(h)$ denote the largest lineage age among such components (Prop. 5.71 of §§ 5.20 and 5.22). On such a class the mixed derivative of this part is bounded by

$$(\log x)^C \Big[e^{-c\,\hat{\mathsf{d}}} + L^{C\check{R}_{k_0}} L^{8a(h)} \Big] \prod \|f_i\|_\infty .$$

It is the mean that is small: $|\mathbb{E}_{\mathsf{P}} \Phi_{12}| \le o(1)\, x^{-2} \prod \|f_i\|_\infty$. This follows from the age series of §§ 5.20 and 5.22 (Prop. 5.71 and its proof), taken with rate $b \ge 8$. The growth of the amplitude and the decay of the series are governed by one and the same age, namely the age of the lineage. The age recorded in the label restarts wherever $\mathbf{R}$ leaves a component standing as an island, and it is not larger. The number of cells of level k_0 in contact with the supports is $\le C\hat{\mathsf{d}}^4$, so

$$\mathbb{E}_{\mathsf{P}} \Big[\mathbf{1}\{\text{contact}\}\, L^{8a(h)} \Big] \le C\hat{\mathsf{d}}^4 \sum_{a\ge 0} L^{8a} \max_{\mathfrak{c}} \tilde{\nu}\big(\mathfrak{lv}_{k_0}^{\ge a}(\mathfrak{c})\big) \le C\hat{\mathsf{d}}^4 e^{-c\,p_0(g(\mathsf{d}))},$$

and this bound overcomes $(\log x)^C L^{C\check{R}_{k_0}} x^2$ because $\mathfrak{p}_0 \gg r$. *At level k_0 the two-point function draws on this series twice*, both times at a rate $b \ge 8$. At level k_1, in (c), it draws on the series once, at the same rate. The first use is the present one, the bound on the mean of the live part's mixed derivative. The second occurs in (b), in the covariances of the live first derivatives; there the product of two such derivatives carries $L^{4a} \cdot L^{4a}$. At level k_0 these two uses are the source of the weight L^{8a} for two points. At level k_1 its source is (c1). Of the growth, only one property enters: as a function of the age, it is no faster than geometric. A different exponent, or an additional

factor polynomial in a, is handled by a larger rate b, that is, by a larger c_a, a constant that may be increased freely. Hence the theorem on the ages (Prop. 5.71) underlies Thm. A (c)(3) and (c)(4). It also underlies (c)(5), for which Thm. A(c)(5) employs this series with a larger rate.

(b) *The marginal part.* Here the coupling carries the source. Let $h_y^{(j)} \geq 0$, with $\sum_y h_y^{(j)} = 1$, be the tent functions of §5.20.1.1, §5.20.1.2. These weights have range CMa_{K-j} and serve to localise the counterterm of step j. At a fixed level these are the functions h_z in the source profiles. Let p_y be a bare plaquette at y. At points where every profile φ_j, $j \leq k_0$, takes the value 1, that is, off the live components, the running shift satisfies, by its formula in §5.20.1.2,

$$\partial_{z_i} \zeta_{k_0}(p; w)\big|_0 = f_i(x(p)) + \sum_{j \leq k_0} b_j'(0) \sum_{y \in \mathbb{T}^{(j)}} h_y^{(j)}(p)\, f_i(x(p_y)) =: \zeta_{k_0}' \tilde{f}_i(p),$$

$$|\tilde{f}_i - f_i| \leq \tfrac{CM}{\vartheta \hat{\mathsf{d}}} \sum_j |b_j'(0)|\, \|f_i\|_\infty;$$

the factor $\zeta_K(\mathsf{d})^2$ arises here. Differentiating $-A(x_{k_0}(\cdot) - \zeta_{k_0}(\cdot\,; w), U_{k_0})$ gives

$$\Phi_i = \mathrm{const} + \zeta_{k_0}' X_i + (\mathrm{irrelevant}) + (\mathrm{live}) + (\mathrm{far}),$$

$$X_i(V) := \sum_p \tilde{f}_i(p)\, \chi_{k_0}(\square(p))\, a_p(U_{k_0, \square(p)}(V)).$$

In this formula $\square(p)$ is the test cube containing $x(p)$, and $U_{k_0,\square(p)}$ is the background localised about that cube, hence near $\mathrm{supp}\, f_i$. The test $\chi_{k_0}(\square(p))$ acts as a window: a plaquette contributes only if its localised background passes the plaquette test. Consequently X_i depends on V only near the support and is the same for every history. It also satisfies $|X_i| \leq Cx^{-1} p_0^2\, \hat{\mathsf{d}}^4 \|f_i\|_\infty$. Away from the large-field regions, the global background differs from the localised one by an amount exponentially small in the radius of localisation; this difference is the term (far). The size of the irrelevant terms is $\leq C(\log x)^{3\mathfrak{p}_0 - q} x^{-1} \hat{\mathsf{d}}^4 \|f_i\|_\infty$. The physical bound uses the source-family coefficient and a quadratic estimate at the real field size, together with the Wilson subtraction at each grouped core. The factor x^{-1} cannot be dispensed with. The law uses $p_0^2\, \hat{\mathsf{d}}^8 (\log x)^{3\mathfrak{p}_0 - q} \to 0$ as the coefficient of x^{-2}, and Cauchy bounds over the source radius ϱ yield no power of x. The factor comes from the bound on the regular family produced by a step (§4.17.1.45, "Dependence of the regular family on the array"). That bound also holds for shifts of the coupling that vary with position, and it weights a difference of shifts by $CM^4 \alpha_{0,k}^2$. We apply it to the sourced and the unsourced arrays of §5.20.1.2. The remainders enter through the slope towards the constants carried by the induction of §5.20.1.2, and they are small because of their size. The result is a linear recursion for the slopes in the source, and the small factor in front of the bound closes this recursion over the levels. Its solution is $\approx x_j^{-1} (\log x_j)^{\mathfrak{p}_0 + q}$, and this takes the place of ϱ^{-1}. The oscillating part of the source, namely what remains after subtracting from the source its value at a single point of the domain, has a slope bounded in the same way, with an extra factor $L^{-(k_0 - j)}$. The live terms become larger as the age increases. If a live component has $\mathrm{age}^{\mathrm{lab}} = a$, the fields stored in it are those of every level from $k_0 - a$ onwards, together with those of the next finer level. For a component holding an island, the block of which retains the fields of its core §4.17.1.3, the stored fields begin at the first level of its lineage. Over one cube of level k_0, the plaquette sums of these fields contain at most $L^{4(a+1)}$ terms. For the live terms, only their first two moments on the events of contact enter, so that, as in (a), it suffices that their growth be geometric in the age. Let h be a history in which a live component is in contact with $\mathrm{supp}\, f_i$. On such a history the live contribution to Φ_i is bounded by $(\log x)^C \big[e^{-c\hat{\mathsf{d}}} + L^{C\check{R}_{k_0}(a(h)+2)^C L^{4a(h)}}\big] \|f_i\|_\infty$. The power of the age in this bound is the one of Thm. A(c)(5). In the bound $Ce^{-cp_0(g_j)}(2L^b)^{-a}$ of Prop. 5.71, the factor 2^{-a} absorbs this power, so the age series is used at the same rate. This live contribution

has two covariances. One is with the live contribution of the other factor, with weight $L^{8a(h)}$. The other is with those functions of V that occur in the other factor, with weight $L^{4a(h)}$, taken against their supremum bound. By the age series of §§ 5.20 and 5.22, as in (a), both of these covariances are $o(1)\,x^{-2}\prod\|f_i\|_\infty$.

From the two witness insertions to the physical sources. Let λ_{k_0} be the marginal in V of the unsourced law P on the class, V and the stored variables. Write $\mathsf{r} = \mathsf{d}/a_s$, $x = x_{k_0}$, and set $u = x^{-2}\|f_1\|_\infty\|f_2\|_\infty$. The identity obtained by differentiating conservation of mass at the witness is

$$S_2^T(f_1, f_2) = \mathbb{E}_{\mathsf{P}}\Phi_{12} + \mathrm{Cov}_{\mathsf{P}}(\Phi_1, \Phi_2).$$

The law on the right is the full unsourced law. In particular, integrating out the stored variables before differentiating would add the conditional covariance of their two source derivatives to the mixed term.

Use the decomposition $\Phi_i = c_i + \zeta'_{k_0}X_i + I_i + B_i$ at k_0. Here

$$c_i = \partial_{z_i}\sum_{j\le k_0}\sum_{X} e_j(X; w_z)\Big|_{z=0}.$$

This is the same number for every class. The difference between the actual share of source energy in a class and this sum is included in B_i. Count the missing shares of the actual resummed label in the level units of its retained regions. A healed region already removed by resummation enters through its refiled activity and the compensated label. It is not a present lineage contact of the witness. The coefficient of X_i is obtained by summing the single-point source shifts with their own tents. The sourced exponent on this ordinary carrier uses the running weight $x_{k_0} - \zeta_{k_0}$ and the regular members with their tent counterterms already subtracted. The difference of those counterterms is the accumulated shift $\zeta_{k_0} - w$ there. One can first cancel it against the shift in the weight and then extract the Wilson part from the unsubtracted regular derivative. Equivalently keep ζ'_{k_0} in the readout and differentiate the already subtracted regular members. In either form the term $b'_j(0)f_i(x(p_y))A(h_y^{(j)}, \cdot)$ is counted once. There is no analogous mixed derivative of a pointed piece: it is a function of one source value and $f_1 f_2 = 0$.

For I_i, apply the regular formation estimate eq. 4.clxxvii and the window estimates eq. 4.clxxx–eq. 4.clxxxi at $n = k_0$. The real regular windows used here have complete retained data of size $C\delta_n$. In the interior of the padded small-field set, use eq. 3.cdiii and the local gauge estimate on the full stencil of the localized background. The input is the passed tests on the retained datum with its regular background profile, rather than just the curvature cutoff in X_i. The fixed factors in the real gauge estimate fit the regular analytic radius for small g. The independent-coordinate room in the window estimates is the room of the ordinary regular formation rule. Writing $a = n - j$ and $s_n = \delta_n/\alpha_n$, the near part per witness window is bounded by

$$C\|f_i\|_\infty\sum_{j\le n} A_j\left[\left(\frac{\delta_n}{\alpha_j}\right)^2 L^{-\alpha_H a} + \left(\frac{\delta_n}{\alpha_j}\right)^3 L^{-2a}\right] + C\delta_n^2 s_n\,\mathrm{Lip}(f_i)\sum_{j\le n} h_j.$$

Indeed $A_j/\alpha_j^2 \le Cs_n$, $\delta_n/\alpha_j \le Cs_n(1+a)^{1/2}$, and $h_j = h_n L^{-a}$. Both geometric series, including the polynomial in a in the cubic term, give $C\delta_n^2 s_n\|f_i\|_{\sharp,n}$. Here $\|f_i\|_{\sharp,n} \le C\|f_i\|_\infty$ by the lower bound on r. The quadratic term that survives the Wilson subtraction is included in this estimate. Its coefficient is bounded by A_j/α_j^2, so the small factor s_n comes from the formed source derivative. The cubic Cauchy estimate alone would leave this quadratic term at the size of the insertion.

For the ordinary old remainder, the vacuum subtraction gives $(\delta_n/\alpha_j)^2 L^{-4a}$ on the admitted core, which pays for the fine-site count. Its derivative has the additional factor $x_j^{-\kappa_0/2}$ from the

ordinary remainder bound and eq. 4.clxxvi. Its contribution per witness window is at most

$$C\|f_i\|_\infty \delta_n^2 \sum_{j\le n} x_j^{-\kappa_0/2}\alpha_j^{-2} \le C\|f_i\|_\infty x^{-1}p_0^2 x^{2-\kappa_0/2}.$$

The last inequality uses $\alpha_j^{-2} \le Cx_j$ and the lower flow bound. It is useful to retain the small field ratio until after the sum. The common-background, common-base and pointed assumptions of the ordinary formation estimate are needed for these estimates. A bound for a constant source on a larger disc cannot furnish the estimate for the derivative in f_i.

For a long ordinary domain entirely in a homogeneous nonwrapping window, the same vacuum subtraction is performed in its axial chart. At age a the complete field has potential at most $C(2+\operatorname{diam}_j X)\delta_n L^{-2a}$ in that chart, and the normalized current has size at most $C\delta_n L^{-3a}$. The first derivative at the trivial pair is zero by constant colour invariance. The quadratic Cauchy bound therefore contributes at most

$$CA_j\|f_i\|_\infty e^{-\kappa d_j(X)}(2+\operatorname{diam}_j X)^C(\delta_n/\alpha_j)^2 L^{-4a}.$$

The bound is used only on the admitted core. If the polynomially enlarged field ratio is at least the half-disc threshold, the unexpanded ordinary core bound gives the same majorant after enlarging the constant. For domains reaching beyond a fixed enlargement of the witness window around their source anchor, a spare exponential in $d_j(X) \gtrsim L^a$ pays for the polynomial and gives a summable gain after the fine-site count. This argument concerns only the homogeneous domains. For an ordinary domain depending on f_i whose enlargement reaches a live region outside the contact neighborhood, the length is at least $c\mathfrak{r}L^a/M - C$, since the determining set must also reach $\operatorname{supp} f_i$. For a winding domain the bound is $c(\ell/a_s)L^a/M - C$. The ordinary source-disc estimate and the rooted count then put these terms into the exponentially small far error. No small homogeneous field ratio is used on them. Inside the contact neighborhood the live terms are estimated by the age series. The formation and remainder bounds have to hold on the actual regular domains of the unsourced histories.

Let $i(x) = C[(\log x)^{3\mathfrak{p}_0-q} + p_0^2 x^{2-\kappa_0/2}]$, allowing a larger constant for the ordinary far sum. The estimates give $\|I_i\|_\infty \le C\mathfrak{r}^4 x^{-1} i(x)\|f_i\|_\infty$ for the regular part and $\|X_i\|_\infty \le C\mathfrak{r}^4 x^{-1}p_0^2\|f_i\|_\infty$.
A bound using the physical readings. The correlation expansion gives a second way to obtain the irrelevant-source bound. On the same bare torus it starts with the product Haar measure, the same plaquette profiles, and the action $A(\beta - w, U)$. Its extra bare constant is source independent and cancels in $Z(w)/Z(0)$. One can therefore use this calculation for the physical generating function with its own standing histories and running coefficients.

Use the vacuum-subtracted source derivatives of that expansion on their original domains. Write a_j for its tube radius and v_{j-1} for the running maximum of its source weights. The source-disc estimate gives the majorant $Cv_{j-1}a_j^2$ before decay and the norm of the test function. The old remainder has the separate majorant $Cr_{\mathrm{s}}^{-1}g_j^{\kappa_0}$, with r_{s} the source radius. These bounds precede evaluation at a field.

At witness level n, write $t = L^{j-n}$, $\nu = 1+n-j$ and $D_X = \operatorname{diam}_j X + 5M$. First group the constant-source terms contained in the ν-layer enlargement of the anchor cube with their Wilson subtraction at coefficient $b_j'(0)$. For the remaining constant-source terms and for the nonconstant-source differences and old remainders, retain a domain in the short sum when

$$D_X t \le \rho/16, \qquad C_M D_X t^2 \mathfrak{e}/a_j \le 1,$$

where ρ is the witness separation in its lattice units and $\mathfrak{e} = C_{\mathrm{w}}\varepsilon_n$ is a fixed bound for the real-field amplitude. The native grouped core estimate uses its analytic box extension on the field-rescaling disc. At the real endpoint the extension must give the same field and current as the read on the smaller box, up to gauge. The grouped coefficient vanishes to second order at the trivial field.

Schwarz's estimate on this disc gives the factor

$$Cv_{j-1}a_j^2\left(\frac{\mathfrak{e}_Q}{a_n}\right)^2\left(\frac{a_n}{a_j}\right)^2\nu^3(1+a_n/a_j)t^{4+\hat{\alpha}},\qquad \mathfrak{e}_Q\le C\varepsilon_n.$$

Here $\hat{\alpha}>0$ is the exponent in the grouped core estimate. The grouped core uses the same counterterm coefficient as the running source. For the individual terms in the rest of the short sum, the vacuum value and the first field derivative vanish after subtraction and constant colour invariance. In the real box gauge the quadratic estimate costs $(C_MD_Xt^2\mathfrak{e}/a_j)^2$ times the original majorant. Thus the two radii cancel in the grouped core, and a_j^2 cancels in each individual term with majorant $Cv_{j-1}a_j^2$.

The factor t^4 pays for the $O(|S^+|t^{-4})$ older anchors over the enlarged witness support S^+. In the core the remaining factor $\nu^3(1+a_n/a_j)t^{\hat{\alpha}}$ is summable by the running radius comparison. The constant-source tails outside the core have length at least $\nu-1$, and the absolute domain sum pays for D_X^2 and gives exponential decay in ν. The comparison of nonconstant and constant sources uses the Lipschitz profile and has the summable factor $L^{-(n-j)/2}$. For the old remainder the corresponding age sum is bounded by its memory majorant $Cr_{\mathrm{s}}^{-1}\mathfrak{m}_n$.

Outside the grouped cores, if either short-domain inequality fails, then

$$d_j(X)+5\ge c\,t^{-1}\min\{\rho/M,\ a_n/(M\mathfrak{e})\}.$$

This uses $D_X\le 4M(d_j(X)+5)$ and the bound on ta_n/a_j. Use twice the original analytic majorant on these long terms. The length gain pays for the anchor count and the ratio $a_n^2/\mathfrak{e}^2$ at weak coupling. Indeed $a_n/\mathfrak{e}$ grows as $(\log x)^{q-\mathfrak{p}_0}$ and the lower witness bound for ρ grows as $(\log x)^{2\mathfrak{p}_0}$. The exponential decay at the smaller of these two scales pays for the logarithmic ratio. With the kept part this gives

$$|I(f)|\le C|S^+|\,\|f\|_{\sharp,n}\big[\widehat{v}_{n-1}\varepsilon_n^2+r_{\mathrm{s}}^{-1}\mathfrak{m}_n\big],\qquad \widehat{v}_{n-1}=\max_{j\le n}v_{j-1}.$$

At the witness, $\widehat{v}_{n-1}\le C(\log x)^{\mathfrak{p}_0-q}$ and $\mathfrak{m}_n\le Cx^{-(\kappa_0-2)/2}$. This gives the power $3\mathfrak{p}_0-q$ in $i(x)$. The source bound on the analytic tube by itself has the larger power $\mathfrak{p}_0+q$.

The localized function of V evaluates only the shortened sum at the prolonged box field and is zero off its window. For the global field add the whole long sum. On a history with no live label meeting the neighborhood $S_i^{+\rho/4}$ and with the window test passed, evaluate the shortened sum at its real background and add only those long domains in its ordinary region $\Lambda_j(h)$ at each level. The buffer $M\check{R}_jt\le\rho/8$ puts the source anchors inside the ordinary region with their required margin. The source profiles there are one. Use equality with the whole-lattice constituents on the admitted ordinary reads. In the joint law multiply this irrelevant insertion and the corresponding main insertion by the same per-support indicator. The long terms use their own original pair domains. The history bound is uniform before averaging the integrated variables of a history. The discarded indicators, the replacement by the localized main insertion, and any history-dependent share of the vacuum subtraction enter the separate comparison terms.

In a standing history, the geometric part of the reading comparison uses the empty trace. The record sums out a healed component and keeps its contribution in the ordinary activities and constants. The live regions are those still present at the witness level. On the event that none meets $N_i=S_i^{+\rho/4}$, the standing trace is empty throughout N_i. For the grouped core, νL^{j-n} is bounded independently of j, so its enlarged anchor cubes have bounded size in witness units. The box-extension margins of the core also have fixed size in those units, so its reads fit inside $S_i^{+3\rho/16}$. For the other short terms the diameter bound $D_Xt\le\rho/16$ and the source support put their complete reads inside $S_i^{+3\rho/16}$. This leaves $\rho/16$ for rounding to the larger history cells. By

eq. 6.xxxv, this rounding costs at most $C_{\mathrm{tr}} M \check{R}_n$ in witness units. The lower witness bound for ρ dominates this cost at weak coupling. Thus all these short trace windows are inside N_i.

For the history background on that window the preceding levels obey $x_j \geq x_n - C$. It follows that $g_j \leq \sqrt{2}\, g_n$ when $x_n \geq 2C$. The degree function $g(\log g^{-2})^{\mathfrak{p}_0}$ is increasing for $\log g^{-2} > 2\mathfrak{p}_0$. Take x_n large enough that this interval contains $\sqrt{2}\, g_n$. Then $\varepsilon_j \leq \sqrt{2}\, \varepsilon_n$ throughout the older levels. The native data bounds therefore use one real-field amplitude at the witness. On each common admitted pair domain, Lem. 6.5 and Prop. 6.6 identify the short history terms with their own whole-lattice terms, for the same input list and pointing. This identity also holds for their first source derivatives. The long terms keep their history-dependent domains and use the long-domain bound.

In this reading keep the variables integrated inside each history in the unsourced joint probability law. Let $\mathcal{G}$ be the data fixed for its inner integral. In the representation with a fixed reference measure and a source-dependent exponent $A(z)$, the history's first jet is $\mathbb{E}[\partial_i A(0) \mid \mathcal{G}]$. Its mixed jet is the conditional mean of $\partial_{12} A(0)$ plus the conditional covariance of the first derivatives. Total covariance gives

$$\mathbb{E}[\mathrm{Cov}(\partial_1 A(0), \partial_2 A(0) \mid \mathcal{G})] + \mathrm{Cov}(\mathbb{E}[\partial_1 A(0) \mid \mathcal{G}], \mathbb{E}[\partial_2 A(0) \mid \mathcal{G}]) = \mathrm{Cov}(\partial_1 A(0), \partial_2 A(0)).$$

Apply the uniform physical bound to the three irrelevant covariances in this joint law. These pair one irrelevant insertion with the other main insertion, or the two irrelevant insertions with each other. The two sources' factors give the bound $C\mathsf{r}^8 x^{-2} i(x)(p_0^2 + i(x)) \prod_i \|f_i\|_\infty$. This accounts for their shares both inside and between histories, giving the same covariance error in the bound below. The bound on these three covariances holds under any probability law with the stated physical supremum bounds. To use it in the standing-class decomposition here, it suffices to identify the evaluated first-source sum, with its vacuum and Wilson subtractions, on its admitted real pairs. The empty trace comparison gives equality within one whole-lattice recipe. For a transfer between the two expansions one must also match their formed whole-lattice sums and counterterms. The mixed derivative of the exponent itself uses the support and age estimates below.

In the mixed derivative the regular support must reach both original supports, and at age a its length is at least $c\mathsf{r} L^a/M - C$. The Cauchy cost in the slow sources is uniform at the witness. The anchor count times the spare exponential is summable in a and gives $Ce^{-c'\mathsf{r}} \prod_i \|f_i\|_\infty$. For the remaining terms put $\epsilon_{\mathrm{far}} = e^{-c\mathsf{r}} + e^{-c\check{R}_{k_0}}$ and $\Upsilon = L^{C\check{R}_{k_0}}$. The localized-background error uses both radii: the collar at the test cube and the distance to the nearest live region. The bound on B_i has a factor $\epsilon_{\mathrm{far}} + \mathbf{1}_{\mathcal{B}_i} \Upsilon L^{4a_i}$; the live mixed derivative has the corresponding L^{8a} bound. Here the ages are lineage ages. Summing over the $C\mathsf{r}^4$ cells in contact with the supports and applying Prop. 5.71 at rate at least eight gives

$$\mathbb{E}_{\mathsf{P}}\big[\mathbf{1}_{\mathcal{B}} L^{8a}\big] \leq C\mathsf{r}^4 e^{-cp_0}.$$

Since X_i depend only on V, covariance bilinearity and $|\mathrm{Cov}(A,B)| \leq 2\|A\|_\infty \|B\|_\infty$ for the bounded regular terms give

$$\begin{aligned} S_2^T(f_1, f_2) &= (\zeta'_{k_0})^2 \,\mathrm{Cov}_{\lambda_{k_0}}(X_1, X_2) + E, \\ |E|/u &\leq C\mathsf{r}^8 i(x)(p_0^2 + i(x)) + x^2 (\log x)^C \big[\epsilon_{\mathrm{far}} + \Upsilon^2 \mathsf{r}^4 e^{-cp_0}\big]. \end{aligned}$$

The second line uses the first and second contact moments for the covariances involving B_i, and the first moment of the mixed derivative. In the witness window $\mathsf{r} \leq C(\log x)^{2\mathfrak{p}_0}$; the first term tends to zero for $q > 21\mathfrak{p}_0$ and sufficiently large κ_0. The other terms tend to zero by the lower window bound, $r > 1$, and $\mathfrak{p}_0 > \max\{1, r\}$.

The preceding error bound is uniform under the bare lattice translations used in the witness covariance estimate. The physical left-hand side is invariant under these translations, so average the identity over the same translations whenever the witness estimate is an average. The covariance estimate is applied with the widened profiles $\tilde{f}_i$. The widening is at most CMa_s, and these supports

still have separation comparable to d. In the resulting bare kernel sum, replacing $\tilde{f}_i$ by f_i costs at most $C\|\tilde{f}_i - f_i\|_\infty \|f_{3-i}\|_\infty$ times the coupling factor x^{-2}. Indeed the squared curvature kernel on the separated supports has a bounded absolute sum with the two plaquette volume factors. By (b) the cost relative to u is $O(M/(\vartheta \mathsf{r}))$. This replacement precedes the Riemann estimate, which uses the Lipschitz bounds of the original profiles.

(c) *Gaussian extraction: the free template.* The covariance of the bounded witness fields X_i is obtained from the generating function on the fluctuation segment. Denote by $\mathcal{H}_j B$ the exact bare 2-cochain of smallest norm that satisfies $Q_j^{\mathrm{pl}} \mathcal{H}_j B = \mathrm{d}B$. It is the curvature of the linear minimiser, namely $\mathrm{d}\,\mathsf{H}_j$ at $U = \mathbf{1}$, a point at which $J = 0$ and the three Green's functions of § 3.12.1 agree. We then have

$$\mathcal{C}_{(j)} = \mathcal{H}_{j-1} C_j^{\mathrm{tr}} \mathcal{H}_{j-1}^*,$$

$$|\mathcal{H}_j(p,b)| \le C\eta_j^2 e^{-\delta |x(p) - x_b|/a_{K-j}},$$

$$|\mathcal{C}_{(j)}(p,q)| \le C\eta_{j-1}^4 e^{-\delta |x(p)-x(q)|/a_{K-j+1}}.$$

The free propagator framework is developed in [B84a]. For the centered blocks used here, the uniform pointwise estimate follows from Prop. 3.182 and its exponentially weighted version. Rescale a level-j block to side one and put $h = \eta_j$. At the trivial flat reference, let $H_h B$ be the solution with fine force zero and coarse datum B. In the notation of eq. 3.mccxlvii,

$$H_h = K_0^{-1} Q^\sharp (Q K_0^{-1} Q^\sharp)^{-1}.$$

This uses the straight row in eq. 3.mccxxiv. The gauge penalty vanishes: testing the first saddle equation against $D\lambda$ with $q\lambda = 0$ eliminates both its curl term and its multiplier term, while eq. 3.mccxlix makes the remaining gauge test surjective. Thus $RD^* H_h B = 0$. The first equation is consequently the Euler equation for the curl energy on $QA = B$, and its curvature is the least-norm exact curvature with datum $\mathrm{d}B$. Indeed, if $f = \mathrm{d}v$ is exact and $Q^{\mathrm{pl}} f = \mathrm{d}B$, then $Qv - B$ is a closed coarse one-form. On the trivial periodic lattice it is a coarse gradient plus a constant. The identities $qE_q = 1$, $QD = \mathrm{d}_c q$ and $Q(\text{constant}) = \text{constant}$ change v by a closed fine one-form to impose $Qv = B$ without changing f. This identifies the curvature with $\mathcal{H}_j$ modulo closed forms.

Take B to be a unit vector on the coarse bond b. The weighted bound eq. 3.mccxlv gives

$$|\mathrm{d}_h H_h(p,b)| \le C e^{-\delta\, \mathrm{dist}_{\mathrm{phys}}(p,b)}.$$

Its constants are uniform in the fine subdivision and in the volume. A raw bare plaquette curvature is $h^2 \mathrm{d}_h H_h$; restoring the physical block side therefore proves the factor η_j^2 and the distance scale a_{K-j} in the displayed estimate for $\mathcal{H}_j$. This argument uses the scalar equation and projector smoothing in § 3.43, so it does not require a differentiated resolvent to map L^2 into L^8. The symbol C_j^{tr} denotes the single-step covariance in a tree gauge,

$$C_j^{\mathrm{tr}} := \iota \left(\iota^* \mathcal{H}_{j-1}^* \mathcal{H}_{j-1}\, \iota\right)^{-1} \iota^*,$$

$$\mathrm{d}'\, C_j^{\mathrm{tr}}\, \mathrm{d}'^* = C_j^{\mathrm{curv}},$$

where ι embeds into the 1-forms B of level $j-1$ the subspace of those that satisfy $B = 0$ on one contour for each site (a tree in each block, imposed sharply) together with $Q^{\mathrm{st}} B = 0$. In this formula Q^{st} denotes the straight average over the blocks of the single step from level $j-1$ to level j, at $U = \mathbf{1}$. It is thus the covariance, on that subspace, of the quadratic form $\langle B, \mathcal{H}_{j-1}^* \mathcal{H}_{j-1} B\rangle = \|\mathcal{H}_{j-1} B\|^2$, which equals twice the free action of the minimiser with datum B. On the subspace one has $\|\mathcal{H}_{j-1} B\|^2 \ge c\|\mathrm{d}'B\|^2 \ge c_L \|B\|^2$. It differs from the covariance $C^{(j-1)}$ of § 3.12.1-§ 4.5 at the trivial background in two ways. The gauge differs: there it is imposed softly, on the means over all

contours. The constraint also differs: the straight average is not the linearisation of $\mathcal{M}$. The two gauges induce the same curvature law.

Let d' and d'' be the fine and coarse coboundaries, and A the plaquette average for this step. The flat identities $d''Q = d''Q^{\mathrm{st}} = \mathsf{A}d'$ give the common image of the two constraints under d'. To see surjectivity, take $h = d'B$ with $\mathsf{A}h = 0$. The coarse defect QB is closed. Remove its constant harmonic part by a fine constant cochain, since the average on constants is invertible. Remove its exact part by a fine gradient whose scalar has the prescribed values at the coarse centers. For Q^{st} prescribe the corresponding block means of the scalar instead. Both corrections preserve h.

In $QB = 0$ the fibre of h consists of gradients with scalar zero at the coarse centers after subtraction of one constant. A fine harmonic difference would give a nonzero coarse harmonic difference. On that fibre the contour mean to a site changes by the scalar at the site minus its value at the center. Integration of the normalized quadratic contour weight in these coordinates has the same value on each fibre. In $Q^{\mathrm{st}}B = 0$, subtract the tree path sums by a gradient with zero block means to set the tree bonds to zero. A gradient vanishing on the trees has a scalar constant on each block, and $Q^{\mathrm{st}}d'\lambda = 0$ then forces these constants to agree. The tree condition therefore selects one lift of each h. All changes of coordinates are linear, with constant measure factors canceled in normalization.

Consequently both flat quadratic laws induce the Gaussian with curvature precision V_{j-1}^{+} restricted to the exact curvatures satisfying $\mathsf{A}h = 0$, where V_{j-1} is the unconditioned covariance of $Q_{j-1}^{\mathrm{pl}}F$. Its covariance is C_j^{curv}. Transport by $\mathcal{H}_{j-1}$, which depends only on h, gives the same bare slice $\mathcal{C}_{(j)}$ in either gauge. This calculation uses the full quadratic laws. The comparison to the cut windows uses the separate window estimates.

Summing over $j \le k_0$, where the coarsest slice gives the dominant contribution, one obtains the following bound. Here $t = |x(p) - x(q)|/a_s \ge \frac{1}{2}C_W(s)$, and $\delta_{\mathfrak{fl}} > 0$ is a rate formed from the rates δ of the slices, depending only on L and the dimension.

$$|C_{K,s}^{\mathfrak{fl}}(p,q)| \le C\big(\tfrac{a_K}{a_s}\big)^4 e^{-\delta_{\mathfrak{fl}}t} = C\pi^2 t^4 e^{-\delta_{\mathfrak{fl}}t}\,\sigma_{pq}\,:$$

the fluctuation part is small because the curvature of the linear minimiser decays. Because $t^4e^{-\delta_{\mathfrak{fl}}t}$ is decreasing only for $t \ge 4/\delta_{\mathfrak{fl}}$, the room is given the floor $C_{W,0}A_0^2 \ge 8/\delta_{\mathfrak{fl}}$. Over $j > k_0$ the sum of the exponentials reconstitutes the power law: $\sum_i L^{-4i}e^{-tL^{-i}} \le Ct^{-4}$.

The interacting measure. We apply the formula of the Strategy at level k_1, whose backgrounds are flat on the scale of the pair. Only the classes $[h]$ occur, and no finer class of histories: the sourced exponent of level k_1 is the one that §5.20.1.2 provides. (c1) *The first member is an error term.* Consider the terms of the levels $k_0 < j \le k_1$ and a source that is rough on their scale. Their slopes in such a source remain $\le Cx^{-1}(\log x)^{\mathfrak{p}_0+q}$, measured against $\|f_i\|_\infty$ (the norm $\|f_i\|_{\sharp,K-j}$ of the level of the term can exceed it by a factor of up to L^{j-k_0}). The recursion for these slopes closes since $\mathsf{n} \le C\log x$ (its size is set through $\bar{x}_s \le Cx$). Hence $\mathsf{n}^2(\log x)^{\mathfrak{p}_0-q} \le C(\log x)^{2+\mathfrak{p}_0-q}$ is small ($q - \mathfrak{p}_0 > 2$, g small). Suppose first that no large-field region touches the supports at level k_1. Then $|\Phi_i^{(k_1)} - c_i| \le o(1)\,x^{-1}\|f_i\|_\infty$ for a constant c_i, where $o(1)$ refers to $\mathsf{d} \to 0$, uniformly in the datum. In the other case $|\Phi_i^{(k_1)} - c_i|$ grows no faster than $L^{\mathsf{n}}L^{4a}\|f_i\|_\infty$ in the age a of the touching region. The age series of §§ 5.20 and 5.22, taken at the single level k_1 with $b \ge 8$, beats this growth: $L^{\mathsf{n}} \le L\bar{x}_s^2$ is a power of x, while the series lies below every power. Consequently $|\langle\Phi_1^{(k_1)};\Phi_2^{(k_1)}\rangle_{\mathsf{P}^{(k_1)}}| \le o(1)\,x^{-2}\prod\|f_i\|_\infty$. (c2) *The second member becomes one number.* The quantity $\Phi_{12}^{(k_1)}$ is the sum of two parts. The first is the mixed derivative of the sum $\sum_{j\le k_1}\sum_X e_j(X;w)$ of localised source energies from § 5.20. The second is a part that depends on the fields and is bounded only crudely, by a quantity of order $L^{2\mathsf{n}}$ for each bond of the determining set; by § 5.20, the size of that set is counted by the unit volumes of level k_1 together with the sites $\sum_{j\le k_1}\#_j(Z_j)$ of the large-field regions (every source derivative costs a factor L^{n}). We translate the pair by the points v

of a grid $\mathfrak{P} \subset \Lambda_{s,\ell}$ whose spacing is comparable to d, and we write $f_i^v := f_i(\cdot - v)$ for the translated sources. The left-hand side of the formula is unchanged by this. The sum over v of the mixed derivatives equals the mixed derivative evaluated at the two array sources $\sum_v \epsilon_v f_i^v$, whose norms are those of f_i, averaged over the signs $\epsilon \in \{\pm 1\}^{\mathfrak{P}}$ (this is the sign-averaging argument proving eq. 6.vi). The crude bound is therefore divided by the number $\approx L^{4\mathsf{n}}\hat{\mathsf{d}}^{-4}$ of pairs contained in a unit volume of level k_1. What survives is $L^{-2\mathsf{n}}\hat{\mathsf{d}}^4 \le \bar{x}_s^{-4}\hat{\mathsf{d}}^4$, and this requirement fixes n. There remains the number

$$c_{12} := |\mathfrak{P}|^{-1} \sum_{v \in \mathfrak{P}} \partial_{z_1}\partial_{z_2} \sum_{j \le k_1} \sum_{X} e_j(X; z_1 f_1^v + z_2 f_2^v)|_0$$

. (c3) *The number is evaluated.* The number c_{12} is the value at a single point of the mean of $\Phi_{12}^{(k_1)}$ over $\mathfrak{P}$, namely of the term without large-field regions, taken at the trivial block field. Its exact single-step recursion runs from level k to level $k+1$ for $k_0 \le k < k_1$ and is evaluated at the flat terminal field. The measures there are positive, so a remainder is carried through a step by its supremum alone. For each step, two inequalities on a single fluctuation integral § 4.5 are then required. That integral belongs to the small-field step taken over the whole lattice, with a background that is real and regular and with coupling $x_j \approx x$. The first inequality concerns the covariance of two sums of background plaquette energies. The second concerns the mean value of a bilinear form whose arguments are the background plaquette angles. The expansion of § 4.5 gives terms for these comparisons. We must bound the interacting errors on the actual fluctuation integral, using Cauchy estimates on its admitted polydisc, and control the Taylor error in replacing the regular background by the flat one. At the flat background, the object that agrees with the free template is the curvature covariance C_j^{curv} introduced above. It determines $\mathcal{C}_{(j)}$, and a_p depends on nothing else.

6.1.1.3. The clean restriction at fixed exterior data. The clean restriction has to be made on a standing class with its stored variables still present. Fix one such class and keep its exterior datum fixed. At a step of level t above the first level of the clean window, add a small complex constant s to the input boundary term at each level-$(t-1)$ live cube near the clean neighbourhood. The modified boundary system belongs to the complex box of the step identity for s in a neighbourhood of zero. The real moves are independent of the boundary system, so an input term with N marked cubes acquires just e^{sN}. With the stored variables retained, the summed step identity over the fixed output standing part therefore equates two polynomials in $z = e^s$ near $z = 1$. The constant coefficient is the sum of the allowed histories and, on the bracket side, the same bracket with the marked inner histories omitted. The standing input at the first level already enforces its live condition. Take the coefficient algebraically, keeping the original moves, shifts and counterterms. Healings at or below the first level of the window have no such mark. With profiles redrawn after healing and compensated at each plaquette, the coupling lag vanishes on the clean box.

To estimate the quotient, restrict the inner-history measure of each bracket to the histories allowed by the mark. At the same stored datum a restriction decreases its total variation. An inadmissible collar gets weight zero. Keep the empty-family factor, the relative geometry and the interaction potential on each surviving tuple. Thus every absolute activity majorant of the full bracket still applies to the restricted one, including the small factor for each healed collar. The rooted logarithm bound for the relative bracket is $Ce^{-5p_0(g_t)/4}$ per root, with the same field-independent majorant for both sums. Only terms that meet a deleted inner-history choice or collar can differ. Root a changed term in the healed collar $C^{\sim}$ of the deleted choice. In the fixed output label S' we have $C^{\sim 2} \subset \Lambda_t(S')$. Thus $C^{\sim}$ is contained in the one-layer erosion of $\Lambda_t(S')$ and avoids the fixed hulls of the standing components at all levels. The ordinary rooted entropy sum applies there. The marked input cube is in the padded box of the deleted choice. Its possible roots lie within the operation's read radius. The number of such roots per marked cube is polynomial in

$\check{R}_t$, and that polynomial is absorbed by decreasing the reserve in $e^{-5p_0(g_t)/4}$. Summing the two absolute bounds over the resulting roots gives, with $0 < c < 1/4$,

$$0 \le \Delta_t := \log K_t - \log K_t^{\mathrm{cl}} \le C c_t e^{-(1+c)p_0(g_t)}.$$

The lower bound follows by positivity before exponentiation. This comparison uses the standing-class identity with the stored variables, the absolute bracket majorants and the full carrier count. The restriction is of the coefficients of that identity. The covariance and counterterms used to form it are those of the full input.

Positive kernels preserve the resulting domination in later moves. Thus, with $\epsilon_j = C\sum_{t\le j} c_t e^{-(1+c)p_0(g_t)}$ over the marked levels, the clean and full incoming measures have ratio $r_{j-1} \in [e^{-\epsilon_{j-1}}, 1]$ on their common standing variables. At step j, use only the strings of that step that remain clean on both sides. At a fixed output datum, let $\mathbb{E}_j^{\mathrm{ref}}$ be their positive conditional expectation with the full incoming measure. Disintegration and normalization give

$$\mathbb{E}_j^{\mathrm{cl}} F = \frac{\mathbb{E}_j^{\mathrm{ref}}(r_{j-1}F)}{\mathbb{E}_j^{\mathrm{ref}} r_{j-1}}, \qquad e^{-\epsilon_{j-1}} \le \frac{r_{j-1}}{\mathbb{E}_j^{\mathrm{ref}} r_{j-1}} \le e^{\epsilon_{j-1}}.$$

These statements are on the common positive output support, up to null sets of its marginal. The lower bound splits off a reference kernel with weight $e^{-\epsilon_{j-1}}$. Composing the splits leaves a reference branch of weight $P_0 = \exp(-\sum_{k_0<j\le k_1} \epsilon_{j-1})$ on the clean classes. The lost mass is at most the unclean mass plus $1 - P_0 \le \mathsf{n}\epsilon_{k_1}$. This branch uses the original run weights and no counterterms formed from a restricted exponent.

6.1.1.4. The product window on a clean interior box. At step $j = i + 1$ let I be the free bonds of the comparison box. In input-level units let r_{dec} bound the diameter of the enlarged decision cube plus the read of its affected pivot rows. Form I^+ by enlarging I by r_{dec}. Include every decision cube whose enlarged stencil meets I^+ in the clean neighborhood. In the native box geometry a sufficient collar width over I, in these same units, is

$$\max\{100M\check{R}_i + 4r_{\mathrm{dec}},\ 111LM\check{R}_j\}.$$

The first width covers the complete decision stencils. The second places the box on the ordinary side of the live and creation buffers. The native cube count for these enlargements costs a fixed factor bounded by $CL^8 + (2L)^4$, which the rarity exponent absorbs. Use the clean condition before the integrations and healing of step j. The box and its read margin are then inside Λ_j: no creation or live component meets that margin and no operation of $\mathbf{R}$ at this step acts there. In particular no rim, collar or strip test reaches the changed bonds.

Write $\widehat{g}_i = \theta_i^{-1/2}$ for the coordinate scale of the reference frame. Fix $W = V_j$ and the exterior variables of the positive standing class. Take the averaging fibre in the original block axial frame at $V_* = V_i^{\mathrm{bg}}(W)$, with the older prescribed datum held fixed. A change of the literal nonpivot coordinates $\widehat{g}_i y_b$ for $b \in I$ changes only those bonds and the pivots in their one-step read sets. Every such pivot solves its one coarse constraint on the admitted chart. The change leaves the determining rows, the coarse field W, and the older stored variables fixed. In particular the coarse plaquette tests and the test backgrounds computed from W have the same values.

On the box the exact fluctuation test of each retained cube is the full-threshold bound on the supremum of the free bond logarithms that it reads. Its product over the cubes therefore imposes exactly $|\widehat{g}_i y_b| < \delta_i$ for $b \in I$. Every such bond is tested by a cube inside the ordinary split. The tests involving both box and exterior bonds contribute these same bounds and restrictions on the fixed exterior. There is no additional pivot cutoff. The pivot change of variables fixes the nonpivot coordinates and has a single solution on this support, with pivot values of size at most $C_L\delta_i$.

To check the converse, keep the exterior of an admitted clean term and vary the box coordinates throughout these balls. On the affected approximate tests the fixed centers differ from V_* by at most a small fraction of δ_i by the real collar comparison on the test cube. Thus the exact threshold

δ_i implies the approximate threshold $2\delta_i$ at every changed nonpivot read. The contour cutoffs also pass, since their deviation is at most $C_L\delta_i$ and the gauge cutoff uses ε_i. The new-test implication of Lem. 4.57 applies on the full old density carriers and gives the old threshold with its fixed margin. At $i = 0$ check the bare plaquette test on each affected plaquette. The complete ordinary read margin contains all four bonds. At the retained background its plaquette deviation is at most $CL^{-2}\varepsilon_1$ in bare units, by the curvature estimate of that lemma. Relative to this background the nonpivots on the window and its fixed exterior are within δ_0, and the solved pivots are within $C_L\delta_0$. Telescoping the four unitary factors bounds the plaquette deviation by $CL^{-2}\varepsilon_1 + 4C_L\delta_0$. The adjacent frame radii bound $\varepsilon_1/\varepsilon_0$. Choose L for the curvature term, then use the ordinary ceiling on δ_0/ε_0 to put $CL^{-2}(\varepsilon_1/\varepsilon_0) + 4C_L\delta_0/\varepsilon_0$ strictly below one on the whole window. This check uses the estimates on the changed fields and their read sets. The earlier recorded answers alone would not show that they still pass. All other tests or decisions of the step are exterior reads, or use only the fixed W. The local geometry and the clean restriction of this step are therefore constant throughout the box window. The gauge coins inside the box have been integrated in the gauge-fixing factor. Insert the normalized ordinary gauge weight on the summed standing input before conditioning on the exterior. The ordinary gauge group fixes the coarse centres and the older held datum sites. The incoming density and insertion are invariant on these orbits, and the normalized gauge weight has orbit integral one. A draw at an interior site can move an incident exterior fine bond, so disintegrate at the exterior *after* this gauge integration. That exterior contains the retained coarse field, the older stored data used by the standing term, and the fine exterior free coordinates. A fine pivot is reconstructed from its constraint even if its location is outside I. Include its full double block when forming the test read. The exterior may also contain coins of later moves. Integrate out the coins of the collar or ordinary gauge draws made before the tests. At an interior site such a coin fixes the contour and would impose an extra equation on the free box coordinates. Its integrated contribution is the gauge-fixing factor in the coarea integral. The ordinary strip centre, its relative coordinate and Jacobian use the held fine exterior rows and the coarse strip datum. Thus a strip selector in its original coordinate is also fixed in this box integral.

Check the clean margin from the large-field region Z_j before healing, on the whole enlarged family of test reads, including the reconstructed pivots. The collar and rim exploration reads only the successive enlarging large-field sets, all contained in Z_j, the complement of the small-field integration region. The selected exterior decisions therefore stay fixed as the free box varies. When the earlier density indicator reads the changed box, the prospective new-test implication above proves its value on the full product window before it can be kept among the fixed answers. Sum out the unused interior diagnostic flags and apply the coarea formula to the term summed over its standing part.

It follows that on the admitted clean reference class the indicator in eq. 6.xi is the product $\prod_{b\in I} \mathbf{1}\{|y_b| < b_j\}$ with $b_j = \delta_i/\widehat{g}_i$, times an exterior indicator. Use the exact coarea density of eq. 6.x in both numerator and denominator. The retained gauge-fixing exponential and the Haar and pivot densities still occur in the weight. At fixed exterior, freezing the other coordinates of the full quadratic form gives the compression on I and its linear cross force. The exterior mixing measure is proportional to $Z_e m(de)$, since the same box integral Z_e normalizes every inserted observable. This identifies the window and integration variables for the matched conditional comparison.

The positive run also specifies how to impose later tests. On the admitted box fibre let $s_j(e)$ be the state after deleting the integrated slots of step j. The retained field W, the exterior fine slots, the older stored slots and the completed label are fixed by e. The pivots which change with y are integrated slots, since the full read margin separates the box from the retained strip. Hence $s_j(e)$ is constant as y varies on this fibre. The state includes all retained outcomes read by the subsequent moves. The subsequent draws, tests and integrations form a positive kernel $\mathsf{K}_j(s_j(e), d\omega)$ on the later records. Use the kernel conditional on any later coins already included in e, with the remaining coins integrated in the kernel. For a selection A of these records and the fixed exterior,

set $k_A(e) = \mathsf{K}_j(s_j(e), A_e)$. The conditional quotient with a box insertion F is then

$$\frac{\int m(de)\, k_A(e) Z_e\, \nu_e(F)}{\int m(de)\, k_A(e) Z_e}.$$

This follows by performing the box integral before the later kernel integral, for a finite positive denominator. For a standing class sum the positive terms on their shared retained data, keeping each term's own Z_e and $k_A(e)$ in the mixture. A selection on a field already deleted by the run can change the conditional domain and must be kept in the joint integral.

6.1.1.5. Composition on the retained states. Let $\widehat{\tau}_j$ be the measure on the disjoint union of the level-j state spaces, with the block field, all still stored slots and the labels used by the run. Use the original positive operations of step j as a map $\mathcal{T}_j$ on measures, including the sums at merges. For the carried insertion G put $\widehat{\tau}^G_{k_0} = G\widehat{\tau}_{k_0}$ and apply the same operations to $\widehat{\tau}^G_j$ and $\widehat{\tau}_j$. A test splits a measure by its indicator and complement, an integration or change of variables is a positive kernel, and a merge adds the images from its incoming summands. Use gauge fixing as a normalized orbit draw. The gauge-invariant insertions used here can pass through this draw. These operations conserve total mass after summing the labels. At each output, the carried density obeys

$$G^{[j]} = \frac{d\widehat{\tau}^G_j}{d\widehat{\tau}_j} = \mathbb{E}_j G^{[j-1]}, \qquad \mathbb{E}_j F = \frac{d\mathcal{T}_j(F\widehat{\tau}_{j-1})}{d\mathcal{T}_j(\widehat{\tau}_{j-1})}.$$

Positivity gives $|\mathbb{E}_j F| \le \|F\|_\infty$, and $F = 1$ gives $\mathbb{E}_j 1 = 1$. At a merge the two measures in this derivative are the sums of the respective images. In particular the merge uses the conditional weights of the original run.

For a terminal class retained by the run or by an explicit refinement of it, restrict the terminal measures to that class and disintegrate over $V_{k_1} = W$. The conditional expectation of G is the conditional mean of $G^{[k_1]}$ under the uninserted terminal class measure. This follows by testing the carried terminal measure against a bounded function of W. Thus the recursion composes on complete states before projecting to the block field. For a refined class that imposes conditions on earlier deleted slots, retain those conditions in the positive integrals used to form the refinement. We must check the product window and the box estimates for its actual conditional law before applying the Gaussian comparison to that class.

The deletion at an isolated ordinary cell gives a useful case for later prepared and healed exterior observations. At output level j, take I on the bonds of e^{+1} for a cell e, and use the event $e^{+2} \cap Z_j = \varnothing$. The rim width is less than one cell. Each test of the cascade reads within that width of its current stage set. Run the cascade from the data off I, with the output field, the older determining data and the coins fixed, until a stage set first approaches the padded cell. Up to that point the two cascades have the same reads. Thus whether the approach occurs is determined by this exterior. On the event of no approach, the complete post-step state depends only on that exterior. The slots of I are integrated in the ordinary product window.

Write ν_ξ for their conditional law at exterior ξ. Later observations are obtained by positive kernels from the retained state. For a bounded insertion G in I and a later test function F, the integral therefore has the form $\int \nu_\xi(G)\, K_\xi(F)\, d\pi(\xi)$, where π is the pre-deletion exterior measure on this event and K_ξ is the later kernel. Disintegrating over a later prepared or healed observation takes a positive mixture of the ν_ξ. On a class with a common reference law, a uniform normalized density bound against that reference is preserved by this mixture. A finer condition on an earlier deleted coordinate instead enters the original conditional integral.

For two bounded witness reads, also carry $G_1 G_2$ as a single insertion. Put

$$T_j = (G_1 G_2)^{[j]} - G_1^{[j]} G_2^{[j]}.$$

Then $T_{k_0} = 0$ and the recursion on the retained states gives

$$T_j = \mathbb{E}_j T_{j-1} + \mathrm{Cov}_j(G_1^{[j-1]}, G_2^{[j-1]}).$$

Here $\mathrm{Cov}_j(F, H) = \mathbb{E}_j(FH) - \mathbb{E}_j F\, \mathbb{E}_j H$. Indeed, expand the carried product at level $j-1$, apply $\mathbb{E}_j$, and subtract the product of the propagated means. Thus T_{k_1} is the sum of the one-step covariances transported by the later $\mathbb{E}_j$'s, with the weights of the actual merges. In the terminal class, let $\mathbb{E}^W$ denote conditioning on $V_{k_1} = W$ in the uninserted law. The covariance under the terminal conditional law Π of the original reads is

$$\mathrm{Cov}_\Pi(G_1, G_2) = \mathbb{E}^W T_{k_1} + \mathrm{Cov}^W(G_1^{[k_1]}, G_2^{[k_1]}).$$

Only the errors in the propagated means contribute to the last covariance if their leading terms depend on W alone. This is the decomposition used when estimating one-step covariances separately. 6.1.1.6. The two one-step Gaussian comparisons. Fix $k_0 < j \le k_1$. Work in level-$(j-1)$ units on a nonwrapping box containing the read sets in its interior. Write $V_* = V_{j-1}^{\mathrm{bg}}(V_j)$, and take derivatives in the bond logarithms $V = e^{iZ} V_*$. Let y have the centered Gaussian law of the admitted reference box with its covariance $C^{(j-1)}$ on free coordinates. This is the covariance with the reference frame scaling and the actual quadratic weight $\tau_{j-1} = x_{j-1}/\theta_{j-1}$ in the Wilson term. The trace over bond or free coordinates includes the colour slots. The first variation of the physical bond logarithms is $\widehat{g}_{j-1}\mathsf{C}y$, where C is the actual pivot tangent map. Set $C_* = \mathsf{C}C^{(j-1)}\mathsf{C}^{\mathsf{T}}$. Use the uniform covariance bound and the derivative bounds for the actual pivot map, including its higher jets, in the norm of these readouts. The box dimension and the real window radius are bounded by fixed powers of $\log x$. In the following error bounds $g = x^{-1/2} \asymp \widehat{g}_{j-1}$.

Use the normalized conditional law on the clean class, with its actual product window, coarea factors and exterior mixture as in § 6.3. The comparison requires the complete quadratic form and the same chart for the source numerators and the denominator. Assume the exterior comparison on the read set has density ratio between $e^{-\Xi_j}$ and e^{Ξ_j}, with $0 \le \Xi_j \le 1$, the Gaussian window tail is $0 \le t_j \le 1/2$, and the old activity, marked remainder and any coupling lag contributions to the reference box tilt have total bound θ_j^{E}. The intrinsic odd cubic and even higher terms have bounds $Cgn_j\mathsf{b}_j^3$ and $Cg^2 n_j \mathsf{b}_j^4$, respectively, where n_j counts the box coordinates and b_j is the window radius. These parity bounds use an intrinsic reference with every exterior fluctuation argument set to zero. In particular they apply to the homogeneous step with no stored exterior. To use them on a box with stored exterior one must include the change from those arguments in the exterior comparison. The generating-function estimate with the stored values fixed uses the full intrinsic oscillation instead, as in §6.3.0.4. These estimates and the gauge-equivariant means used below require a common admitted analytic tube with room around the symmetric product window and a small bound for the complete tilt.

Use the following formulas at a fixed compatible exterior, with the matched reference having zero exterior fluctuation arguments. For an exterior mixture they apply with a single reference only after the density and readout comparisons to that reference. If the reference varies with the exterior, averaging the conditional covariances also requires the covariance of the conditional means.

Let G, G_1, G_2 be the gauge-invariant readouts, with common tube bound M and Taylor derivative bounds μ_m. Put $\bar{\mu} = \max_m \mu_m$ over the derivatives used here. Write κ for the curvature size of V_* on the read set, κ_i for its curvature size on the box of G_i, and $\kappa_{\mathcal{B}}$ for the curvature size of V_j on the window box. The curvatures are measured in their respective levels, with $\ell'\kappa$ small for a read box of side ℓ' in the common nonwrapping gauge. On the admitted clean boxes use $\kappa, \kappa_1, \kappa_2 \le Cgp_0$. This permits the variation of an old tilt to be bounded by its size times the oscillation of the readout, using the first derivative bound $C\mu_2\kappa$ and the second-order Taylor bound. The mean and covariance comparisons have the form

$$\mathbb{E}_j G = G(V_*) + \tfrac{1}{2}\widehat{g}_{j-1}^2 \,\mathrm{tr}(C_* D^2 G(V_*)) + E_1,$$

$$\operatorname{Cov}_j(G_1,G_2)=\widehat{g}_{j-1}^{2}\langle DG_1(V_*),C_*DG_2(V_*)\rangle + \tfrac{1}{2}\widehat{g}_{j-1}^{4}\operatorname{tr}(D^2G_1(V_*)C_*D^2G_2(V_*)C_*)+E_2.$$

Put $s_i=g\mu_2\kappa_i+g^2\bar{\mu}$. For readouts compared in the same coordinates the required errors are bounded by

$$|E_1|\le C(\log x)^C\{(g^4+\theta_j^{\mathrm{E}}g^2)\bar{\mu}+(g^2+(\log x)^{-2q})\mu_2\kappa\kappa_{\mathcal{B}}\}+C\operatorname{osc}(G)\Xi_j+C(\log x)^C(\mathsf{M}+\bar{\mu})\sqrt{t_j},$$
$$|E_2|\le C(\log x)^C\{(g^2+\theta_j^{\mathrm{E}})(g^4\bar{\mu}^2+g^2\mu_2^2\kappa_1\kappa_2)+(g+\theta_j^{\mathrm{E}})g^3\mu_2\bar{\mu}(\kappa_1+\kappa_2)\}$$
$$+C(\log x)^C\Xi_j s_1s_2+C(\log x)^C(\mathsf{M}+\bar{\mu})^2\sqrt{t_j}.$$

If the exterior changes the readout map, let η_i bound the supremum difference between its i-th pullback and the reference pullback on the same window. It costs η_i in the mean. For the covariance subtract the reference constants $G_i(V_*)$ first. Writing B_i for the resulting reference suprema, the pullback error is bounded by $2\eta_1(B_2+\eta_2)+2\eta_2B_1$. Indeed, under the positive joint law of the exterior and the box, expand the covariance in one pullback difference at a time and use $|\operatorname{Cov}(A,B)|\le 2\|A\|_\infty\|B\|_\infty$. Here $B_i\le C(\log x)^Cs_i$ by the same Taylor bounds as in the density comparison.

Expand the readouts in the actual pivot chart and compare with the centered Gaussian on its symmetric window. The two linear variations give the first covariance term. It vanishes at the flat reference, since a gauge-invariant scalar has zero first variation there. The two quadratic variations give the second term by Wick contraction. For the mean, the trace is the quadratic variation. The extra terms pairing DG with the quadratic pivot increment, the odd cubic tilt, or the linear old-activity increment use the vanishing of their gauge-equivariant means at flat data.

For the covariance, first work on the symmetric product window at the matched reference. Write $\mathbb{E}_0$ for the normalized restricted Gaussian, P for its tilt and $A_i=G_i-\mathbb{E}_0G_i$. Put $\delta=\|P\|_\infty$. Expanding the normalized expectation at $P=0$ gives $\mathbb{E}_PH=\mathbb{E}_0H+\operatorname{Cov}_0(H,P)+O(\delta^2\mathbb{E}_0|H-\mathbb{E}_0H|)$. Indeed $\mathbb{E}_0e^P\ge e^{-\delta}$ for this real tilt, and the linear term of its inverse subtracts $\mathbb{E}_0P$. Apply the identity to A_1A_2 and then to each A_i. Subtracting the shifted means gives

$$\operatorname{Cov}_P(G_1,G_2)=\operatorname{Cov}_0(G_1,G_2)+\operatorname{Cov}_0(A_1A_2,P)-\operatorname{Cov}_0(G_1,P)\operatorname{Cov}_0(G_2,P)+O(\delta^2\|A_1\|_2\|A_2\|_2).$$

The norms here are under the restricted Gaussian. The product of shifted means has the same quadratic size in δ.

The even part of A_i is $O(g^2\bar{\mu})$ and the odd part is $O(g\mu_2\kappa_i+g^3\bar{\mu})$, in the Gaussian norms, with the fixed logarithmic factors from the window. The two same-parity products pair only with P^+, whose size is $O(g^2+\theta_j^{\mathrm{E}})$ with those factors. The mixed products pair only with P^-, of size $O(g+\theta_j^{\mathrm{E}})$. This gives the two displayed orders for the linear tilt correction. Since θ_j^{E} is small, δ^2 is bounded by a fixed logarithmic factor times $g^2+\theta_j^{\mathrm{E}}$. The quadratic normalization terms have the same orders. In the untilted covariance, the extra quadratic pivot term is multiplied by the first derivative of the readout. Its pairing with the main quadratic term, and the pairing of a linear term with a cubic term, cost $O(g^4\mu_2\bar{\mu}(\kappa_1+\kappa_2))$. The remaining higher-order pairings cost $O(g^6\bar{\mu}^2)$, with the logarithmic factors included. In passing to the full Gaussian apply Cauchy–Schwarz on the window complement to the products and to each mean. This gives the $\sqrt{t_j}$ error in the comparison.

For a common pair of pullbacks the exterior density ratio in the normalized comparison is bounded by $e^{\pm\Xi_j}$. The bound for the covariance from the product of two centered suprema therefore costs $C(e^{\Xi_j}-1)\prod_i\|G_i-G_i(V_*)\|_\infty$. The Taylor bounds on the window give $\|G_i-G_i(V_*)\|_\infty\le C(\log x)^Cs_i$. For $\Xi_j\le 1$ this is the stated exterior term. The bound applies to the positive exterior mixture relative to the same reference density. For the first two means the argument uses fixed-radius analytic tubes in the retained datum V_j and the corresponding bounds for the mean on those tubes. For the regular old origins the required joint chart is obtained by combining the retained field and the solved free field before taking the old averages. In the matched local recipe

write $W = e^{iA}$, let $p_k(W)$ be its background link field, and use $e^{i\Phi_{p_k(W)}(u)}p_k(W)$ with the physical free variable u. At $u = 0$ the induced datum agrees with the coarser background by the nested constraint identity. The local contour and pivot charts bound the logarithm of the combined field by $C(\|A\|_\infty + \|u\|_\infty)$. On a joint disc $\|A\|_\infty, \|u\|_\infty < c\alpha_k$ we need the actual maps of the matched recipe to enter the same window section as in eq. 4.cxcv. The constant c must leave room for the sum of the two displacements. Along the retained axial line its actual size is at most $C\,\mathrm{side}(\mathcal{B})\kappa_{\mathcal{B}}$, which must fit on the smaller disc.

The window cancellation uses this combined field: form the old averages, use their common critical window solution, and subtract the vacuum and its own tent counterterm at each old pointing. Sum at that pointing before applying the common bracket. The full pointed quadratic tensor is zero. The excluded domains give a long-domain tail, with length at least $2/\sigma_i - 2$ for a window at relative spacing $\sigma_i = L^{-(k-i)}$. The affine and Hölder estimates then give the pointed remainder with the gain $\rho_i^2\sigma_i^{4+\alpha_H} + \rho_i^3\sigma_i^6$ in units of e_i. Here ρ_i is the ratio of the output radius to the old radius. Counting the σ_i^{-4} pointings in a current-scale window gives the age weight ω_{k+1-i} of eq. 4.cxcviii. Once the actual old readers are identified on this joint chart, the bound there is uniform in (A, u) for the same filed families.

Apply Cauchy's estimate in one retained direction and one physical free coordinate. For a regular term on Y it costs

$$Ce_i\omega_{k+1-i}\alpha_k^{-2}e^{-\lambda d_k(Y)}.$$

If the free coordinate is outside the full carrier its derivative is zero. The first free derivative of the scalar regular sum vanishes at the matched flat recipe with zero exterior free coordinates, by constant colour invariance. Integrating the mixed derivative along the retained axial line and rooting at the free bond gives $CE_0\alpha_k^{-2}\,\mathrm{side}(\mathcal{B})\kappa_{\mathcal{B}}$. The box side costs a fixed power of $\log x$. This estimate concerns the regular part of the old Wick vector. The vacuum-only remainders, Wilson lag and boundary factors use their own origin bounds. A factor with a fixed noncentral spectator need not have zero free derivative at the flat value of the varied datum. The factor $g^2\alpha^{-2}$ gives the inverse logarithmic power in E_1. These bounds, paired with the small first derivative of G, give the product $\kappa\kappa_{\mathcal{B}}$.

The three vectors in the mean correction can be computed from the actual chart coefficients. Write Φ_V for the pivot graph in eq. 4.ccxxx, with $\mathsf{C} = D\Phi_V(0)$, and put $C = C^{(j-1)}$. For two free directions u, v, the quadratic pivot coefficient is given by eq. 4.ccxx. In particular, $D^2\Phi_V(0)[u, v] = -hD^2q_V(0)[\mathsf{C}u, \mathsf{C}v]$ for the pivot right inverse h of $Dq_V(0)$. Write the intrinsic first coefficient of the exponent as $P_1^{\mathrm{int}}(y) = \ell[y] + T[y, y, y]/6$, so that the first-order exponent is $\widehat{g}_{j-1}P_1^{\mathrm{int}}(y)$. Here ℓ is the first log-coarea derivative including Haar density, and T is the signed third derivative of the complete centered action and contour gauge, with the action weight retained as in eq. 4.cccxviii. Write ℓ_{old} for the first derivative of the actual old exponent after substitution in the same graph. Take this derivative in the physical free coordinate $u = \widehat{g}_{j-1}y$, with the sign of the old term in the exponent.

Use first the full Gaussian for these polynomial contractions. Wick's formula gives the three vectors before multiplication by $\widehat{g}_{j-1}^2$:

$$\frac{1}{2}D^2\Phi_V(0) : C, \qquad \mathsf{C}C(\ell + \tfrac{1}{2}T : C), \qquad \mathsf{C}C\ell_{\mathrm{old}}.$$

The contraction in $T : C$ is over two of its three indices. For example, the second identity follows by pairing y with one of the three factors of the cubic. Each pairing leaves the same contraction, hence the coefficient $1/2$. The other two identities use only the second Gaussian moment. For a polynomial vector A, passage back to the real Gaussian conditioned on the window costs at most $C\sqrt{t_j}\|A\|_{L^2(\gamma)}$ when $t_j \le 1/2$. This follows by subtracting the two normalized expectations and using Cauchy–Schwarz on the complement of the window. The polynomial moments are bounded using the same chart jets and covariance. This tail comparison uses the real Gaussian.

For the homogeneous chart near the trivial datum, compose the first two contractions with the actual intermediate field $p_k(W)$ of eq. 4.cccvi. The fixed output radius for that map, the outer chart radius in eq. 4.ccxxx, and the precision bounds in eq. 4.cclxxxv give a common smaller fixed complex radius for the Wick polynomials. The action family in eq. 4.cclxxix and the local coarea factors in eq. 4.ccliv bound the intrinsic coefficients on the read coordinates. At the trivial datum each vector is fixed by all constant colour rotations, so it vanishes. Cauchy's estimate on this homogeneous datum ball bounds each of the first two vectors by $C(\log x)^C \|\log W\|_\infty$ on a fixed smaller ball, with the polylogarithmic factors from the box count. The third vector is bounded by the norm of the summed old first derivative times the pivot and covariance bounds.

For the conditional calculation first compare with its matched local law with zero exterior free coordinates. The density-ratio and readout comparisons account for that change. For the Wick tensors of the local law, keep its box, free and pivot masks, guard and weights fixed. Compare its retained datum to the trivial datum in the same chart. On the nonwrapping box choose the coarse axial logarithm A_W with $\|A_W\|_\infty \le C\,\mathrm{side}(\mathcal{B})\kappa_{\mathcal{B}}$ in coarse units. Use the line e^{itA_W} in the common admitted datum ball. The local pivot jets and coarea derivative use complete fixed stencils. For the cubic action use the rooted coefficient bounds of eq. 4.cclxxix, and for the covariance use the resolvent identity for the same precision and mask. They give a holomorphic comparison on a smaller fixed radius. Expand each contraction by replacing one coefficient at a time along that line. The fixed number of contracted indices costs at most a power of the box count. Both tensors are zero at the trivial datum since all the fixed data there preserve constant colour rotations. The size of $\mathcal{B}$ is bounded by a power of $\log x$, so the first two vectors of the matched local law are bounded by $C(\log x)^C\kappa_{\mathcal{B}}$. For the old regular near terms on this intrinsic box, take the retained angular datum and the physical free coordinate u as separate analytic arguments. Use the jointly admitted old-box substitution of eq. 4.cxlii, with no fixed colour spectators. Keep the box and its filing fixed. In its smaller ball, the amplitude bound eq. 4.cxcviii holds as the retained datum varies through angular size $c\alpha_k$, $k = j-1$, while $\sup|u| \le c\alpha_k$. Here the pointed counterterm is removed before summing the old terms. The bound uses the same age sum $\mathcal{E}_k$ on this joint ball.

To take the first derivative of this sum, put the retained field on the line e^{itA_W}. For a free bond b, let $F_b(t)$ be the u_b-derivative at $u = 0$ of the summed regular exponent in the chart. On the trivial retained datum this derivative vanishes. Indeed the whole intrinsic substitution commutes with constant colour rotations, and their adjoint action has no invariant covector. Cauchy's estimate in u_b, followed by the rooted sum, bounds $|F_b(t)|$ by $C\mathcal{E}_k/\alpha_k$ on $|t|\|A_W\|_\infty < c\alpha_k$. On the half datum ball, the zero at $t = 0$ then gives

$$\|\ell^{\mathrm{reg}}_{\mathrm{old}}\|_\infty \le C\mathcal{E}_k\alpha_k^{-2}\|A_W\|_\infty.$$

This takes the derivative in the physical coordinate. After multiplication by $g_{j-1}^2\mathsf{C}C$, the summable covariance and pivot rows give the bound $C\mathcal{E}_k(\log x)^{-2q}\,\mathrm{side}(\mathcal{B})\kappa_{\mathcal{B}}$ for the regular part of the third vector. Pairing it with the derivative of an invariant readout supplies the second curvature factor, by the same vanishing derivative at the trivial field on the readout's own box. For ordinary spectator-free remainders with the same joint domain, replace $\mathcal{E}_k$ by $\sum_{i\le k}\rho_i^2 r_i$. The vacuum-only bound supplies the amplitude in the same calculation, and eq. 4.ccv sums these weights along the flow.

For ambient coefficients one must also count carriers reaching the exterior. Their exponential tails are the separate boundary error. Terms with fixed colour spectators or without the joint activity-radius domain need their own first derivative bound.

The quadratic part of the first covariance term is a bilinear form in the retained angles. Its mean at later steps requires the first comparison for the carried readout, with its own derivative bounds. On the admitted conditional kernels of the run, let $G_i^{[j]}$ be the propagated conditional mean of the i-th readout. Write it as $M_{i,j} + J_{i,j}$, with $M_{i,j}$ the background read and its accumulated second-order traces. The normalized conditional expectation propagates $J_{i,j}$ in supremum norm.

In the conditional covariance its mixed contribution is bounded by

$$|\mathrm{Cov}_j(M,J)| \le \|J\|_\infty \, \mathbb{E}_j|M - \mathbb{E}_j M|.$$

For the scalar plaquette read on the clean boxes, the mean-value bound for its background part uses the curvature of the retained datum. With a fluctuation of size g times a power of $\log x$, the bound is a power of $\log x$ times $g\kappa_{\mathcal{B}} + g^2$. The trace part already has a factor g^2 and its fixed-radius derivatives cost only powers of $\log x$. The corresponding contribution of two remainders is at most $2\|J_1\|_\infty \|J_2\|_\infty$. This is why the iteration can use bounds on the values of the old remainders.

For the principal half-square term at p, q, put $c_j = x_{j-1}^{-1} \mathcal{C}_{(j)}(p,q)$ at the flat reference. At a fixed retained background with curvature readouts m_p, m_q, the part linear in each fluctuation has the flat-matrix term $c_j \langle m_p, m_q \rangle$. It has a quadratic zero at the flat retained datum. In a later step $l > j$, its leading second-order trace increases its conditional mean by $(N^2-1)c_j c_l$. The two symmetric terms in the Hessian of the bilinear form cancel the $1/2$ of the trace. This produces the cross-level term in the principal covariance, in addition to the single-step term $(N^2-1)c_j^2/2$. The normalized comparison on the actual run must bound the error in these transported traces on the common admitted chart. It also must bound the covariance of the remaining terminal means. The calculation uses the conditional kernels of the run, with the standing data carried by them. Conditioning the initial law on a plain composite block average defines a different law when the operations have redrawn exterior fields.

6.1.1.7. Carrying a scalar plaquette read to a coarser datum. On the nested clean boxes let $T_p(V)$ be the logarithm of a level-k_0 plaquette read from the background at level $k_0 + i$, in the common chart. Use at each finer step the actual datum induced by the coarser background. The finer constraint fibre is contained in the coarser one. Restriction and uniqueness of the regular orbit identify the composed read with the read from the single level-$(k_0 + i)$ background. This applies on the exact common constraints. When using two different localization boxes, keep their collar comparison as a separate error.

The fixed complex Landau tube for that background gives $\|T_p\| \le CL^{-2i}$ on the tube, with a constant independent of i. The real bound at the datum is $CL^{-2i}\kappa(V)$. Cauchy's estimate on a fixed smaller datum ball gives $\|DT_p\| + \|D^2 T_p\| \le CL^{-2i}$. Let G be a scalar read of a fixed family of these holonomies, gauge invariant on the nonwrapping box with the other arguments fixed. At the trivial field constant colour rotations leave the datum fixed. Their adjoint action on each logarithm has no invariant linear functional, so $DG(0) = 0$. Thus in the read chart $\|DG(T)\| \le C\mu_2 \|T\|$. For the traced plaquette weight this cancellation also follows by taking the trace of its traceless linear logarithm. The two chain-rule terms give

$$\|D(G \circ T)(V)\| \le C\mu_2 L^{-4i} \kappa(V),$$
$$\|D^2(G \circ T)(V)\| \le C\mu_2 L^{-4i}.$$

Indeed the first part of the second derivative has two first derivatives of T, while the part with $D^2 T$ gains the other factor through $DG(T)$. With the bounded one-step Gaussian covariance the trace of this latter part at depth i, including the fluctuation scale, costs $C(\log x)^C g_{k_0+i}^2 \mu_2 L^{-4i} \kappa(V)$. It sums geometrically over the clean segment. These are the derivative estimates for this scalar readout family. A matrix plaquette has only the L^{-2i} estimate for its derivatives. The covariance kernels and the differentiated old-origin sums have their own bounds in the iteration.

Prop. 4.22 proves the mean and covariance replacement for the specified plaquette readouts of the flat homogeneous classical-pullback fibre. For the actual clean run, the bounds just stated use the normalized box law, the full tilted exponent, exterior control, and uniform derivative bounds for the carried readouts. These inputs must be verified on the same chart.

6.1.1.8. The transported covariance on the fixed datum chart. At step j use the local reference with its masks and all other chart choices fixed. For a level-k_0 plaquette p let $T_p(u; W)$ be its logarithm in the common frame, after the physical free displacement u and the actual pivot substitution. Write

$m_p = T_p(0;W)$ and $R_{j,p}(W) = D_u T_p(0;W)$. The physical matrix pairing between two plaquette reads is

$$K_{j,pq}(W) = \widehat{g}_{j-1}^2 R_{j,p}(W) C^{(j-1)}(W) R_{j,q}(W)^{\mathsf{T}}.$$

All transposes here use the real coordinate inner products and their bilinear continuations on the complex chart. The first covariance term for the two half-squares is exactly $\langle m_p, K_{j,pq}(W) m_q\rangle$. The second-order term in the mean of one half-square is

$$\tfrac{1}{2}\operatorname{tr} K_{j,pp}(W) + \tfrac{1}{2}\widehat{g}_{j-1}^2 \langle m_p, D_u^2 T_p(0;W) : C^{(j-1)}(W)\rangle.$$

The trace is in the colour space. The second summand uses the composed derivative and therefore includes the quadratic pivot contribution to the trace. When using the separate bond Taylor and pivot terms, count that contribution only once.

The fixed complex datum tube and the nested curvature bound give $\|R_{j,p}\|_{\ell^\infty \to \mathfrak{g}} \le C\eta_{j-1}^2$ on a smaller tube. To see this, apply the plaquette bound to the read with the perturbed datum on the tube and use Cauchy's estimate in a physical free direction, with the bounded pivot tangent included. In particular this bounds the row in ℓ^2. The covariance is uniformly bounded on the same smaller tube by the precision estimates for the fixed masks. Therefore $K_{j,pq}$ and any fixed number of its datum derivatives have bounds of size $C_m x_{j-1}^{-1}\eta_{j-1}^4$, allowing fixed powers of $\log x$ from the box and chart constants. This follows by applying Cauchy's estimate to the bounded product on the larger common tube. The scalar half-square also has the corresponding fixed-order derivative bound without the factor x_{j-1}^{-1}, by applying Cauchy's estimate to the bilinear square of the holomorphic logarithm. These bounds use fixed readsets and the admitted common datum radius.

Along the coarse axial line, subtracting $K_{j,pq}(\mathbf{1})$ costs this same bound times the size of the coarse potential. That size is bounded by the box side times its curvature. The second summand of the mean trace contains m_p itself and so also gains the small curvature of the datum. At the flat datum first compare the box covariance with the full flat covariance restricted to the read set, at the same relative weight τ_{j-1}. The Schur correction in the flat marginal comparison bounds this discrepancy on the read set by $Ce^{-c\mathsf{D}}$, where D is its distance from the edge in the box units. The ℓ^1 bounds on the two readout rows give a cost at most $Cx_{j-1}^{-1}\eta_{j-1}^4 e^{-c\mathsf{D}}$ in the physical pairing. With this marginal the local read gives the local unit-weight slice times x_{j-1}^{-1} in each colour, since $\widehat{g}_{j-1}^2\tau_{j-1}^{-1} = x_{j-1}^{-1}$. Then compare the local and full readout rows by eq. 6.i. Thus the difference from c_j times the identity in colour is bounded by

$$C(\log x)^C x_{j-1}^{-1}\eta_{j-1}^4\big(\operatorname{side}(\mathcal{B})\kappa_{\mathcal{B}} + e^{-c\mathsf{D}} + e^{-cd_{j-1,p}} + e^{-cd_{j-1,q}}\big).$$

In the curved one-line covariance this bound is multiplied by $|m_p||m_q|$. Its part coming from $K_{j,pq}(W) - K_{j,pq}(\mathbf{1})$ has zero quadratic jet at the flat datum, since both m's and the matrix difference vanish there. The flat matrix error can contribute to the quadratic jet, with the exponential losses in the displayed bound and the two factors from the derivatives of the plaquette reads.

In the later mean step the derivative of a trace already carries a factor of x_{j-1}^{-1}. Taking another Gaussian trace at level $l > j$ costs at most $C(\log x)^C x_{l-1}^{-1}x_{j-1}^{-1}\eta_{j-1}^4$ for the mean. The sum of the η_{j-1}^4 factors is geometric. The number of later steps is $O(\log x)$, so these bounds retain a power of x^{-1} beyond the first trace. The principal quadratic term of the transported covariance instead contributes the cross-level contraction described above.

On an admitted clean terminal datum the background half-square contributes at most $C\|\phi_i\|_\infty x^{-1}\mathsf{r}^4 p_0^2 L^{-4\mathsf{n}}$ to the mean after summing its plaquettes. Here n is the number of transported steps and r is the read box size at the initial scale. This follows from the terminal curvature bound $Cp_0 x^{-1/2}$ and the area factor $L^{-2\mathsf{n}}$ in the nested read. Subtract the deterministic reference

mean

$$c_i = \frac{N^2-1}{2} \sum_p \phi_i(x(p)) \sum_j x_{j-1}^{-1} \mathcal{C}_{(j)}(p,p).$$

The trace differences above sum in j by the same geometric bound. The remaining one-step errors propagate by the supremum norm. Thus in using total covariance on the clean terminal law the covariance of the means costs at most $2\|\mathbb{E}(G_1 \mid W) - c_1\|_\infty \|\mathbb{E}(G_2 \mid W) - c_2\|_\infty$, with the conditioning index enlarged to include any class variable. The estimates must be uniform over that index on the clean set. In the generating-function argument the average is taken before the logarithm, and this separate covariance estimate is unnecessary.

6.1.1.9. The linear readout and the free slice. At level $q = j-1$, write $H_q^\square(p)$ for the linearized curvature read of the localized problem for p, with its input row extended by zero to the whole level-q torus. Write $H_q(p)$ for the linearized read of the regular critical problem on that torus with every level-q bond prescribed. Use the same averaging scheme in both problems. Let $d_{q,p}$ be the distance in level-q spacings to the boundary of the localization, with the full read stencil and the fixed collar width included in measuring the margin.

For a real coarse 1-form A, take $V(t)(b) = \exp(itA(b))$ on the whole level-q lattice. Its test holonomies have defect at most $C|t|\|A\|_\infty$, so the homogeneous torus problem and the prescribed joined localization are admitted for small $|t|\|A\|_\infty$. Use the restriction of $V(t)$ on common rows and its prescribed face lift on the new collar rows. By eq. 3.cdi, the discrepancy from the induced datum is bounded by $C|t|\|A\|_\infty$. The weighted response eq. 3.cdii therefore bounds the difference of the plaquette defects in the comparison frame by $C\eta_q^2|t|\|A\|_\infty e^{-cd_{q,p}}$. The comparison can also be made in the ancestor frame of the plaquette. The tower transport and the normalized node factor equal one at the trivial field and are continuous on the datum line. Consequently their conjugations have identity linear part on a defect vanishing at $t=0$. Dividing by $|t|$ and letting t tend to zero gives

$$\left|(H_q^\square(p) - H_q(p))A\right| \le C\eta_q^2 e^{-cd_{q,p}} \|A\|_\infty.$$

For one colour this is the ℓ^1 norm bound of the row, by duality. In the same norm the two rows are bounded by $C\eta_q^2$, from the flat response bound on the torus and the corresponding bound on the localized datum ball. The constants are independent of volume and depth. Here we differentiate a real path with a fixed determining sequence in each problem. The argument uses the actual full read domain and gives no derivative estimate for changing history labels or for an old activity.

Let Γ_j^0 be the covariance of the complete flat fluctuation law on the free bonds of the level-$(j-1)$ torus in the step's contour gauge, at unit relative Wilson weight. In the actual frame coordinates the weight is τ_{j-1}. On curvature reads the actual flat covariance is τ_{j-1}^{-1} times the one at unit weight, by the constrained curvature form and the separate Gaussian integration along gauge directions. Consequently $\widehat{g}_{j-1}^2 \tau_{j-1}^{-1} = x_{j-1}^{-1}$ is the physical covariance factor multiplying the unit-weight slice. Use one colour and put

$$R_{j,p}^\square = H_{j-1}^\square(p)\mathsf{C}^0, \qquad R_{j,p} = H_{j-1}(p)\mathsf{C}^0.$$

Here C^0 is the flat pivot inclusion of the actual step. Its fixed finite range and bounded row sums preserve the bounds for the readout rows. All free bonds used by $R_{j,p}^\square$ lie in $\mathcal{S}_j$. Thus after removing the windows its covariance under the flat read-set marginal is exactly

$$\mathcal{C}_j^\square(p,p') = R_{j,p}^\square \Gamma_j^0 (R_{j,p'}^\square)^{\mathsf{T}}.$$

The whole-torus covariance is $\mathcal{C}_{(j)}(p,p') = R_{j,p}\Gamma_j^0(R_{j,p'})^{\mathsf{T}}$, by the identification of the curvature covariance in the contour and tree gauges. It is this whole-torus operator that is the orthogonal slice. Since $\|\Gamma_j^0\|_{2\to 2} \le C$, subtract the two products one row at a time and use the row bounds to obtain

$$\left|\mathcal{C}_j^\square(p,p') - \mathcal{C}_{(j)}(p,p')\right| \le C\eta_{j-1}^4 \left(e^{-cd_{j-1,p}} + e^{-cd_{j-1,p'}}\right). \tag{6.i}$$

The Gaussian used in both products is the same complete flat Gaussian. The comparison of an interacting box marginal with its flat restriction is the preceding separate estimate.

6.1.1.10. The error on the generating function disc. Let $d_* = \min_{p,j} d_{j-1,p}$ for the plaquettes and levels in the segment. Since $x_{j-1} \asymp x$ and $\eta_{j-1} = L^{-(j-1-k_0)}\eta_{k_0}$, the difference of the covariances of the two sums of independent slices is bounded entrywise by $Cx^{-1}\eta_{k_0}^4 e^{-cd_*}$. To estimate the determinant without a factor counting the total number of covariance entries, use the same standard Gaussian on the direct sum of the flat free bond spaces for both sums. For the localized read its row is

$$u_p = \bigoplus_{j=k_0+1}^{k_1} x_{j-1}^{-1/2} R_{j,p}^{\square} (\Gamma_j^0)^{1/2}.$$

Let v_p denote the row with $R_{j,p}$ in its place. The geometric sum of the squared row bounds gives

$$\|u_p\| + \|v_p\| \le Cx^{-1/2}\eta_{k_0}^2, \qquad \|u_p - v_p\| \le Cx^{-1/2}\eta_{k_0}^2 e^{-cd_*}.$$

For $z_p = \sum_a \lambda_a \phi_a(x(p))$, the matrices of the quadratic Gaussian exponents are $K_\square = \sum_p z_p u_p^{\mathsf{T}} u_p$ and $K = \sum_p z_p v_p^{\mathsf{T}} v_p$, with the factor $1/2$ outside the quadratic form. The trace norm of a rank-one term $u^{\mathsf{T}} v$ is $\|u\|\|v\|$. Hence

$$\|K_\square - K\|_1 \le Cx^{-1}\eta_{k_0}^4 e^{-cd_*} \sum_p |z_p|, \qquad \|K_\square\|_1 + \|K\|_1 \le Cx^{-1}\eta_{k_0}^4 \sum_p |z_p|.$$

For n profiles, the radii

$$|\lambda_a| \le \frac{c_* x}{n\mathsf{r}^4 p_0^2 \|\phi_a\|_\infty}$$

and the count $C\mathsf{r}^4\eta_{k_0}^{-4}$ of plaquettes per profile give $x^{-1}\eta_{k_0}^4 \sum_p |z_p| \le Cc_* p_0^{-2}$. Zero profiles may be omitted. Take c_* small enough that the two operator norms are at most $1/2$. The logarithms of the Gaussian generating functions are then given by the convergent trace series, each with the common colour factor $3/2$ for SU(2). Telescoping each difference of matrix powers and using the trace norm on its changed factor bounds the difference of these logarithms by

$$Cc_* p_0^{-2} e^{-cd_*}.$$

The same bound, with another fixed constant, holds for the generating functions. Cauchy's inequality multiplies this cost by the product of the inverse radii for the insertions being differentiated. For the actual test box and the later boxes, the native margins give $d_* \ge c_0 \min\{\mathsf{D}, \check{R}_{k_0}\} - C_0$. Taking $\mathsf{D} = A \log x$ in this range therefore makes the cost smaller than any prescribed inverse power of $\log x$ after a fixed number of differentiations. The comparison allows the exact whole-torus free projection and its ring sums to be used for the Gaussian target. The normalized nonlinear conditional comparison and the removal of the fluctuation windows enter separately.

For the free calculation, write F_j for the background curvature at level j, with covariance $G_j = C^{\mathrm{bg}}_{K,K-j}$. The nested projections give $F_{j-1} = F_j + Z_j$, where Z_j is independent of F_j and has covariance $\mathcal{C}_{(j)}$. The recursion is evaluated at the zero terminal field $F_{k_1} = 0$. In this Gaussian law F_j is the sum of the slices with $j < l \le k_1$, and its covariance is $G_j^\circ = G_j - G_{k_1}$. For one colour, the covariance of the two half-squares at p, q, conditional on F_j, is

$$\frac{1}{2}\mathcal{C}_{(j)}(p,q)^2 + F_j(p)F_j(q)\mathcal{C}_{(j)}(p,q).$$

The second term comes from the two terms linear in Z_j when the half-squares are expanded at F_j. Averaging over F_j with the terminal field fixed gives

$$\frac{1}{2}\left(G_{j-1}^\circ(p,q)^2 - G_j^\circ(p,q)^2\right).$$

Thus the free contributions telescope to $\frac{1}{2}(G_{k_0}-G_{k_1})(p,q)^2$. For separated supports $|G_{k_0}(p,q)|\le Ca_K^4\mathsf{d}^{-4}$, and the coarse covariance bound gives $|G_{k_1}(p,q)|\le CL^{-4k_1}$. The error in replacing the square by $G_{k_0}(p,q)^2$ includes a product of these two kernels and the square of the coarse kernel. Each support has at most $C(\mathsf{d}/a_K)^4$ plaquettes. After smearing, the error is therefore at most

$$C\left[(\hat{\mathsf{d}}L^{-\mathsf{n}})^4+(\hat{\mathsf{d}}L^{-\mathsf{n}})^8\right]\|f_1\|_\infty\|f_2\|_\infty.$$

This tends to zero at the stated choice of n.

Three facts are used here. The source arrives at level k_0 in the form $\zeta'_{k_0}\tilde{f}_i$ ((b)). Next, $a_p\approx\frac{1}{2}|F(p)|^2$, where $F(p)$, an element of the Lie algebra, is the plaquette angle at p of $U_{k_0,\square}(V)$ (the same angle is written Y_p in Thm. A(c)(5)). Finally, half-squares of Gaussian variables have covariance $\frac{1}{2}$(covariance)^2 for each colour. With the two interacting comparisons and the earlier reductions, we obtain

$$\left|\langle\mathcal{O}(f_1);\mathcal{O}(f_2)\rangle-\zeta_{k_0}'^2\,\tfrac{N^2-1}{2}\,x^{-2}\,\mathcal{K}_{K,s}(\tilde{f}_1,\tilde{f}_2)\right|\le o(1)\,x^{-2}\prod\|f_i\|_\infty.$$

The formula at level k_0, combined with (a) and (b), gives the same estimate for $\zeta_{k_0}'^2\langle X_1;X_2\rangle_{\mathsf{P}}$ in the average over $\mathfrak{P}$. *Positions.* The cumulants are invariant under the translations of $\Lambda_{K,\ell}$. A translation $v\in\Lambda_{s,\ell}$ carries blocks onto blocks, which finer translations do not do. Hence

$$C^{\mathrm{bg}}_{K,s}(p+v,q+v)=C^{\mathrm{bg}}_{K,s}(p,q),$$

$$\mathcal{K}_{K,s}(f,h)=\frac{1}{|\Lambda_{s,\ell}|}\sum_{v\in\Lambda_{s,\ell}}\mathcal{K}_{K,s}(f(\cdot-v),h(\cdot-v))\,:$$

since both sides of the law are invariant, it is enough to make the comparison in the average over such positions.

(d) *Wild histories.* For two points, the relevant event is that a large-field region touches the supports at the single level k_1 ((c1)). The weight of these histories is $\le C(M\check{R}_{k_1})^4e^{-cp_0(g_{k_1})}$, and no union over the levels is taken. In this bound the prefactor counts the sites of level k_1 in one cell of that level, and $O(1)$ cells touch the supports. For four points Thm. A(c)(5), the unclean histories are the ones that matter. At each level j of the segment of Thm. A(c)(5), $k_0-O(L\check{R}_{k_0})\le j\le k_0+r_4$, the number of cells of level j near the supports, that is, within $C\hat{\mathsf{d}}$ cells of level k_0, is $\le C\hat{\mathsf{d}}^4L^{4\max\{k_0-j,0\}}$; altogether there are $\le e^{CL\check{R}_{k_0}}$ such cells. A component on which $\mathbf{R}$ acts at a level j of the segment contains a component that is live at level $j-1$. The one-cell bounds of §§ 5.20 and 5.22 give $\tilde{\nu}(\mathfrak{c}\subset\mathcal{Z}_j)\le Ce^{-cp_0(g_j)}$, and the same bound for creation at step j. Moreover $p_0(g_j)\ge cp_0(g(\mathsf{d}))$, because $x_j\ge x^{1/2}$. Hence $\tilde{\nu}(\text{unclean})\le e^{CL\check{R}_{k_0}-cp_0(g(\mathsf{d}))}$, and this is small because $\mathfrak{p}_0\gg r$. Even here these one-cell bounds must hold uniformly in the volume (prolonged run, translation covariance up to the level, first moment of the prepaid end mark: §§ 5.20 and 5.22). The reason is that $T_{\ell_\star}$ contains $(\ell_\star/Ma_s)^4$ cubes of level k_0, and this number is unbounded.

What must be overcome. The natural size of a factor is $x^{-1}\|f_i\|_\infty$. The bound on X_i is larger by $p_0^2\,\hat{\mathsf{d}}^4=(\log x)^{C\mathfrak{p}_0}$, and the irrelevant terms are controlled by sup bounds only. This is the reason for $q\gg\mathfrak{p}_0$ and for the super-polynomial smallness in (a), (d). The effective action is that of Bałaban (Comm. Math. Phys. 109 (1987) 249; 122 (1989) 175, 355); the sources and the extraction are added to it.

The setting and the objects. In §6.1.1.1 the two-point law is stated for two bumps f,h whose size and mutual separation are both $\approx\mathsf{d}$. They are placed on a lattice of spacing $a_K\ll\mathsf{d}$ inside a volume of side $\ell\gg\mathsf{d}$. Isolating the scale d has two aspects. *From below*: $K-s(\mathsf{d})$ renormalisation steps integrate out the scales between a_K and d. In the leading term these scales survive only through two numbers of the run: $g(\mathsf{d})$, the coupling, and $\zeta_K(\mathsf{d})$, the normalisation. *From above*: comparing T_ℓ

with a single fixed torus eliminates the scales from d up to ℓ, together with the volume itself. This comparison costs $O(\mathsf{d}^2)$, which is of lower order than the main term $\approx (\ln \frac{1}{\mathsf{d}})^{-2}$. This part defines the two numbers, bounds them uniformly in the cutoff and in the bare coupling, and carries out the comparison of volumes. The Gaussian main term is extracted in §6.1.1.1, at the level $K - s(\mathsf{d})$ on the fixed torus. There the cumulant is written in terms of a law on resummed histories and block fields (the history-resummation part of the conditional-law hypothesis). Resummed histories are classes of histories that become equal once their entries inside healed components are deleted. The large-field operation $\mathbf{R}$ sums over the outcomes inside the components it heals, so an exponent is attached to such a class rather than to an individual history; write h for this history class.

6.1.1.11. The law passed to the limits.

Corollary 6.4 (Thm. A(c)(4))**.** Let S be a continuum limit, either on T_ℓ of Thm. A(a)(ii) or on $\mathbb{R}^4$ of Thm. A(a)(iii). Let $\mathsf{d} \le \mathsf{d}_0$, and let $(f,h) \in \mathfrak{T}_{\mathbb{E}}(\mathsf{d};\vartheta)$ be a pair of class C^1. Then the conclusion of Prop. 6.1(ii) is valid with

$$(1-\bar\varepsilon)\big(1-\bar\eta(\mathsf{d})\big)^4 \le 1+\eta \le (1+\bar\varepsilon)\big(1+\bar\eta(\mathsf{d})\big)^4,$$

in which $\bar\eta$ and $\bar\varepsilon_\ell$ denote the functions of Prop. 6.1. Their values lie in $[0,\frac13]$ and $[0,\frac12]$ respectively, and both tend to 0 with d. The quantity $\bar\eta(\mathsf{d})$ is a common bound for $|\zeta_K(\mathsf{d})-1|$ and for $|\frac{11N^2}{12\pi^2} g(\mathsf{d})^2 \ln\frac{1}{\mathsf{d}} - 1|$. On T_ℓ one has $\bar\varepsilon = \bar\varepsilon_\ell(\mathsf{d})$, and on $\mathbb{R}^4$ one has $\bar\varepsilon = \frac12$. Consequently $S_2(f,h) > 0$, and on $\mathbb{R}^4$ we have $\dim \mathcal{H}(S) \ge 2$. ■□

Proof outline. The argument follows from the uniformity in Prop. 6.1(i). In the lattice law, the only quantities that depend on (K,ℓ,β) are $\zeta_K(\mathsf{d}) = 1+\eta''$, $g(\mathsf{d})^2 \propto (1+\eta')/\ln(1/\mathsf{d})$ and ε. Therefore

$$\frac{S^T_{2;K,\ell,\beta}(f,h)\,(\ln(1/\mathsf{d}))^2}{\frac{3(N^2-1)}{\pi^4}(\frac{12\pi^2}{11N^2})^2 \mathcal{K}_{\mathrm{free}}(f,h)} = (1+\eta'')^2(1+\eta')^2(1+\varepsilon)$$

takes its value in the closed interval of the display above, for every datum. For fixed d, we have $K_j - s(\mathsf{d}) \ge n_0$ once j is large. Every pair on $\mathbb{R}^4$ is contained in some ball of radius $5\mathsf{d}$. Hence, once transported to T_{ℓ_j}, it belongs to the class and keeps the same free kernel. A closed condition is preserved in the limit. The bound on ε that clause (c)(4) records on $\mathbb{R}^4$ is the only one in Prop. 6.1(i) that is free of any side, namely $|\varepsilon| \le \frac12$.

The Hilbert space. Let f_{d} be a C^1 bump whose support is the ball $B(2\mathsf{d}e_4, \mathsf{d})$. Then $(\theta f_{\mathsf{d}}, f_{\mathsf{d}})$ is a test pair. Its shape ϑ_1 is fixed and does not depend on d, because the bumps are dilates of a single profile. When $\vartheta > \vartheta_1$, the pair may fail to belong to $\mathfrak{T}_{\mathbb{R}^4}(\mathsf{d};\vartheta)$. We take the ceiling $\gamma_W(\vartheta)$ smaller than the ceiling under which Prop. 6.1(i) is valid at the shape ϑ_1. That theorem is applied there with the witness depth $s_1(\cdot)$, which is built from the room constant $C_{W,0}$ of that shape, and with the thresholds of the same shape. Once d is below its threshold, the three inequalities $\zeta'_{K-s_1(\mathsf{d})} \ge \frac23$, $1+\varepsilon \ge \frac12$ and $g^{-2}_{K-s_1(\mathsf{d})} \le \bar x_{s_1(\mathsf{d})}$ bound $S^T_{2;K_j,\ell_j,\beta_j}(\theta f_{\mathsf{d}}, f_{\mathsf{d}})$ from below by a positive number that does not depend on j. Consequently § 6.16 gives

$$\big\|[(f_{\mathsf{d}})]\big\|^2 = \sigma_S(\theta f_{\mathsf{d}}, f_{\mathsf{d}}) = S_2(\theta f_{\mathsf{d}}, f_{\mathsf{d}}) > 0,$$
$$\langle \Omega, [(f_{\mathsf{d}})]\rangle = \sigma_S((f_{\mathsf{d}})) = 0.$$

Periodic Gibbs states. The expansion concerns torus measures. The law is carried over to these states by eq. 6.vi, under its common-normalizer and reference-comparison hypotheses. That lemma relies on the periodic-state domination in eq. 5.cdxxxiii, according to which the chessboard dominates the periodic Gibbs states. Precisely: let F be a function of a single board cell of side $\mathsf{l} = O(1)$, and on T_ℓ let the chessboard seminorm be denoted $\|\cdot\|_{\mathrm{ch},\ell}$. Then

$$|\nu(F)| \le \limsup_{\ell\to\infty} \|F\|_{\mathrm{ch},\ell}.$$

This is a separate lemma. It is not the chessboard estimate, whose subject is torus measures. Its proof, taken in the form that involves all mirror copies, combines four ingredients: the reflections of the cells leave ν invariant § 5.24 and appendix A.6; Jensen's inequality is used together with the Gibbs property; the boundary condition is changed at the cost of a surface term, which is weighed against a volume; and finally the seminorm enters.

Ergodic components. At (K_j, β_j), each periodic Gibbs state obeys the law. A closed condition that all of these states satisfy is inherited by the components § 7.7. This yields Thm. B(3)(ii): for a volume-first limit, each of its ergodic components satisfies the law in the form it takes on $\mathbb{R}^4$, with d_0 and $\bar\eta$ unchanged.

6.2. **Covariance bounds for interacting extraction.** The finite insertion, renewed pointing, window formation and linear bootstrap sections derive the ordinary regular first response under their explicit unmarked, background, domain and slope inputs. They retain the potential normalization through local integration and give the near bound $C\delta^2 s$ on complete nonwrapping fields of size δ. The remainder below must also include the separately bounded marked, remote and boundary contributions. None of these estimates proves an interacting Gaussian law.

6.2.1. *Covariance bookkeeping with the retained source normalization.* A source-disc bound alone cannot replace the potential estimate. Indeed $H(z,B) = (z/\rho)(B/\alpha)^4$ is bounded by one on its product unit balls, but its source derivative at $B = \epsilon$ is $\rho^{-1}(\epsilon/\alpha)^4$. Relative to $\alpha^2(\epsilon/\alpha)^3$, this is $x(\log x)^{p-3q}/\rho$ when $\alpha = x^{-1/2}(\log x)^q$ and $\epsilon = x^{-1/2}(\log x)^p$; it diverges at fixed ρ. The finite construction supplies its response by differentiating the inserted potential, with the stated unmarked hypotheses.

Here is the corresponding covariance bookkeeping. Let λ be any probability measure, put $n_i = \|f_i\|_\infty$, fix $p > 0$, and suppose, uniformly in $x \to \infty$,

$$\begin{aligned} \|\mathsf{O}_i\|_\infty &\le C x^{-1} r^4 (\log x)^{2p} n_i, \\ \|\mathsf{I}_i\|_\infty &\le C x^{-1} r^4 [(\log x)^{3p-q} + x^{-a}] n_i, \qquad a > 0, \\ r &\le C_r (\log x)^{2p}, \qquad q > 21p. \end{aligned} \tag{6.ii}$$

Then

$$\begin{aligned} &|\operatorname{Cov}_\lambda(\mathsf{O}_1, \mathsf{I}_2)| + |\operatorname{Cov}_\lambda(\mathsf{I}_1, \mathsf{O}_2)| + |\operatorname{Cov}_\lambda(\mathsf{I}_1, \mathsf{I}_2)| \\ &\qquad \le C' x^{-2} \big[(\log x)^{21p-q} + (\log x)^{18p} x^{-a}\big] n_1 n_2 = o(x^{-2} n_1 n_2). \end{aligned} \tag{6.iii}$$

To prove it use $|\operatorname{Cov}(A,B)| \le 2\|A\|_\infty \|B\|_\infty$. The product of the two support counts costs $r^8 \le C(\log x)^{16p}$, and the a priori insertion costs another $(\log x)^{2p}$. For large x the bracket defining I_i is at most one, so its square is absorbed by itself. This gives eq. 6.iii. The numerical inequality $q > 21p$ is a sufficient bound for this particular sup-norm step; it does not claim to be the optimal requirement for the full extraction.

6.2.2. *A scalar transfer estimate with a genuinely common normalizer.* Let ρ, τ be two probability measures with real bounded observables $\mathcal{O}(f)$ linear in a real compactly supported Lipschitz function f. They may be measures on different configuration spaces. Write

$$D(f,h) = \operatorname{Cov}_\rho(\mathcal{O}(f), \mathcal{O}(h)) - \operatorname{Cov}_\tau(\mathcal{O}(f), \mathcal{O}(h)).$$

Assume that D is invariant under joint translations by $a\mathbb{Z}^4$. Set

$$\|f\|_\sharp = \max(\|f\|_\infty, c_M \operatorname{Lip} f)$$

with c_M fixed.

Suppose there are $r_0 > 0$ and $Q \geq 1$ such that, for every pair F_1, F_2 supported in one common unit ball, there is one holomorphic function $E(z_1, z_2)$, $E(0) = 0$, serving both measures, for which

$$\left| e^{-E(z)} \omega\Big(e^{z_1 \mathcal{O}(F_1) + z_2 \mathcal{O}(F_2)} \Big) \right| \leq Q, \qquad \omega \in \{\rho, \tau\}, \tag{6.iv}$$

on $|z_1| \|F_1\|_\sharp + |z_2| \|F_2\|_\sharp < r_0$. The constants are uniform in the ball position and in the measures. The tests in this hypothesis may overlap and have either sign.

Put $c_i = \|F_i\|_\sharp / r_0$ and denote the normalized holomorphic function in eq. 6.iv by h_ω. It has $h_\omega(0) = 1$. Schwarz's lemma along rays gives $|h_\omega(z) - 1| \leq (Q+1) \sum_i c_i |z_i|$. On the bidisc with radii $[4(Q+1)c_i]^{-1}$ its principal logarithm has modulus at most $\log 2$. Thus Cauchy's formula gives

$$|D(F_1, F_2)| \leq 32 \log 2 \, (Q+1)^2 r_0^{-2} \|F_1\|_\sharp \|F_2\|_\sharp. \tag{6.v}$$

The derivatives of E cancel because it is the same function for both measures. If an entry is zero the conclusion is immediate. No global zero-free statement for the original generating functions is needed.

Suppose now $a \leq d$ is sufficiently small, and f, h have supports in one common ball of radius $5d$, with $\mathrm{Lip}\, f \leq \|f\|_\infty / (\vartheta d)$ and the analogous condition for h. Choose a lattice multiple $r' \in [5d, 10d)$ and $N \geq c d^{-4}$ translates of that ball, with centers in $4r'\mathbb{Z}^4$, all lying inside a common unit ball. For each choice of signs $\varepsilon_v = \pm 1$ let $F^\varepsilon = \sum_v \varepsilon_v \tau_v f$ and $H^\varepsilon = \sum_v \varepsilon_v \tau_v h$. The translated balls are disjoint. Since the functions vanish on their ball boundaries, these signed sums do not increase either supremum or Lipschitz norm. Independent signs with the same sign used in the two arguments give

$$\mathbb{E}_\varepsilon D(F^\varepsilon, H^\varepsilon) = N D(f, h).$$

Apply eq. 6.v and divide by N. The result is

$$|D(f, h)| \leq C(Q, r_0, c_M) \vartheta^{-2} d^2 \|f\|_\infty \|h\|_\infty. \tag{6.vi}$$

The exponent is $2 = 4 - 2$: the number of copies gains four powers and the two Lipschitz norms lose one power each.

If a reference law has a main term bounded below by $c_\vartheta x^{-2} \|f\|_\infty \|h\|_\infty$, its relative transfer error is at most $C_\vartheta d^2 x^2$. In the actual short-distance shape class, each nonnegative entry also has the explicit mass lower bound $\int f \geq \vartheta d^4 \|f\|_\infty$, and the two supports are at distance between d and $6d$. These requirements give $\iint f(x) h(y) |x - y|^{-8} \, dx \, dy \geq 10^{-8} \vartheta^2 \|f\|_\infty \|h\|_\infty$. The mass requirement is additional to the Lipschitz bound in eq. 6.vi. At a witness depth with $x \leq \bar{x}_s = O(s)$ and $d < L C_W(s) L^{-s}$, where C_W is polylogarithmic in s, this tends to zero uniformly. For a fixed $\vartheta = 1/12000$ all constants remain finite; their dependence on that fixed shape may affect the permitted coupling and distance thresholds.

The common-normalizer hypothesis in eq. 6.iv is not a consequence of having unrelated bounded normalizers for the two measures. There are two different ways of supplying it. If the scalar stability construction already provides one common cell normalizer for every periodic infinite-volume Gibbs state at the same datum, then eq. 6.iv holds for any two such states. This includes a reference state obtained by taking finite-torus limits, provided its Gaussian estimate was uniform along arbitrarily large tori for each fixed cutoff and pair. The source $z_1 F_1 + z_2 F_2$ is a single cell source, even when the supports overlap. This route needs no comparison with a fixed finite torus.

If, instead, the reference Gaussian estimate has only been proved on one prescribed finite torus, a comparison of that torus with the infinite-volume states remains necessary. Compatible local energies and vacuum-density/floor bounds give one scalar chessboard route to eq. 6.iv. Bounds valid on each torus with a distance threshold tending to zero as its side grows do not by themselves furnish an infinite reference with the needed fixed-pair estimate. In either route, a typed Ward insertion estimate is not needed for eq. 6.v–eq. 6.vi.

A local companion criterion for vacuum-density compatibility. For the finite-reference route just described, the following criterion can remove a separate vacuum-pressure comparison assumption. It is not needed for comparison of infinite-volume states when their common cell normalizer is already available. It does not follow from upper stability and a partition floor alone. Fix $L > 1$ and a cutoff K, and put $a_j = L^{j-K}$ for $0 \le j \le K$. Take compatible side lengths ℓ for which ℓ/a_j is integral. Suppose the vacuum constant has the form

$$E_{\ell,K} = \sum_{j=0}^{K} \left[(\ell/a_j)^4 c_{j,K} + \sum_{z \in (a_j\mathbb{Z}/\ell\mathbb{Z})^4} \sum_{D \in \mathcal{D}_{\ell,j}(z)} v_{\ell,j}(D,z) \right]. \tag{6.vii}$$

The numbers $c_{j,K}$, the coupling sequence and every auxiliary choice are the same for all ℓ. There is a translation-covariant infinite companion $v_{\infty,j}$ and an integer length $m(D) \ge 0$. For both families, assume that the number of domains of length m at a root is at most $C_D e^{\kappa_D m}$ and $|v_{\ell,j}(D,z)|, |v_{\infty,j}(D,z)| \le C_E e^{-\kappa_E m}$ with $\kappa_E > \kappa_D$. The constants are uniform in j, K, ℓ. Assume that rooted domains with $m < \ell/(C_0 a_j)$ correspond bijectively to companion domains, with equal energy values. This is an explicit locality and nonwrapping assumption, with C_0 fixed. It is stronger than simply asserting that the two models use the same formula for their energies.

Absolute convergence defines $\bar{v}_j = \sum_{D \in \mathcal{D}_{\infty,j}(0)} v_{\infty,j}(D,0)$ and $A_K = \sum_{j=0}^{K} a_j^{-4}(c_{j,K} + \bar{v}_j)$. At each root all terms below the stated threshold cancel in the difference from the companion. Sum the two tails of the geometric series with rate $\delta = \kappa_E - \kappa_D > 0$. Division by the physical volume therefore gives

$$\left| \ell^{-4} E_{\ell,K} - A_K \right| \le C \sum_{j=0}^{K} a_j^{-4} e^{-c\ell/a_j}. \tag{6.viii}$$

For every fixed $\ell_0 > 0$ and $\ell \ge \ell_0$, this is bounded by $C_{\ell_0} e^{-c\ell/2}$, independently of K. Indeed, with $b = K - j$,

$$\sum_{b \ge 0} L^{4b} e^{-c\ell L^b} \le e^{-c\ell/2} \sum_{b \ge 0} L^{4b} e^{-(c\ell_0/2)L^b} \le C_{\ell_0} e^{-c\ell/2}. \tag{6.ix}$$

Thus two compatible tori obey the same bound with $2C_{\ell_0} e^{-c \min(\ell,\ell')/2}$. The divergent common number A_K need not converge as the cutoff is removed; it cancels exactly in the comparison.

In a localized source argument, equality of the corresponding nonwrapping source energies also supplies the same interior-cell counterterm for all tori. Bounds on the energies crossing the cell faces and the appropriate partition floor are still needed to obtain eq. 6.iv. This lemma addresses its vacuum-density datum only. If the coupling sequence or local normalizer numbers differ between tori, or if nonwrapping compatibility has not been established for the actual formation rule, eq. 6.viii has not been proved for that construction.

A common source normalizer from the reference torus. Fix one first-passage datum and let $\ell_\star$ be the least compatible side at its reference coupling. Choose board cells of side $\mathsf{l}_c = L^m$ such that a unit ball can be placed in a cell with a fixed positive face clearance, and $\ell_\star/\mathsf{l}_c$ is even. This is possible with a fixed m for the small reference couplings under consideration. Each compatible side is an integer multiple of $\ell_\star$. Translate the two tests jointly by a bare lattice vector to the interior of the designated cell. Write $w_z = z_1 F_1 + z_2 F_2$ and $N_\ell = (\ell/\mathsf{l}_c)^4$. Disseminate this source by reflection and conjugation, using $\bar{z}$ in the odd cells, and call the resulting source W_z. Its supports have the same face clearance in each cell. The dissemination of $e^{\mathcal{O}(w_z)}$ is $e^{\mathcal{O}(W_z)}$; plaquettes in the support have all their corners in a single cell. Joining the reflected profiles across faces leaves the Lipschitz bound unchanged since each profile vanishes near the faces. Treating even and odd copies separately gives $\|W_z\|_\flat \le 2 \sum_i |z_i| \|F_i\|_\sharp$. In particular, $\sum_i |z_i| \|F_i\|_\sharp < \varrho$ is within the source domain of Prop. 5.63.

The numerator of the chessboard seminorm is nonnegative, and

$$\|e^{\mathcal{O}(w_z)}\|_{\mathrm{ch},\ell} = \left(\frac{Z_\ell(W_z)}{Z_\ell(0)}\right)^{1/N_\ell}, \qquad Z_\ell(W_z) \le Z_{\ell_\star}(W_z)^{(\ell/\ell_\star)^4}.$$

To see the second inequality, vary one side at a time, keeping the other three fixed. Across a cell face there is no source. After integrating the crossing bonds the Wilson transfer factor is the product of the gauge-invariant projection and the convolution with the product of the one-bond class functions $c(u) = e^{-\beta(1-\mathrm{tr}(u)/2)}$. These operators commute. The character coefficients of c are nonnegative: expand $e^{(\beta/2)\chi_{1/2}}$ in powers and decompose each tensor power of the defining representation. Hence the crossing factor is positive, with self-adjoint square root S. In a cross-section there are finitely many bonds, and the convolution is trace class since the nonnegative character series at the identity converges. The intervening slab operator with the internal source has the form $A = SBS$, and its mirror copy is A^*. The trace of the shorter period is $\mathrm{Tr}\, T$, where T is the appropriate integer power of AA^*. Repeating the period b times gives $\mathrm{Tr}\, T^b$, at most $(\mathrm{Tr}\, T)^b$ by positivity. Applying this in the four directions proves the comparison. The intermediate rectangular tori here use the same Wilson integrals and need no renormalisation construction.

The actual vacuum constants have the decomposition

$$E_{\ell,K} = \sum_{j<K} \left[\mathsf{E}_{\mathrm{I}}^{(j)} + \sum_y \sum_{X \ni y} E^{(j+1)}(X, \mathbf{1}, y) + \sum_X R^{(j+1)}(X, \mathbf{1}) \right].$$

In $\mathsf{E}_{\mathrm{I}}^{(j)}$, the Haar and Gaussian factor is one scalar per nonpivot bond and the gauge-fixing factor is one scalar per cell of the next lattice. The common coupling sequence and fixed choice of gauges give the same two scalars for the two tori, and both counts per unit volume are the same. Point the remainder term by assigning $R^{(j+1)}(X, \mathbf{1})/|X|$ to each root of X. A domain whose complete window lifts to a cube of side at most $\min(\ell, \ell_\star)/4$ has the same rooted value on either torus by the common companion rule of § 5.2.2. The density of these terms agrees, since the rooted family has the periods of the smaller side. For the other domains the length at depth u is at least $c\ell_\star L^u/M - C$. Summing over their roots and then over u gives

$$\left| E_{\ell,K}/\ell^4 - E_{\ell_\star,K}/\ell_\star^4 \right| \le C \sum_{u \ge 0} L^{4u} e^{-c\ell_\star L^u/M}.$$

Thus the common companion comparison applies to the vacuum constant in the sourced construction. Neither vacuum density need have a cutoff-independent limit.

Use upper stability of Prop. 5.63 on $T_{\ell_\star}$ and the partition floor on T_ℓ. Writing $\mathcal{E}_\star(W_z) = \sum_{j,X} e_j(X; W_z)$ for the reference source energy, the preceding estimates give

$$\|e^{\mathcal{O}(w_z)}\|_{\mathrm{ch},\ell} \le \exp\left[N_{\ell_\star}^{-1} \,\mathrm{Re}\, \mathcal{E}_\star(W_z) + C_g |_c^4 \right].$$

Define $E^\circ(z)$ on the reference torus as the average over its cells of the sums of $e_j(X; \cdot)$ with the complete source footprint contained in one open cell. This includes the barycentres of all bare plaquettes with a corner in $X^{\sim 1}$. Evaluate the energy on that cell's reflected source. In an odd cell, also conjugate the answer. Such terms have the form $\overline{h(\bar{z})}$ with h holomorphic, so E° is holomorphic and $E^\circ(0) = 0$. Its real part is exactly the corresponding interior portion of $N_{\ell_\star}^{-1} \,\mathrm{Re}\, \mathcal{E}_\star(W_z)$. This identification uses locality on the complete source footprint and compares the same energy function in each fixed domain.

A nonzero omitted term must meet a cell face and reach a plaquette whose barycentre is in a source support. The face clearance implies a lower bound $[cL^u/M - C]_+$ on its length at depth u, with the additional bare reach included in C. There are at most $C(1 + L^u/M)^4$ possible roots per cell near a support. The length entropy is smaller than the rate κ_e of Prop. 5.63. Thus the omitted

sum per cell is bounded independently of K by

$$C\sum_{u\geq 0}(1+L^u/M)^4\exp\big(-(\kappa_e-\kappa_{\mathcal{D}})[cL^u/M-C]_+\big).$$

The same E° now gives eq. 6.iv for the reference torus and every compatible torus, by the one-cell chessboard inequality. It gives that estimate for every periodic Gibbs state of the theorem by eq. 5.cdxxxiii. The constants are uniform in the datum. This construction compares with the prescribed finite reference side; it does not require taking a subsequential torus limit.

By Prop. A.11 and the composition of a site reflection with the adjacent link reflection, the states in the theorem are invariant under bare lattice translations. Therefore eq. 6.vi applies to their differences from the reference. Its error is $C_{g,\vartheta}\mathsf{d}^2\|f_1\|_\infty\|f_2\|_\infty$; relative to the nonnegative reference main term in the stated shape class, this is bounded by $C_{g,\vartheta}\mathsf{d}^2x^2$. It tends uniformly to zero by the witness depth bounds. The comparison extends the reference estimate whenever the physical source remainder and the reference witness covariance have the estimates used above.

6.3. **The conditional law and its connected errors.** The short-distance coefficient concerns an interacting probability law. Comparing quadratic kernels does not identify that law. We specify the conditional measure and its complete exponent, then derive the boundary terms, connected errors and exterior average. Applying these identities requires the run-window identification and uniform estimates stated at the end. The primary route is the resummed clean run; an averaging-fibre transfer is a distinct alternative.

Identify the measure before estimating its density. Fix the exterior sigma-field of the run window, with value e. The identity concerns that specified sigma-field and the resummed positive term. A finer history or interpolation resolution need not be positive or carry the same conditional measure.

In an admitted real pivot chart write the raw logarithms as $a=(p,u)$. Suppose the constraints $q(p,u)=0$ have invertible D_pq and solution $p=\varphi(u)$. If the original coordinate density is $w(p,u)$, the constrained density is

$$w(\varphi(u),u)|\det D_pq(\varphi(u),u)|^{-1}\,du. \tag{6.x}$$

This is the change of variables from (p,u) to $(q(p,u),u)$, followed by evaluation of the constraint delta function. Haar factors, delta normalizations and the exact gauge-quotient density belong in w. A gauge-fixing factor requires the separate identity inserting it.

Under a canonical linear rescaling $u=gCy$ retain its determinant. For a variable-dependent map use its full Jacobian. The domain is the image of the actual integration set; a product window is an identity to establish.

On a positive component the complete conditional density may be written

$$d\nu_e(y)=Z_e^{-1}1_{D_e}(y)\exp\{-\tfrac12 y^{\mathsf T}Q_ey-\ell_e^{\mathsf T}y+P_e(y)\}\,dy. \tag{6.xi}$$

The actual extraction rule fixes Q_e. The complete P_e contains old activities, nonlinear action, coarea and Haar logarithms, boundary and stored terms, and healed-origin remainders. A factor outside this exponential is carried in every numerator, or absorbed where its logarithm exists. Zeros require a domain or a decomposition.

An arbitrary choice of Q_e would make eq. 6.xi merely a rewriting. The extraction rule, sigma-field, domain, normalizer and observable numerators all belong to the required identification. For the exact calculus below assume a bounded piecewise smooth domain and a density in $C^1(\overline{D})$, or in $W^{1,1}(D)$ with the indicated integrable traces and integration-by-parts identity. All displayed force integrals are required to be integrable. A rectangle suffices. Unbounded domains require an exhaustion and justified boundary limits.

The complete Hessian and the exterior force. Set

$$V_e = \tfrac{1}{2} y^{\mathsf{T}} Q_e y + \ell_e^{\mathsf{T}} y - P_e(y), \qquad r_e = \nabla P_e - \ell_e. \tag{6.xii}$$

The Hessian is $Q_e - P_e''$. The old-activity theorem controls its stated old-origin sum, not every other term in P_e. Relative to a specified reference the exact force difference is

$$\nabla V_e - \nabla V_0 = (Q_e - Q_0)y + (\ell_e - \ell_0) - \nabla(P_e - P_0). \tag{6.xiii}$$

In the actual run this includes the marginal Schur force $Q^{\mathrm{sc}} y$, the integrated exterior force $Q^e_{IO} y_O$, the newly stored exterior force ℓ^e_E, the interior precision discrepancy and the interaction derivative. Let $\mathcal{B}_{\mathrm{ext}}$ consist of $O \cup E$ and the complement of the padded common region on which the two operator geometries and coordinate masks agree. The force bound required at an interior coordinate is

$$|f_b| \le C b_j e^{-\mu d(b, \mathcal{B}_{\mathrm{ext}})} \tag{6.xiv}$$

uniformly in the admitted exterior data.

6.3.0.1. The determining data and the response to the free box. The restriction identity eq. 3.cccxciii identifies the box background on its induced datum. In the step from j to $j+1$, fixing V_{j+1} and the exterior free fluctuations still leaves the retained lower determining data as arguments of the background and the conditional precision.

One part of those arguments drops out exactly. Let E_1 be the fine bonds incident to Ω_1, E_0 their complement, and $C_0 \subset E_0$ the bonds in a plaquette touching E_1. The bare datum fixes all of E_0. Enlarge C_0 by the portions of E_0 read by the positive-level double blocks or the fixed axial gauge stencil. In the outward-row convention the additional averaging reads come from the level-one outward rows, within the reach of a level-one double block. Fix the nest and axial frame. If two data agree at every positive level and on this enlarged set, the constraints on E_1 and their chosen gauge slice coincide. For any field on that slice, the Wilson actions agree on plaquettes touching E_1, and the other plaquettes give a scalar difference independent of the field on E_1. It follows that the constrained axial solve and the constrained Wilson Hessian on E_1 agree exactly. The scalar cancels in normalized box expectations. In this argument the deep bare fields may be rough. The other terms of the density have their own reads.

On the native small-field support the retained rows below j have the zone and interface plaquette bounds of the determining nest. At the top level, start with the bound $2\varepsilon_j$ on V_j. Replacing an interior bond by the average from the next step changes its factor by at most $c'\varepsilon_j$, with the same bound in the reversed orientation. Telescoping the product of four unitary factors gives at most $4c'\varepsilon_j$ in additional plaquette error. This also covers mixed top plaquettes at the cut. At the action collar in zone zero, the native small-field guard gives the bare bound ε_0. These are bounds on the actual base datum before varying the free box.

For a free box variation about one base datum, extend its coordinate y by zero on the other fluctuation bonds, writing $\widetilde{y}$ for the extension. In the native top rows the variation is multiplication by $e^{iB(y)}$, where

$$B(y) = g_j \mathbf{C}\widetilde{y} - \mathbf{h}\,\widetilde{D}(g_j \mathbf{C}\widetilde{y}).$$

Here $\mathbf{C}$ is the linearized constraint lift, $\mathbf{h}$ the corridor operator and $\widetilde{D}$ the analytic correction vanishing to second order. On a tube of size Y, its quadratic bound gives $\|B\|_\infty \le 2 g_j c_C Y$, below the datum radius by the native ceiling. For a unit direction in one bond b, the derivative of B is $O(g_j)$. The linear lift reaches only b and the pivots of its incident block pairs. The corridor correction reads those block pairs and their adjacent corridors. Consequently this derivative reaches at most $(4d{+}2)^2$ top bonds within $4L{+}2$ input-level units of b. The clean guard puts both endpoints of every bond in that support inside Ω_{j+1}, including the pivots. All lower rows are left fixed.

On the admitted retained datum let $\mathcal{H}(B)$ be the analytic response at its fixed base U_0. For real parameters the solution with the varied top rows is gauge equivalent to $e^{i\eta\mathcal{H}(B(y))}U_0$. The finite support of $D_b B$ makes the chain rule a sum over the bounded list of top rows. The derivative

bound of the retained response applies on these carriers. Use its comparison of distances to the top rows and identify the derivative in its plaquette estimate with the covariant difference at U_0. This gives, for $H(y) = \mathcal{H}(B(y))$,

$$\eta|D_b H(y)(x)| \le C g_j L^{-n(x)} E(x,b), \qquad \eta^2 |D_{U_0} D_b H(y)(p)| \le C g_j L^{-2n(x)} E(x,b).$$

Here $n(x)$ is the retained zone and D_{U_0} is the covariant lattice difference at the plaquette p based at x. The response weight is $E(x,b) = \min\{1, e^{-c\rho(x,b)+c_1}\}$, where ρ is the retained response distance with the top spacing as unit. The constant c_1 allows for the displacement of the rows of $D_b B$ from b. On a smaller tube the two orders of Cauchy differentiation give a mixed bound with the minimum of the two weights and the inverse tube margin. This constructs the read and its derivatives on a fixed labelled nest with admitted restricted data and response. The comparison of masks or of positive-level data across different exteriors still uses their matching estimates.

6.3.0.2. Terms outside the box that read the background. The ordinary pre-strip chart also allows nonzero fixed exterior fluctuations. In that chart let z be the other original free coordinates. The native real windows give $\|z\|_\infty \le C b_j$. The complete level-j datum uses the multiplier $e^{iB_{\mathrm{full}}(y,z)}$, with the same lift and nonlinear correction as above, applied to the full vector (y,z). Keep the outgoing target and all lower data fixed. Apply the bound for the lift and its correction with $R = \max(Y, \|z\|_\infty)$. On the joint chart the smallness of $g_j c_C R$ gives $\|B_{\mathrm{full}}(y,z)\|_\infty \le 2 g_j c_C R$ and $\|D_y B_{\mathrm{full}}\|_{\infty\to\infty} \le 2 g_j c_C$. The individual derivative D_b uses the same rows within $4L+2$ of b. These statements concern the original free slots, including an exterior slot once its identification with an original free coordinate has been made.

Choose y_* on the supported real fibre for the fixed z. Use the actual datum there as the base. The relative logarithm for a variation is

$$A_{z,*}(y) = \frac{1}{i} \log\Big(e^{iB_{\mathrm{full}}(y,z)} e^{-iB_{\mathrm{full}}(y_*,z)} \Big).$$

It is zero at y_*. On the fixed exponential and logarithm balls its norm is at most $C_L g_j Y$ and its derivative in one unit bond direction is at most $C_L g_j$. For the size bound use the segment from y_* to y; for the derivative use the fixed second factor of the relative product. Outside the full top carriers of I the product is the identity. The native response theorem is applied at the real regular datum on the supported fibre, with $A_{z,*}$ in its input ball. Its chain rule gives the same bond and plaquette estimates as above, with a fixed change of constants. If the base is needed at zero, the same segment varies only the clean top carriers. Telescoping the four factors of each affected top plaquette enlarges its real regularity bound by $C_L g_j \|y_*\|_\infty$. The lower interface and bare collar reads are unchanged when the full carriers are in the padded top interior.

For the ordinary strip substitution this identification is exact at fixed retained data. The global centre is determined by the outgoing block field, the level-j field off the incident stock of Ω_{j+1}, and the lower determining rows. The joined local centre uses the outgoing rows and the old retained rows of the output label. The latter are fixed when the free box is varied. In particular the old level-j determining member used here has both endpoints outside the released region. In the join for the strip, the inner cut is in the top layer and its new rows lift the fixed outgoing rows. The outer cut is in the previous layer outside Ω_{j+1} and lifts the fixed old rows there. The averaged local strip field is the one in the axial frame of this joined set. Neither centre reads the shifted strip nonpivots. Thus both centres, and their relative shift on a strip bond, are fixed throughout this variation. The real cutoff in the inverse strip map is a function of that bond's stored coordinate. Consequently a held ordinary post-strip nonpivot yields a fixed pre-strip nonpivot, including on the cutoff's transition shell. The Jacobian of that held slot is also fixed. The box coordinates themselves are unchanged on the ordinary passing mask, and the pivots are recomputed at the same target. The ordinary response calculation therefore applies to these conditional slots.

At the top preparatory stage of this same output level the two centres stay fixed under the original clean-box variation as well. The stage member contains the old Ω_{j+1}. Its old level-j determining

rows are the rows outside that member, with neither endpoint inside it. Thus they miss the box variation and its complete pivot support inside the old Ω_{j+1}. Keep the added coarse targets and exterior data fixed. The joined background uses the lift of the fixed output field on the old inner region and the retained datum on the outer region. The two stage centres and the bondwise cutoff translation are then fixed when the original box varies. At a held real stage slot this again fixes its inverse coordinate. A variation of the released collar variables themselves must use their stage chart.

There is also an exact fixed-coordinate case for the healed reference draw. If its component and full retained exterior rows are outside the padded box read, fix those rows in the exterior disintegration. The basic centre and the normalized reference law depend only on that retained exterior of the component. With its relative reference draw held fixed, the restored physical field $V'V_\Lambda$ is then fixed, and the reference density is scalar in y. The previous box variables have already been integrated in this kernel. The completed global background and the main-step density subsequently read the replacement rows, and their comparison uses those actual reads.

Consider a term f whose remaining dependence on y is its gauge-invariant evaluation on the responding background, restricted to a bond set X_f. Its other arguments are held fixed. The response estimates give size $C_H\Theta(x)$ in each of the bond and plaquette units above, where $\Theta(x) = g_j Y \sum_{b\in I} E(x,b)$ for a tube of size Y. Integrate from the base, where the response vanishes, along the segment to y. For the term's analytic norm divide the two units by their radii $\rho_f^{(1)}$ and $\rho_f^{(2)}$. Write $r_f^{-1} = \max_i(\rho_f^{(i)})^{-1}$. If $C_H r_f^{-1} \max_{x\in V(X_f)} \Theta(x) \le 1/2$, the restricted field lies in the half ball for that norm. A term bounded by M_f on the full ball has the continuation $\varphi_f(y) = f(W^{(y)}|_{X_f})$, where $W^{(y)} = e^{i\eta H(y)}U_0$ in the response gauge at its base. Apply Cauchy's estimate in the direction of the response derivative inside the remaining half ball. With $w_f = g_j M_f/r_f$, this gives

$$|D_b\varphi_f(y)| \le 2C_H w_f \max_{x\in V(X_f)} E(x,b).$$

On a smaller tube with margin r the mixed derivative has the bound $2C_H w_f/r$ times the smaller of the two endpoint weights for b, b'.

Use the scaled path distance in E. A path from zone n to I crosses each intermediate zone. If those zones have width at least M in their own units, each contributes at least M to the scaled distance. Split the response exponential with rates $\mu = \nu$ equal to half the rate in E. The count and the ordinary top-scale distance give, for a level-j cell c,

$$E(x,b) \le Ce^{-\nu d_j(c,b)} e^{-\mu M(j-1-n)_+}, \qquad x \in c \cap Z_n.$$

Select a maximizing endpoint of each X_f. Suppose for any such choice the total w_f in one cell and zone is at most $C(1+j-n)^q L^{4(j-n)}$. The age sum is finite by $L^4 e^{-\mu M} \le 1/2$. If all the reads are at distance at least $D_{\mathrm{far}} \ge 1$ from I in level-j units, the cell sum is at most $CD_{\mathrm{far}}^{d-1} e^{-\nu D_{\mathrm{far}}}$. This bounds the sum of the absolute derivatives at each $b \in I$. It gives an entrywise mixed derivative bound after division by the tube margin.

For the uncompensated frozen coupling, the far term is the sum of Wilson plaquette terms with coefficients $g_j(x_p)^{-2} - g_j^{-2}$, fixed with the exterior and bounded by $C(1+j-n(p))$. Their nonzero plaquette reads are outside the collar of width D_{far}. Plaquettes entirely in the fixed deep bare region have zero derivative. At each responding plaquette the source trace estimate gives $Cg_j(\bar\varepsilon + \theta_*)L^{-4n(p)}E(x_p,b)$ before multiplying by the coefficient. Here $\bar\varepsilon$ bounds the base curvature in its zone units and θ_* is the native trace threshold for Θ on the lag support. On that support the unweighted top distance gives $\Theta(x) \le Cg_j Y D_{\mathrm{far}}^{d-1} e^{-2\nu D_{\mathrm{far}}}$. Use the collar width for which this is at most θ_*. The trace derivative gains one factor of the curvature and one from its variation. There are at most CL^{4j} plaquettes in a level-j cell, so the same cell and age sums give the force bound

$$Cg_j(\bar\varepsilon + \theta_*) D_{\mathrm{far}}^{d-1} e^{-\nu D_{\mathrm{far}}}.$$

For the mixed Hessian of the lag, the plaquette trace bound uses the weight

$$r^{-1}\min\{E(x_p,b),E(x_p,b')\}.$$

In the cell sum the spatial exponential uses the larger of the two distances from c to b,b'. This maximum is at least $D_{\mathrm{far}}-C_d$, at least $(d_j(b,b')-C_d)/2$, and at least $d_j(c,b)$. Use one third of the exponential for each of these three bounds. The last bound sums over cells, and the zone sum is unchanged. Thus the lag Hessian entries are bounded by

$$Cr^{-1}g_j(\bar\varepsilon+\theta_*)e^{-\nu D_{\mathrm{far}}/3}e^{-\nu d_j(b,b')/6}.$$

The weighted row and column sums have the same small prefactor at any smaller fixed rate. At fixed exterior either force estimate bounds the oscillation of the corresponding exponent on the product window by its per-bond bound times $C|I|b_j$, by integrating along a segment in the window. The ratio of the two normalized real densities with and without these terms is between the exponentials of minus and plus this oscillation. Fixed spectator arguments require a compatible gauge comparison of the partial read. A term whose current or stored-colour arguments vary with y must include their derivatives as well.

6.3.0.3. The exterior terms on a matched chart. Fix the retained datum and the coordinate frame of the read set. Write I for the integrated bonds in the box and O for the other integrated bonds of this step. Write E for the newly external fluctuation slots of the same ordinary step, with their fixed values a_E in scaled coordinates. Let Q^e be the complete precision on $I\sqcup O$ before the exterior integrated coordinates are frozen. It includes the ratio correction to the contour gauge quadratic. The conditional mean of the ordinary fluctuation Gaussian gives the additional linear term in the negative log-density

$$\ell^e_E=\tau_k\mathsf{A}^e_{I\sqcup O,E}a_E,\qquad k=j-1.$$

Indeed, for the ordinary Gaussian with precision $\tau_k\mathsf{A}^e_{I\sqcup O,I\sqcup O}$ its mean is $-(\tau_k\mathsf{A}^e_{I\sqcup O,I\sqcup O})^{-1}\ell^e_E$. The gauge compensation has separate integrated and exterior blocks. It changes the precision and leaves this linear term unchanged. Keep the E-slots fixed, including any real near values. At a comparison datum e_0, the centered Gaussian reference on I has covariance $\big((Q^{e_0})^{-1}\big)_{II}$. Its precision is

$$K=Q^{e_0}_{II}-S,\qquad S=Q^{e_0}_{IO}(Q^{e_0}_{OO})^{-1}Q^{e_0}_{OI}.$$

The reference exponent is $-y^{\mathsf T}Ky/2+P_0(y)$. The difference of the gradients of the two negative log-densities gives the terms

$$Sy+Q^e_{IO}y_O+(\ell^e_E)|_I+(Q^e_{II}-Q^{e_0}_{II})y-\nabla(P_e-P_0)(y).$$

All scalar factors depending only on e cancel in this comparison at fixed exterior. This includes the square-completion term of the ordinary move with two external fluctuation arguments: its inverse chain may reach inside the box, but both arguments are fixed. The Schur term S above has two interior arguments and comes from taking the Gaussian marginal of the reference.

The Schur and integrated exterior forces follow from the real precision bounds. Suppose $Q^{e_0}\ge a_-I$, and that Q^{e_0} and Q^e have uniform exponentially weighted row and column sums. Minimizing the quadratic form over the exterior gives $K\ge a_-I$. For a weight e^{φ} with small Lipschitz constant μ, conjugation changes $Q^{e_0}_{OO}$ in operator norm by at most $C\mu$, by its weighted row and column bounds. Its inverse therefore remains bounded in the conjugated norm. Taking $\varphi(b)=\mu d(b,b')$ gives exponential decay of its entries and, at a smaller rate, summable weighted rows and columns. For $b\in I$, the first factor $Q^{e_0}_{IO}(b,\cdot)$ in S already crosses distance $d(b,O)$. Summing the other two factors gives

$$|(Sy)_b|+|(Q^e_{IO}y_O)_b|\le Cb_je^{-cd(b,O)}$$

on the stated windows $|y|_\infty,|y_O|_\infty\le Cb_j$. The old exterior tier bounds give $\sup_E|a_E|\le Cb_j$ on the real support. The weighted row bound for the ordinary cross block therefore gives

$$|(\ell^e_E)_b|\le Cb_je^{-cd(b,E)}.$$

All three bounds hold at the read with the box padding, since both O and E are outside the box. They also hold with the distance to $\mathcal{B}_{\mathrm{ext}}$.

For the change of the interior precision compare the full precision terms before freezing the exterior. Use the local walk expansion with the current, pivot, and relative contour gauge contributions in the same chart.

Fix the outgoing datum V_j and take a collared box W in the common clean top layer of two exteriors. Choose the same collar grid in both settings, with the padding for all the backward blocks and pivots. On W all the layer traces through level j coincide. The only original determining rows with both endpoints in W are top rows, which read the fixed V_j. The joined determining set therefore coincides, and both joined data are formed by the same face lift of those rows. In particular both ambient backgrounds compare to one joined background by eq. 3.cdii. The common comparison box gives one frame for the interior. If a lower read uses the average of either ambient background, apply the local average estimate on its entire double block in that frame. This gives closeness of the two averaged data from the background estimate.

On a union of common standard cells with padding in W, the identical traces give identical indices, row types, outward endpoints, and local carriers of the native walk terms. For the ordinary compressed terms use the part of this union on which both steps have the same integration, pivot, and conditioning masks. A masked term uses this identity only on its full carrier, including the endpoint blocks of its masks.

For the native conditioned covariance, the local resolvent at a cube q uses the sum of the form terms with footprints inside $q^\sharp$, compressed to the kept bonds in $Y' \cap q^*$. Thus one must match the full $q^\sharp$ read and the compression on $Y' \cap q^*$, even for an inverse entry whose endpoints are well inside q^*. On this common support write $R_q^a = (x_a + T_q^a)^{-1}$ for the local resolvent of either datum $a = e, e_0$. Then

$$R_q^e - R_q^{e_0} = -R_q^e\big[(x_e - x_{e_0})I + T_q^e - T_q^{e_0}\big]R_q^{e_0}.$$

Equal data and equal scalar shifts give equality. For nearby data the same identity uses the native inverse bounds on the admitted domain. An extra chain of a labeled reference must have this same form family and compression, or its own comparison.

Write $d_b = d(b, \mathcal{B}_{\mathrm{ext}})$, with the cell and stencil padding included in the common region. Compare the terms in row b whose full carriers stay within distance $d_b/2$ of b. The other terms have charged length at least $cd_b - C$, including the margins of their local read sets. The absolute weighted row bound for each precision gives a cost $Ce^{-c'd_b}$ for this part, with the column variable summed. This distance is bounded by the distance to the actual cut even when the set of exterior integrated bonds has holes.

For the short carriers, compare the terms with common masks in the frame of W. The real pair difference, in local units on a carrier, is bounded by $C\epsilon_0 \sup_{z \text{ on the carrier}} e^{-c_0 d(z, W^c)}$. The real estimates for the potential and its first differences give the field bound, and the full-bond estimates give the current bound. The adjoint rotations preserve the free-bond balls.

The ordinary relative contour square has a direct local comparison. The paths in one block avoid the middle crossing pivots. Thus $G_U h_U = 0$ for those contour rows, and their differential $G_U C_U$ from free coordinates is $G_U \iota$ by eq. 3.cxii. At a common block it has the same path stencils and free mask in both settings. The row coefficients in eq. 3.cclxxiv are analytic in the block links. Their difference is bounded by the field difference on the block, in the common node frame. The weight of the gauge quadratic is one in $Q_\tau = \tau K_A + K_G$. The difference of the two Gram terms is the sum of a bounded row times a row difference and its counterpart with the difference in the first factor. The fixed number of contours per block then gives the short row estimate for this part of the complete precision.

On a common local operator domain with fixed room, Cauchy's estimate on the segment between the two pairs bounds the difference of a short term by its absolute analytic bound times C times the pair difference. Thus the absolute row sum of short differences is at most $C\epsilon_0 e^{-c_0 d_b/2}$. Together

with the long terms this gives

$$\sum_{b'\in I} |(Q^{e}_{II} - Q^{e_0}_{II})(b,b')| \le Ce^{-c'd_b}.$$

Here the row estimate uses the matching for each short summand of the complete precision. For the reference used in the clean mixture, we must file any additional boundary chains under the same local comparison or bound their short contributions separately. Multiplication by $|y|_\infty \le Cb_j$ gives the force bound at depth d_b.

For the interaction force use the full carriers of the evaluated members of P_e. Write $m(Y)$ for their length, with $\operatorname{diam} Y \le C_0(1+m(Y))$ and $\sum_{Y\ni b} e^{-\kappa m(Y)} \le C$. For a carrier reaching $\mathcal{B}_{\mathrm{ext}}$, a derivative bound $v_1 e^{-2\kappa m(Y)}$ on each evaluation gives the needed distance factor by spending half the decay. For a carrier contained in the matched interior, use the matched derivative bound

$$|D_b(P_{e,Y} - P_{0,Y})| \le v_2 e^{-2\kappa m(Y)} \sup_{z\in Y} |U_e(z) - U_{e_0}(z)|$$

in a common gauge. If the last difference is bounded by $\epsilon_0 e^{-c_0 d(z,\mathcal{B}_{\mathrm{ext}})}$ at z, take $c' \le \min(c_0, \kappa/C_0)$ and use $d(b,\mathcal{B}_{\mathrm{ext}}) \le d(z,\mathcal{B}_{\mathrm{ext}}) + C_0(1+m(Y))$. The rooted sum gives $C(v_1+v_2\epsilon_0)e^{-c'd(b,\mathcal{B}_{\mathrm{ext}})}$. The target in eq. 6.xiv follows when $v_1 + v_2\epsilon_0 \le Cb_j$. For the regular old-origin members, the common-domain amplitude estimate in eq. 4.ccvii also suffices, by Cauchy's inequality and the same rooted sum. The force bound must be checked for the other members of the complete exponent.

The readout must be compared in addition to the density. On a common admitted pivot chart eq. 4.ccxxx, the joint Lipschitz bound and finite double-block support of Φ_V bound the difference of the two evaluated link fields by $C\epsilon_0 e^{-c'\mathsf{D}}$ on the read set, when the complete pivot support has distance at least D from $\mathcal{B}_{\mathrm{ext}}$. Apply the background estimate to the coarse field entering the graph, on its whole pivot support. This uses the actual averaging estimate if the comparison was in fine variables, and a fixed margin for the pivot support. Thus a readout with Lipschitz constant L_G costs $\eta_G \le CL_G\epsilon_0 e^{-c'\mathsf{D}}$. For the scalar insertions there is one more small field factor. Put $\Delta = C\epsilon_0 e^{-c'\mathsf{D}}$ for the difference of the two fluctuating link fields at the same free coordinate, after common gauge transport on the full pivot read. Let κ_* bound the curvature of the reference *evaluated* field on the window, including its fluctuation. In the axial gauge of this reference its link logarithms on a box of side ℓ_G are bounded by $C\ell_G\kappa_*$. The short linkwise interpolation to the other field then has logarithms bounded by $C(\ell_G\kappa_* + \Delta)$. The first derivative of the invariant scalar vanishes at the flat field. On the small-field logarithm chart, use the second derivative bound from zero to each point of the path to estimate its first derivative, then integrate along the path. This gives

$$\eta_G \le C\mu_2(\ell_G\kappa_* + \Delta)\Delta.$$

For a Wilson plaquette in SU(2) the same bound follows by subtracting the squared norms of the two plaquette deviations from the identity.

6.3.0.4. Intrinsic terms and the reference Hessian. Work in the canonical free coordinates y, with $g = \widehat{g}_{j-1}$ and a tested radius $b_j \ge 1$. In the intrinsic exponent the action and contour-gauge terms are composed with the actual pivot graph before their quadratic parts are extracted. Their remainders have the form $g^{-2}R_{3,Y}(gy)$, with their signs and fixed coupling weights. Here $R_{3,Y}$ vanishes to order three, and the complete quadratic terms are included in the precision. Any linear term of the full action must be accounted for in the choice of background or in the explicit linear force. At the physical critical background, the tangent of the pivot graph at fixed targets lies in the tangent space of the constraint. The first variation of the Wilson action there vanishes on that tangent space. The contour-gauge action has zero first variation at the axial centre, where its contours are the identity. Extract these Taylor coefficients on the formed carriers before bounding the cubic remainders. Freezing a nonzero exterior argument later still creates the linear terms from the extracted quadratic. The other intrinsic terms are $L_Y(gy) - L_Y(0)$, the local log Haar and pivot coarea factors of eq. 4.ccliv. In particular, the pivot Jacobian is the derivative in the

eliminated coordinates of the actual constraint. The physical cubic and linear coefficients are the ones in eq. 4.cccxviii.

On a fixed unscaled complex radius, let B_Y bound the composed action and the coarea functions on their full carriers. For the homogeneous action these bounds are supplied by eq. 4.cclxxix and its composition with the outer graph in eq. 4.ccxcv. For the local Haar and pivot factors they follow from the joint chart and eq. 4.ccliv. Suppose that gB_* stays within a fixed smaller radius on every complete carrier. Here B_* includes $2b_j$, the real held bound $C_O\widehat{b}_j$ on the other integrated slots, and the full bound on the original exterior slots a_E. Leave a fixed fraction of b_j beyond the real windows for the complex coordinate variations, and use $B_* \le Cb_j$ with the fixed native window constants. Taylor's formula on this joint chart gives the respective bounds $CB_Y gb_j^3$ and $CB_Y gb_j$. For the coarea Hessian subtract its linear Taylor term before estimating derivatives. The subtracted function is bounded by $CB_Y g^2 b_j^2$ there. This subtraction is only for the derivative estimate. The linear term remains in the density. Two coordinate Cauchy estimates at a real point in the tested box give the entry bound

$$|D_b D_{b'} P_{\mathrm{int},Y}| \le CB_Y(gb_j + g^2)\,\mathbf{1}_{\{b,b'\in Y^+\}},$$

where Y^+ is the support of the term in the actual chart. The radii in both derivatives are fixed fractions of b_j. For a repeated coordinate the factorial is 2!. The rooted exponential bound for B_Y absorbs the polynomial number of bonds in Y^+ and the factor $e^{\mu \operatorname{diam} Y^+}$ for a smaller fixed μ. The weighted row and column sums therefore give

$$\|T_\varphi P''_{\mathrm{int}} T_\varphi^{-1}\|_{2\to 2} \le C(gb_j + g^2), \qquad |\varphi(b) - \varphi(b')| \le \mu d(b,b').$$

This bound holds on the proved homogeneous chart, and on a matched reference box with the same rooted intrinsic bounds.

The Haar and coarea part of this calculation applies directly on the labeled clean double blocks at nonzero held coordinates. Each such term is the actual one-step Haar factor or the inverse derivative in the private middle pivot. In a clean complete block the map, the target and the nonpivot and pivot masks are those of the joint local chart. The regularity of the whole double block and the held radii just specified supply its analytic bounds. The number and length of these carriers through one bond are bounded. Two derivatives give Cg^2 in the weighted rows and columns of this part, with the linear coarea term still in the density.

The Wilson action on an ordinary determining set has a direct weighted Hessian estimate on the same chart. Use its exact response package at the physical critical reference. Write F for the bare action in the relative potential, K_0 for the linearized rows, H for their right lift and $\widetilde{\mathsf{G}}$ for the constrained Green operator. The nonlinear row linearization $A = T(A')$ of [B85e] makes the rows linear: $\mathcal{Q}(T(A')) = K_0 A'$. With L_0 the constrained action Hessian, put

$$V_{\mathrm{nl}}(A') = F(T(A')) - F(0) - (F'(0), A') - \tfrac{1}{2}(A', \mathsf{L}_0 A').$$

All pairings and adjoints in this calculation use the native potential, source and row weights. The second variation estimate gives, on a fixed absolute ball,

$$\|V''_{\mathrm{nl}}(A')w\|^\sharp_{\theta,y_0} \le C\|A'\|_\infty \|w\|_{\theta,y_0}.$$

Here θ is a spatial weight rate and can be a fixed positive number below the native response rate. This estimate includes the second derivative of the nonlinear rows contracted with the physical multiplier. The determining-set response package supplies it with constants uniform in the depth and the volume.

For a reduced row datum b, its critical potential is $T(A'(b))$, where

$$A'(b) = \mathsf{H}b + \mathcal{A}_0(b), \qquad K_0\mathcal{A}_0 = 0,$$
$$\mathcal{A}_0 + \widetilde{\mathsf{G}} V'_{\mathrm{nl}}(A') = 0.$$

The gauge condition is $\mathsf{R}D^{\mathsf{T}}\mathcal{A}_0 = 0$. Shrink the fixed absolute datum radius once so that $\|\widetilde{\mathsf{G}}V_{\mathrm{nl}}''(A')\| \le 1/2$ in these weighted spaces. This is possible since $\|A'(b)\|_\infty \le C\|b\|_\infty$. Differentiating the stationary equation gives

$$DA'(b) = (I + \widetilde{\mathsf{G}}V_{\mathrm{nl}}''(A'))^{-1}\mathsf{H}.$$

Set $\mathcal{E}(b) = F(T(A'(b)))$ and $\mathsf{Z} = \mathsf{H}^\sharp\mathsf{L}_0\mathsf{H}$. The identities $\mathsf{L}_0\mathsf{H} = K_0^\sharp\mathsf{Z}$ and $\mathsf{H}^\sharp\mathsf{L}_0 = \mathsf{Z}K_0$ remove the cross terms containing $\mathcal{A}_0$. Stationarity removes its first variations. Thus

$$\mathcal{E}'(b) = \omega_0 + \mathsf{Z}b + \mathsf{H}^\sharp V_{\mathrm{nl}}'(A'),$$
$$\mathcal{E}''(b) - \mathsf{Z} = \mathsf{H}^\sharp V_{\mathrm{nl}}''(A')(I + \widetilde{\mathsf{G}}V_{\mathrm{nl}}''(A'))^{-1}\mathsf{H}.$$

The inverse has norm at most two. The weighted response bounds for H, its adjoint and $\widetilde{\mathsf{G}}$ therefore bound the last operator by $C\|b\|_\infty$. On the highest active rows the scale weights are one. Apply the estimate to a single row and Lie algebra component, with the weight centred at its assigned top site. The output entries then decay exponentially in the distance between the two assigned sites. There are boundedly many active row components per highest-level site. The native exponential sum, at any smaller fixed rate $\mu < \theta$, therefore gives absolute weighted row sums. Symmetry gives the column sums, and the weighted Schur estimate gives the required 2-norm bound.

For this application the varying original datum is confined to the highest level of the ordinary determining set. In the reduced datum, an outward node gauge reads only the interior datum one level below. Those lower increments are zero in the relative chart. There are no inward tying rows. Consequently $\mathsf{b}(B) = B$ on the full varying top stock, as in eq. 3.dxlix; the preceding estimate is already in its physical row coordinates.

Now compose with the actual one-step pivot graph $B = \Phi(v)$, written relative to that reference, so $\Phi(0) = 0$. If $\mathsf{K}(v)$ denotes the Hessian of $\mathcal{E} \circ \Phi$, the full chain rule is

$$\mathsf{K}(v) = D\Phi(v)^\sharp\mathcal{E}''(\Phi(v))D\Phi(v) + \mathcal{E}'(\Phi(v))\, D^2\Phi(v),$$

where the last term denotes contraction in the row coordinate. The joint pivot chart bounds its first three derivatives on the complete double blocks. Their supports have bounded diameter and overlap. The physical multiplier satisfies $\|\omega_0\|_\infty \le C\alpha$. To compare these Hessians, write $J(v) = D\Phi(v)$, $H_2(v) = D^2\Phi(v)$ and $e(v) = \mathcal{E}'(\Phi(v)) - \omega_0$. The difference is the sum of

$$J(v)^\sharp[\mathcal{E}''(\Phi(v)) - \mathsf{Z}]J(v),$$
$$J(v)^\sharp\mathsf{Z}J(v) - J(0)^\sharp\mathsf{Z}J(0),$$
$$e(v)H_2(v), \qquad \omega_0[H_2(v) - H_2(0)].$$

The first term uses the reduced-action estimate. The second and fourth use the local derivatives of the pivot graph. For the third, $\|e(v)\|_\infty \le C\|v\|_\infty$ follows by integrating its bounded Hessian along the segment. Each term therefore gives

$$\|T_\varphi[\mathsf{K}(v) - \mathsf{K}(0)]T_\varphi^{-1}\|_{2\to 2} \le C\|v\|_\infty.$$

In particular, the change in the contraction $\mathcal{E}'(0)D^2\Phi$ is included here. Its value at zero is part of the complete precision eq. 3.dlii; it cannot be discarded before subtracting that precision. For $v = g(y, y_O, a_E)$, the Hessian of the g^{-2}-scaled action remainder is exactly $\mathsf{K}(v) - \mathsf{K}(0)$. This proves its weighted bound Cgb_j throughout the full held window, including nonzero original exterior coordinates. The local contour action has the same bound from its complete block chart after its actual quadratic is subtracted. Together with the Haar and coarea estimate above this proves the intrinsic Hessian estimate on the ordinary labeled clean stock. If lower-level data are also released, keep their reduced-datum derivatives and physical dual weights; the highest-level identification just used does not apply to those directions.

There is a separate parity condition in the value estimate. When all exterior fluctuation arguments of the analytic intrinsic reference are zero, its odd part is bounded by $Cn_j g b_j^3$. The even parts of the action remainder and the coarea increment start at orders four and two, respectively, so their sum is bounded by $Cn_j g^2 b_j^4$. A newly stored a_E held at a nonzero value can enter a cubic with two interior slots, which is even in the interior. With these stored values fixed use the full intrinsic oscillation bound $Cn_j g b_j^3$. On the joint analytic chart the segment (y, ty_O, a_E), $0 \le t \le 1$, still gives the force comparison for setting the other integrated fluctuations to zero. At fixed background and fixed quadratic extraction, the mixed Hessian bound just proved gives

$$|D_b\{P_{\mathrm{int}}(y, y_O) - P_{\mathrm{int}}(y, 0)\}| \le C(gb_j + g^2)b_j e^{-\mu d(b,O)}.$$

Indeed, integrate the mixed derivatives along that segment and sum the weighted row over O. The physical exterior variables remain in the actual law.

To reach the parity reference, this comparison must also set the exterior slots of the current-step analytic intrinsic terms to zero. Use the raw fluctuation coordinates before the strip substitution, at a fixed pair and with the physical tests and Jacobian held in the original density. The larger analytic carrier boxes for these intrinsic terms allow a segment in their current-step stored arguments. On the common admitted box, integrating the mixed Hessian along $(y, 0, ta_E)$ bounds the extra change of interior force by $C(gb_j + g^2)b_j e^{-\mu d(b,E)}$ at bond b. This is a comparison of analytic evaluations. The strip selectors and older stored fields are still present in the physical law and require their own bounds. The frozen quadratic's linear force is accounted for separately.

The regular old-origin contribution is controlled by eq. 4.ccii and its weighted version eq. 4.cciii once the matched reference box reads the same subtracted family on its larger analytic domain. The vacuum-only remainder uses the separate age sum eq. 4.ccv on its admitted class. When the profiles have been redrawn with compensation after healing, the coupling lag vanishes in the clean box. A term whose arguments, including its background read, are fixed by the exterior contributes a scalar to the box. It cancels from the normalized density at that exterior and remains in the exterior mixing weight. A boundary term that still depends on y requires its own weighted Hessian bound in the reference. An estimate for the difference of two exterior forces alone does not supply this. Thus the proved intrinsic bound and the admitted old and vacuum-only bounds can be spent against the Schur gap in eq. 4.cciv. The remaining reference terms must fit in the same gap before applying eq. 6.xv.

6.3.0.5. Freezing only the exterior fluctuations. For a fixed full chart of the small-field step, the pivot graph and the extracted precision are determined before freezing the exterior free coordinates. Keep the retained datum, background, stored spectators and coordinate sets of that chart fixed. In the auxiliary reference put the other integrated fluctuations equal to zero in the smooth exponent and keep the same full precision for forming the centered Gaussian marginal on I. The newly external values a_E remain fixed in the smooth interaction. The force from their cross quadratic is ℓ_E^e in the physical exponent, and dropping it for the centered reference costs the estimate above. In this comparison the interior precision difference vanishes. The Schur correction and the force $Q_{IO}y_O$ are still present. The field readout on its declared read set is also unchanged: each of its pivot values reads only the free bonds of its defining double block, and those bonds are included in the read set. This is the graph in eq. 4.ccxxx. The joint step box for the intrinsic action and coarea factors contains the segment (y, ty_O) with a_E held fixed. The auxiliary zero is an evaluation on that analytic chart. The exterior tests and the recorded exterior values in the physical law are kept.

For any smooth exponent member P admitting the common segment (y, ty_O), its change of interior force is exactly

$$D_b\{P(y, y_O) - P(y, 0)\} = \int_0^1 \sum_{b' \in O} D_b D_{b'} P(y, ty_O)(y_O)_{b'}\, dt.$$

A weighted Hessian row bound A on the full segment therefore gives $CAb_j e^{-\mu d(b,O)}$ on that exterior window. This applies to the intrinsic estimate of §6.3.0.4. It applies to the old terms when their weighted estimate is available on the joint free-coordinate domain, including the exterior slots of these derivatives. A bound on interior derivatives at a fixed exterior does not supply those slots. When the exterior changes the background, stored fields or local masks, freezing its fluctuations first gives an exterior-dependent reference. The direct flat comparison below uses the common rotated read window and the full row estimates to obtain one reference density for the mixture.

6.3.0.6. Charging a boundary tail to the reference Hessian. Let W_I be the union of the current cubes covering the entire free-coordinate box I, with N_W cubes. Suppose the surviving boundary members satisfy the majorants of Prop. 6.9 on one common complex ball of free radius $R_y \geq 2b_j$, after their actual substitutions. Write B_∂ for their sum. Terms independent of the interior coordinates can be set aside as scalars at fixed exterior. Then eq. 6.xlii gives

$$\sup_{\|y\|_\infty < R_y} |B_\partial(y) - B_\partial(0)| \leq CB_* N_W e^{-cs}.$$

Coordinate Cauchy on the real window gives bounds $CB_* N_W R_y^{-1} e^{-cs}$ for each first derivative and $CB_* N_W R_y^{-2} e^{-cs}$ for each Hessian entry. If m_I counts the scalar coordinates and D_I is the diameter of I in the metric of the weights, the weighted Schur bound is

$$\|T_\varphi B''_\partial T_\varphi^{-1}\|_{2\to 2} \leq CB_* N_W m_I R_y^{-2} e^{-cs+\mu D_I}, \qquad \operatorname{Lip}\varphi \leq \mu.$$

This uses the diameter of the box, so it does not require a diameter estimate for an individual carrier in terms of its length after exempt hulls have been removed.

For example, the additional margin $s \geq s_* + (\mu/c)D_I + C_1 \log x$ makes this contribution small when the coordinate counts and B_* grow polylogarithmically. In this inequality the collar and box distances use the units of their respective estimates, with the fixed conversion included in the constants. The enlarged collar still has polylogarithmic size when the original box and the trace padding do. For two exteriors satisfying the same bound, the first derivatives cost at most $CB_* N_W R_y^{-1} e^{-cs}$ in their difference. As a uniform force error it adds at most $Cn_j b_j B_* N_W R_y^{-1} e^{-cs}$ to the logarithmic marginal error. This follows by using the summable weights in eq. 6.xv. The bound requires the larger complex ball for these evaluated boundary members and the stated clean collar around W_I. A real oscillation bound alone gives no Hessian estimate.

For the current ordinary-step boundary and kept potentials one can use the native analytic domain directly. Fix the actual exterior at an admitted support point, with its adapted pair and stored arguments. In the original scaled free coordinates on the clean integrated bonds, the complex step box has radius $3b_j$. Vary y on the ball of radius $2b_j$ and keep every other argument fixed. The support has room in those other coordinates, including the cut strip evaluation. The pinned substitution preserves the stored arguments. Hence the boundary and kept potentials on this ball use their original full carriers and the inherited amplitudes of the ordinary step.

Apply two coordinate Cauchy estimates on each carrier Y. A derivative in the bonds b, b' can occur only if the complete carrier reads both of them. The two root cubes, with the pivot padding included, are nonexempt in the clean box. A hull tree must meet both and spends their separation in ordinary edge length, including the part of the path that passes through any exempt hull. Splitting the rate between this distance and the rooted sum eq. 6.xxxix gives

$$|D_b D_{b'} P_\partial(y)| \leq C_a b_j^{-2} \vartheta_k \big[\mathsf{B}(\log\theta_k)^{-a} + \mathsf{B}_\Phi e^{-L\check{R}_j}\big]\, e^{-\mu_0 d(b,b')}, \qquad k = j-1.$$

Here P_∂ sums these current-step substituted potentials. Their inverse-logarithmic bound uses the native crossing length. The weighted Schur sum is uniform in the number and diameter of the free bonds for $\operatorname{Lip}\varphi < \mu_0$ with a fixed rate reserve. This estimate is for interior derivatives at fixed exterior and can be used in the reference Hessian.

From the exterior force to the normalized marginal. Use the same literal product of free-bond balls $D = \prod_{b\in I} D_b$ for the two real densities. Write

$$H_a(y) = \tfrac{1}{2} y^{\mathsf{T}} A_a y + \ell_a^{\mathsf{T}} y - P_a(y), \qquad d\nu_a = Z_a^{-1} 1_D e^{-H_a}\, dy, \qquad a = 0, 1.$$

Here $a = 0$ denotes the reference with the Gaussian marginal precision K, and $a = 1$ the actual density at fixed exterior. The two real potentials are C^2 in the interior. For $T_\varphi y(b) = e^{\varphi(b)} y(b)$, suppose

$$\langle v, T_\varphi A_0 T_\varphi^{-1} v\rangle \geq \lambda_A |v|^2, \qquad \|T_\varphi P_0'' T_\varphi^{-1}\| \leq \epsilon_0 < \lambda_A.$$

Use $\lambda = \lambda_A - \epsilon_0$, and let δ_b bound the component at b of $\nabla(H_1 - H_0)$. For a real function G with $|G(y) - G(y')| \leq L_G |T_\varphi(y - y')|$, the common-momentum comparison gives

$$|\nu_1(G) - \nu_0(G)| \leq \frac{L_G}{\lambda} \left(\sum_{b\in I} e^{2\varphi(b)} \delta_b^2 \right)^{1/2}. \tag{6.xv}$$

Here is the argument including the hard boundary. First shrink each ball to radius r_b, and choose two intermediate radii between r_b and the original radius. Smooth the metric projection onto the larger intermediate ball by an even mollifier. With support sufficiently small, the resulting map r, taken block by block, is the identity on the smaller intermediate balls, takes values in the original domain and has $\|Dr\| \leq 1$. Replace P_a by $P_a \circ r$ and add the same wall $\epsilon^{-1} \sum_b w(|y_b|^2 - r_b^2)$ to both energies. Take w smooth, convex and nondecreasing, zero on the negative half-line, with positive derivative on the positive half-line and affine for large arguments. The wall is smooth and convex, with bounded Hessian for fixed ϵ. Its Hessian has a positive lower bound off the smaller intermediate ball. In the Hessian of $P_0 \circ r$, the term $Dr^{\mathsf{T}} P_0''(r) Dr$ has weighted norm at most ϵ_0 because Dr commutes with the block weight. The remaining term is block diagonal, vanishes on the smaller intermediate balls in its respective blocks and is dominated by the wall Hessian for small ϵ. Thus the weighted coercivity remains λ on the whole space. The wall cancels from the difference force $f = \nabla(H_1^\epsilon - H_0^\epsilon)$.

For these smooth energies the Hamiltonian flow $\dot q = p,\ \dot p = -\nabla H_a^\epsilon(q)$ preserves the product of its Gibbs law and the standard momentum Gaussian. Energy conservation and zero phase-space divergence give this identity. Start the two flows with the same Gaussian momentum. For $v = T_\varphi(q^1 - q^0)$ their difference satisfies $\ddot v = -M(s) v - T_\varphi f(q^1(s))$ and $\dot v(0) = 0$. The matrix $M(s)$ is the conjugated average of the reference Hessian on the segment between the two positions. It satisfies $\langle z, M(s) z\rangle \geq \lambda |z|^2$, and its norm is at most some Λ at fixed ϵ. The integral equation, for small t, gives

$$|v(t)| \leq (1 - \lambda t^2/2 + C\Lambda^2 t^4)|v(0)| + (1 + C\Lambda t^2) \int_0^t (t - s) |T_\varphi f(q^1(s))|\, ds.$$

Indeed, the average of $M(s)$ with weights $2(t - s)/t^2$ has the same lower bound and norm. Substituting $v(0)$ under the Hessian integral gives the displayed contraction by squaring its norm. One further use of the integral equation bounds the error from $v(s) - v(0)$ by the fourth-order term and the indicated increase of the force bound.

Refresh the common momentum every t units of time. The marginal position laws stay invariant, so the mean of the force integral equals $t^2 \nu_1^\epsilon(|T_\varphi f|)/2$. Iterate the displayed contraction and use the resulting bound on the mean weighted separation for a Lipschitz extension of G. Letting $t \downarrow 0$ at fixed ϵ bounds the observable difference by $L_G \nu_1^\epsilon(|T_\varphi f|)/\lambda$. As $\epsilon \downarrow 0$, the smooth measures converge to the Gibbs laws on the shrunken balls. The walls have quadratic growth outside a bounded set, which gives an integrable majorant for both densities and their first moments for all sufficiently small ϵ. The force has at most linear growth and equals the original force on the shrunken balls. Dominated convergence therefore applies also to its mean. Finally let the shrunken radii increase to the original radii. The bounded reference Hessian and difference force give bounded gradients

on the original bounded convex window, so the last limit is also dominated. This proves eq. 6.xv. Only the reference Hessian was used for coercivity.

Now assume the same coercivity bounds for all weights with Lipschitz constant at most μ. Retain the read coordinates $u = y|_S$ and integrate over $R = I \setminus S$. Write m_a for their marginal densities and ν_a^u for the conditional laws on R. The product window makes the integration domain independent of u, so for $s \in S$

$$\partial_s \log(m_1/m_0) = -\nu_1^u(\partial_s(H_1 - H_0)) - (\nu_1^u - \nu_0^u)(\partial_s H_0).$$

The first term costs δ_s. In the second, apply eq. 6.xv to each unit colour direction of $\partial_s H_0$, with $\varphi(b) = -\mu d(b,s)$ on R. The weighted coercivity survives compression. The Lipschitz constant is at most

$$L_s = \sup_{y \in D} \left(\sum_{b \in R} e^{2\mu d(b,s)} \|H_0''(b,s)\|^2 \right)^{1/2}.$$

Thus the derivative norm is at most $\delta_s + \lambda^{-1} L_s (\sum_{b \in R} e^{-2\mu d(b,s)} \delta_b^2)^{1/2}$. Integrating along segments in the product of read balls bounds the oscillation of $\log(m_1/m_0)$ by the sum of these bounds times the corresponding ball diameters. Since both marginals have mass one, this oscillation bound Ξ_j gives $e^{-\Xi_j} \le m_1/m_0 \le e^{\Xi_j}$.

If the forces obey eq. 6.xiv and the weighted Hessian column bound makes L_s uniform, the triangle inequality $d(b,s) + d(b, \mathcal{B}_{\mathrm{ext}}) \ge d(s, \mathcal{B}_{\mathrm{ext}}) \ge \mathsf{D}$ leaves a summable exponential after extracting a smaller factor $e^{-c'\mathsf{D}}$. The derivative bound at a read coordinate is then $C b_j e^{-c'\mathsf{D}}$. Multiplying by the diameters and the read-coordinate count gives $\Xi_j \le C n_j b_j^2 e^{-c'\mathsf{D}}$. The normalized density bound persists under the positive exterior mixture when each exterior is compared with the same reference density in the common read coordinates. The readout discrepancy η_G remains a separate term.

6.3.0.7. The readout as the retained datum varies. At a fixed output of the step, the exterior mixture keeps the same new field V_j. The following comparison is uniform as that field varies between outputs. Write $\mathsf{r} = L^s \mathsf{d}$ for the separation in witness-level units and $p_0 = p_0(g)$. Put V_j in the axial gauge of the nonwrapping comparison box and extend that gauge constantly on each block to the previous level. Denote the rotated free coordinates by $\widetilde{y}$. If the box has side l in its own units and plaquette bound κ_j, its logarithm satisfies $\|A_j\|_\infty \le C l \kappa_j$. This follows by writing the axial link as a product of at most Cl conjugated plaquettes. For the intermediate background $V_* = \mathcal{M}^{j-1} U_j(V_j)$ in its block axial representative, the contour variables are one, and the actual one-step average is V_j. Apply Lem. 3.8 against the trivial field on the full read double blocks. The intermediate plaquettes are bounded by $C\kappa_j$ by the local averaging estimate. Consequently its logarithm A_* in the same frame obeys $\|A_*\|_\infty \le C(l+1)\kappa_j$.

Let $\mathsf{C}^0 = D\Phi_1(0)$ be the flat pivot inclusion on those blocks. On the joint chart eq. 4.ccxxx, $D\Phi_{V_*}(0) - \mathsf{C}^0$ has norm at most $C\|A_*\|_\infty$ in that frame. The chart remainder is quadratic in the free variables. Multiplying the physical fluctuation by V_* and using the local logarithm of the product gives

$$\|A_{j-1} - A_* - \widehat{g}_{j-1} \mathsf{C}^0 \widetilde{y}\|_\infty \le C(\widehat{g}_{j-1} b_j \|A_*\|_\infty + \widehat{g}_{j-1}^2 b_j^2).$$

Here A_{j-1} is the logarithm of the actual fluctuating field in the chosen frame. The first error includes the commutator from multiplying the two exponentials.

For a bare plaquette p, denote the localized background plaquette minus one at level $j-1$ by $P_p^{(j-1)}(A)$. On its admitted fixed-radius datum ball this readout is bounded by $C\eta_{j-1}^2$. Its derivative at zero is $i\mathcal{H}_{j-1}^{\square}$, the linear curvature response of that same localized background. Cauchy's estimate

on a smaller ball and the preceding inequality give

$$\begin{aligned}\left|P_p^{(j-1)}(A_{j-1}) - P_p^{(j-1)}(A_*) - i\widehat{g}_{j-1}(\mathcal{H}_{j-1}^{\square}\mathsf{C}^0\widetilde{y})(p)\right| \\ \leq C\eta_{j-1}^2(\widehat{g}_{j-1}b_j\|A_*\|_\infty + \widehat{g}_{j-1}^2 b_j^2).\end{aligned}$$

6.3.0.8. The two localized readouts of the retained field. The actual retained datum of step j includes V_j and the lower rows that remain stored. On a fixed output, V_j is common to the exterior mixture. The regular critical field U at an exterior in that mixture still depends on the exterior. In the interior the literal shift in the fluctuation integral uses $V_* = \mathcal{M}^{j-1}U$ in block axial gauge, so $\mathcal{M}(V_*) = V_j$ there. On the remaining level-$(j-1)$ rows keep their stored values, and keep the older rows. This is the datum induced on the truncated sequence by U. Indeed the retained rows already prescribe their averages, and the newly exposed rows read the average V_*. Each equality uses the full double blocks. A variation at fixed induced datum extends by U through the frozen collar. The finer constraints imply the old ones by induction in the averaging, and the fixed inner bonds of crossing plaquettes make their contribution constant. Thus eq. 3.cccxciii identifies the critical field of the truncated problem with U up to residual gauge. This argument keeps the same cut rows and averaging scheme as the step.

For $q = j-1, j$, let $D_{q,p}$ be the domain of the localized minimizer used to read p. At $q = k_0$ this is the prescribed neighborhood of the test cube of p, including its four outer layers. At larger q take the box around the two supports with the prescribed order D margin in level-q units, rounded out on the collar grid. Include all top blocks of the plaquette read and all the double blocks of the retained rows needed by the pivots. The latter cost $O(L)$ extra spacings on the level-$(j-1)$ free-bond grid. The lower box and these double blocks are in the read set of step j, with the extra D margin to its integration-box edge. The upper box reads V_j, which is already fixed in this conditional integral.

Use the clean neighborhood with enough room for these fixed enlargements and their collars. In level-k_1 units the distance from the pair to the farthest of these enlarged boxes is at most $C(\mathsf{r}+\check{R}_{k_0})$: the side at q is at most $C(\mathsf{r}L^{-(q-k_0)} + \mathsf{D} + \check{R}_{k_0})$ in level-q units, and $q \leq k_1$. The same bound allows a further margin of this size in level-k_1 units by increasing the fixed neighborhood constant. The clean-history union bound counts cells meeting the enlarged neighborhood in the same way. On this event there are no standing regions or operations on these boxes and their padded collars, at the two levels of the step. The padded collars lie in the ambient top layer, both for the full problem and for the problem truncated at level $j-1$.

On the padded boxes, the passed coarse tests bound the plaquettes of the stored field V_j by Cgp_0. For V_* use the corresponding bound on the full backward cells of the ambient background and the one-step averaging estimate. This is a bound on the averaged critical field at zero fluctuation. In obtaining the local profile of the ambient background, the fixed ceilings on data outside the clean neighborhood enter with the exponential weight from their distance to the padded boxes. The intervening homogeneous layers have thickness at least $c(\mathsf{r} + \check{R}_{k_0})$ in the native spacings. Their contribution is bounded by $Ce^{-c(\mathsf{r}+\check{R}_{k_0})}$, which is smaller than gp_0 in the short-distance range.

For each $q = j-1, j$, compare the local critical field with the restriction of the same ambient field U. The common rows are those of V_* for the lower comparison and of V_j for the upper comparison. Each localization uses the face lift of its own prescribed datum. The alignment in eq. 3.cdi is performed on each collar using the Cgp_0 local profile. Thus the collar source is of that size. In eq. 3.cdii the source size enters linearly, while the fixed regularity ceilings admit the response path. At a plaquette p the result in the response gauges is bounded by $C\eta_q^2 gp_0 e^{-cd_{q,p}}$, where $d_{q,p}$ is its distance to the localization boundary in level-q units, with the fixed read stencils included in the margin. Write $\Delta_j = \min_{q,p} d_{q,p}$. The native test-cube and box margins give

$$\Delta_j \geq c_0 \min\{\mathsf{D}, \check{R}_{k_0}\} - C_0.$$

For a matrix comparison, express each plaquette defect in the frame at its level-q ancestor. This is conjugation by the product of the averaged contours from the ancestor to its base point. Use the coarse axial frame of the common box as the input frame, extended in the block axial representative for V_*. On the complete order-q double blocks of the ancestor read, write the collar comparison in its aligned real frame as $U' = \exp(i\eta_q A)U$. The potential bound on these blocks gives $a := \|A\|_\infty \le Cgp_0 e^{-c(d_{q,p}-C)}$. The fixed enlargement in the exponent is the size of the full blocks in level-q units. The straightened logarithm and its node factor at level $n \le q$ obey

$$\|a_n^{\mathrm{str}}\|_\infty + \|v_n^{\pm 1} - 1\|_\infty \le CL^n \eta_q a.$$

Apply the one-step contour estimate on the complete block of each contour from the next ancestor to the current one. Covariance with v_n gives a change at most $CL^n\eta_q a$. The product of real unitary transports changes by at most the sum of the changes, which is bounded by Ca. In the collar comparison the gauge at the top is v_q^{-1}, and this differs from one by at most Ca as well. The other gauge factors cancel between successive contours.

For a plaquette defect P, changing the transport to the top therefore changes its conjugation by at most $C|P|a$. The curvature bound gives $|P| \le C\eta_q^2 gp_0$, and the response bound already controls the change of P itself. Together they give $C\eta_q^2 gp_0 e^{-cd_{q,p}}$ for the change in the ancestor-frame defect. On U the two ancestor-frame reads agree. The additional contour from the level-j ancestor to the level-$(j-1)$ ancestor is the identity in the block axial representative used to form V_*.

We use this comparison for the plaquettes in their localized Landau representatives. On each actual local datum ball in the common input frame, its logarithmic datum, including the face lift, is bounded by $Cl\kappa_j$. The normalized potential on the ancestor block has this bound by the weighted response from the flat datum. The same contour length sum makes its transport differ from the identity by $Cl\kappa_j$. Thus each conjugation changes a defect of size $C\eta_q^2\kappa_j$ by at most $C\eta_q^2 l\kappa_j^2$. This argument uses only paths in each localized tower, even when the initial test cubes are disjoint. The common coarse axial gauge has one residual constant rotation, which acts on both plaquettes and leaves the flat Gaussian law invariant. These errors, together with the two collar errors, bound the difference of the lower and upper readouts at zero fluctuation by

$$C\eta_{j-1}^2\big[gp_0 e^{-c\Delta_j} + (l\kappa_j)^2\big].$$

Thus, with $l \le C\mathsf{r}$, $\kappa_j \le Cgp_0$ and $b_j \le Cp_0$, the remainder after retaining the level-j background and the flat linear fluctuation is bounded by

$$C\eta_{j-1}^2\big[(\mathsf{r}gp_0)^2 + gp_0 e^{-c\Delta_j}\big].$$

The term involving Δ_j uses both native margins. For $\mathsf{D} = A\log x$, with A fixed, the initial test margin dominates D when x is sufficiently large.

6.3.0.9. The common part of the two operator recipes. For a fixed step use the same tiling, masks and guard prescription in the two boxes. When comparing a row b, include in a carrier every row of a local coefficient, each endpoint double block of its pivot, its full current stencil, the contour reads, and any held guard used in forming its local Gaussian coefficient. A carrier contained in the common interior uses the same functional recipe on a common admitted pair domain. This follows term by term: its masks are those of the empty standing trace, its pivot is the same local analytic solution, and its walks and guard parameters are specified by the same kit. For the Gaussian root this is the fixed-root restriction of eq. 4.ccxciv. In particular, one must preserve the held guard before restricting a Gaussian functional. Independence of the summed logarithm from auxiliary guard choices is an identity after summation, which does not identify terms filed with different guards.

With d_b the distance to the edge of the common interior, take carriers lying within $d_b/2$ of b including their guards. They are therefore indexed in both recipes. Any term left out of this matching either reaches that edge or has a read or a guard reaching it. Such a term has charged

length at least $cd_b - C$ for the intrinsic and precision families; the fixed guard widths only change C. The absolute rooted majorants give a row sum $Ce^{-c'd_b}$ for the unmatched terms. On each matched carrier use the actual difference of its two potential and current reads before taking Cauchy bounds. For comparison at the same retained datum this difference is the exponential collar error. For comparison with the flat datum it includes the small background displacement $C\mathsf{r}gp_0$. This yields the short-carrier estimates in the real precision and intrinsic force comparisons. Regular old activities also require their own retained-datum radii and origin estimates, and standing old boundary terms use eq. 6.xlii.

6.3.0.10. The Gaussian comparison in the rotated coordinates. The rotation of the actual free variables uses the block-constant extension of the retained axial gauge. In this frame let C_{ax} be the old block-axial centre field. Let u be the Landau gauge of the comparison, restricted to the old sites and with the same residual normalization at the tops. By covariance of the average the old field in the Landau frame is C^u_{ax}. If the Landau potential and its first difference have size ϵ in the upper units, the one-level average estimate bounds each of its old link defects by $CL^{-1}\epsilon$. For a site x and its block centre y, the symmetric mean of the complete block contours satisfies

$$T_{y,x}(C^u_{\mathrm{ax}}) = u(y)u(x)^{-1}.$$

This uses eq. 4.ccxvi and the axial condition $T_{y,x}(C_{\mathrm{ax}}) = 1$. Each path has at most $d(L-1)$ links. Telescoping the path products and applying the local mean estimate bounds their symmetric mean's distance from the identity by $C\epsilon$. At the centre $u(y)$ is the inherited node factor of the localized response, or its inverse according to the direction of the transfer. Its normalized node estimate gives $|u(y) - 1| \le C\epsilon$. Together these estimates give the same bound on $|u(x) - 1|$ at every free site of the complete block. Here $\epsilon \le C\mathsf{r}gp_0$ on the admitted localized core.

On the compression to the admitted blocks, or on short carriers with all their endpoint blocks there, the native precision and covariance transform by the bondwise adjoint matrix R_u at the initial sites. For either matrix A, a spatial weight T_φ commutes with R_u, and

$$\|T_\varphi(R_u^{-1}AR_u - A)T_\varphi^{-1}\| \le 2\|R_u - 1\|\,\|T_\varphi A T_\varphi^{-1}\|.$$

The same estimate holds in the weighted row and column sums, by applying the bound blockwise to the two endpoint rotations. The return to the actual read frame therefore costs $C\epsilon$. It uses the matched masks and full block contours. The other carriers retain the separate exterior decay. In the changed gauge use the relative contour eq. 3.cclxxiv at the transformed centre. It is conjugated at the block node, so its quadratic weight is transported with the same free-bond mask.

On short carriers inside the box, the rotated precision and the flat one use the same local recipe and the same ratio $\tau_{j-1} = x_{j-1}/\theta_{j-1}$ in the Wilson quadratic. The contour-gauge weight retains its original normalization. At the flat pair the actual and straight linearized averages give the same constrained exact curvature space. In that space the action metric at this level is S^+_{j-1}, obtained from the energy of the flat minimizer. The soft contour weight integrates to a constant on each curvature fibre, since its contour values translate along the block gauge orbit. Multiplying the curvature metric by τ_{j-1} gives the covariance factor τ^{-1}_{j-1}. This is the argument of eq. 6.clii with the multiscale action metric. In physical units $\widehat{g}^2_{j-1}\tau^{-1}_{j-1} = x^{-1}_{j-1}$.

6.3.0.11. Matching the precision at a fixed exterior datum. Use the free stock of the step before the strip substitution, with the middle pivot of every eliminated coarse constraint removed. The interior integration stock includes the free bonds with at least one endpoint in the small-field region. In the native prepared chart, the operator at the physical current is $C_V^{\mathsf{T}}\Delta^{(j-1)}C_V$ on that full stock [B87, (2.3)–(2.11)]. The identification uses the perfect action on the actual lower determining set. Its Hessian is the first quadratic term. The change of variables in the plain outer constraint contracts its second derivative with the current of that perfect action. The relative contour square supplies the remaining term.

The same algebra identifies the symmetric-contour form on an admitted compression of a physical graded branch. On the active top datum, keep the finer arguments of the outward node factor fixed. The relative datum then has derivative equal to the active injection and second derivative zero on those directions, as in eq. 3.dxlix. Consequently the reduced action Hessian is the compression of $(QG_1Q^\sharp)^{-1}-a$ by eq. 3.dxlv. At the physical current $j_U = Q^\sharp\omega$, both right lifts have adjoint readout ω, since they are right inverses of the same Q. Convert this Hessian and the coarse current to the raw bond coordinates by eq. 3.dliv. In the actual next pivot graph the constraint contraction uses $h_V^\sharp \widehat{J}$, where $\widehat{J}$ is that raw coarse current. Equation eq. 3.dlii therefore gives the outer action Hessian including its curvature term. Adding the relative contour Gram in the same free coordinates gives eq. 3.dliii. This is the compressed physical value of the completed form when the two constructions use the same branch, active mask and contour gauge.

Freezing exterior fluctuation coordinates in this formed quadratic leaves its principal interior block as the conditional precision. If the full form is K and the fixed coordinates are a_{E}, its mean is $-K_{\mathrm{II}}^{-1}K_{\mathrm{IE}}a_{\mathrm{E}}$. The exterior Schur term is independent of the integrated coordinates. For the comparison Gaussian, form the full precision at the reference datum with the exterior fluctuation set to zero. Its Gaussian marginal on the box has covariance $(K^{-1})_{\mathrm{II}}$ and precision $K_{\mathrm{II}} - K_{\mathrm{IE}}K_{\mathrm{EE}}^{-1}K_{\mathrm{EI}}$, with K now evaluated at that reference datum. This accounts for the Schur correction in the force comparison. The interactions and cutoffs enter the normalized comparison separately.

At unit ratio use the inverse walks of this matched step precision on each of the two nests. The native operator theorem gives this identification and inversion on its admitted prepared geometry. The homogeneous symmetric-contour construction gives it by eq. 5.cclix and eq. 5.cclxxii. For a general labeled nest in the symmetric construction we must admit the same completed carrier families on the actual free stock, including the separation and current bounds of Prop. 3.112. The local algebra above identifies their physical matrix wherever this formation is admitted. The two-level real representation gives, on the padded top territory, a rotated potential of size $C\epsilon/L$, its first difference of size $C\epsilon/L^2$, and scaled current of size $C\epsilon$, all in input units. Let $\epsilon_\star$ bound the complete pair in the local operator norm on this territory. Here $\epsilon_\star \le Crgp_0$.

The clean geometry identifies the top territory, with its free and pivot indices, in both nests. A walk whose enlarged carrier lies there is consequently assigned the same kernel T_ω in both expansions. In the local extension use $\chi_\omega = (1-(2L/M)d_{\mathrm{w}}(\,\cdot\,,[\omega]))_+$, where d_{w} is the operator's weighted distance and $[\omega]$ is the full read. Thus the cutoff is one on the read and its support lies in the padded territory. If (A', J') is the rotated pair based at the identity, the local ball for the operator admits

$$z \longmapsto (e^{iz\eta_{j-1}\chi_\omega A'},\, z\chi_\omega J'), \qquad |z| < R_\star := \frac{\varepsilon_1}{2\epsilon_\star},$$

where ε_1 is the fixed operator radius. The current on this disc is the independent coordinate of the operator. At $z=1$ locality gives the physical kernel on this walk, and at $z=0$ it gives the flat kernel. Weak coupling on the comparison window gives $R_\star \ge 2$. If $\epsilon_\star = 0$ the short-walk values coincide. Otherwise summing the Cauchy bounds for the positive Taylor orders gives $2/R_\star$ times the walk majorant. The sum of the rooted majorants is bounded. For a walk whose enlarged carrier exits the territory, the tree from a read bond to that exit has length at least the distance to the edge minus the fixed padding allowance of the walk domains. The two outer sums are therefore $O(e^{-c\mathsf{D}})$. Returning to the read frame costs $C\epsilon$ by the endpoint estimate above. Thus at unit ratio the entrywise comparison follows directly for the full covariances restricted to the read set.

For the ratio tube use the affine precision $\tau(K_A+K_G)+(1-\tau)K_G$ from eq. 4.ccxxiv. Take a common compression I on complete blocks between the read set and the edge of the matched territory, with a fixed fraction of the margin on each side. Retain part of the exponential walk rate for the distance between the two endpoints in the preceding estimates. The weighted row and column sums then bound the difference of the compressed unit-ratio inverses by $C(\epsilon_\star + e^{-c\mathsf{D}})$. The

local relative gauge forms on I differ by $C\epsilon$ in the same norms. This follows from the fixed-radius contour derivatives on the matched complete blocks.

Write C_a for a unit-ratio inverse on I, G_a for the corresponding compressed gauge form, and $\lambda = (1-\tau)/\tau$. Its inverse at ratio τ is $\tau^{-1}(1+\lambda C_a G_a)^{-1}C_a$. The weighted row and column norms are submultiplicative. The tube makes $|\lambda|\|C_a G_a\|$ small there. After taking out the common τ^{-1}, the difference has a middle factor between $(1+\lambda C_1 G_1)^{-1}$ and $(1+\lambda G_2 C_2)^{-1}$. That middle factor is

$$C_1 - C_2 - \lambda C_1(G_1 - G_2)C_2.$$

This gives the same bound on I at the actual ratio. To return to the full covariance, use the corresponding weighted inverse bound on each full free-bond stock. For a full precision Q_τ and its inverse Γ_τ, block multiplication gives

$$(\Gamma_\tau)_{II} - (Q_\tau)_{II}^{-1} = -(Q_\tau)_{II}^{-1}(Q_\tau)_{II^c}(\Gamma_\tau)_{I^c I}.$$

At a real admitted ratio, symmetry and the other block equation give the factorization

$$(\Gamma_\tau)_{II} - (Q_\tau)_{II}^{-1} = B(\Gamma_\tau)_{I^c I^c}B^*, \qquad B = (Q_\tau)_{II}^{-1}(Q_\tau)_{II^c}.$$

For a linear read supported in I, the weighted inverse and precision bounds give an $\ell^2(I^c)$ tail for its row of B. The tail spends its exponential rate on the distance from the full read to I^c. Include the contour stencil and the plaquette stencil before measuring this distance. If the two reads have depths d_1, d_2 after that padding, the bounded exterior covariance gives an error $Ce^{-c(d_1+d_2)}$ for unit read norms. This implies the required $Ce^{-c\mathsf{D}}$ bound on the buffered read set. The endpoint rotations return this estimate to the read frame. The ratio comparison thus requires the native unit-ratio inverse and the affine gauge correction on the actual free stock, with the same pivot elimination. The resulting bound in scaled free coordinates is

$$\varpi_j \le C\big[\mathsf{r}gp_0 + e^{-c\mathsf{D}}\big]$$

against the flat covariance. This comparison uses the complete precision, including the current and contour gauge terms, in the common local recipe. In a physical plaquette pairing each linear readout also carries its own factor $\widehat{g}_{j-1}\eta_{j-1}^2$.

Let C_0, C_1 be the flat and rotated Gaussian covariances on the read coordinates, and put $C_t = (1-t)C_0 + tC_1$. The uniform precision bounds give common positive lower and upper eigenvalue bounds for C_t, including after compression to the read coordinates. If h_t is its centered Gaussian density and $D = C_1 - C_0$, then

$$\partial_t h_t(y) = \tfrac{1}{2}h_t(y)(y^{\mathsf{T}}C_t^{-1}DC_t^{-1}y - \mathrm{tr}(C_t^{-1}D)).$$

The bracket has mean zero under h_t and second moment $2\|C_t^{-1/2}DC_t^{-1/2}\|_{\mathrm{HS}}^2$, by Wick's formula. Integrating the L^1 bound on the derivative gives a density difference at most $C\|D\|_{\mathrm{HS}}$. On the common product window, normalization costs at most another fixed factor when its Gaussian masses are at least one half. The scalar read dimension is at most $3n_j$, so the entrywise bound above costs $Cn_j\varpi_j$ in the normalized Gaussian comparison. The nonlinear box tilt and exterior comparison enter separately.

6.3.0.12. The change in the intrinsic force. For the intrinsic terms of §6.3.0.4, take the same zero-exterior fluctuation argument for both backgrounds. Put $a_j = C\mathsf{r}gp_0$, which bounds the rotated background potential on the short carriers. On their common fixed-radius chart, the value bounds $CB_Y gb_j^3$ for the action remainder and $CB_Y gb_j$ for the coarea term also hold on the larger fluctuation ball. Cauchy in a fluctuation variable costs C/b_j. Cauchy in the background direction on its fixed radius, followed by integration to the flat datum, costs Ca_j. Thus the short-carrier part of the force difference at bond b is at most $C(gb_j^2 + g)a_j$ after the rooted sum. For the long carriers take

the two force bounds separately and use the distance to the edge as in the precision comparison. The resulting bound is

$$C(gb_j^2+g)\big[a_j+e^{-cd(b,O)}\big].$$

The additional comparison of nonzero exterior fluctuations uses the mixed Hessian estimate on the admitted segment. The old terms need their own retained-datum radii and origin sums. The fixed-radius derivative used here applies to the intrinsic terms.

6.3.0.13. A common flat reference for the exterior mixture. Use the same flat precision on the common free-coordinate box I and the same product window for every admitted exterior. In eq. 6.xv, take the reference potential to be the quadratic of this flat law. The weighted gap of its precision gives the required coercivity and the weighted column bound. The reference has no nonlinear tilt or exterior linear force.

First set aside the old-origin exponent, whose oscillation costs at most $2\epsilon_j^{\mathrm{old}}$ in the normalized log density. Keep the actual intrinsic action and coarea terms in the other potential. Write $a_j = C\mathsf{r}gp_0$ as in the precision comparison. In the rotated coordinates the difference of quadratic forces is bounded on a row by the precision row estimate times b_j. The Schur and exterior forces have the row bounds at O and E. The intrinsic value bounds on the larger ball, followed by one coordinate Cauchy estimate and the rooted sum, give $C(gb_j^2+g)$ for its force on that row at the actual fixed exterior. Thus, with $B=\partial I\cup O\cup E$, the total force difference after the old-origin removal is bounded by

$$\delta_b \le Cb_j\big[a_j+gb_j+e^{-cd(b,B)}\big] \qquad (b_j\ge 1).$$

This uses the complete precision row estimate, including the matching of the gauge weight and the current stencil.

At a read coordinate $s\in S$, the marginal log-density estimate following eq. 6.xv weights the remaining force components by $e^{-\mu d(b,s)}$. The two constant terms sum uniformly, and the last term gains $e^{-c'\mathsf{D}}$ when $d(s,B)\ge \mathsf{D}$. The read-window diameters are at most Cb_j. Restoring the old-origin exponent, the normalized read marginal therefore has density ratio to the same flat box-window marginal in $[e^{-\Xi},e^{\Xi}]$, where

$$\Xi \le 2\epsilon_j^{\mathrm{old}} + C|S|b_j^2\big[a_j+gb_j+e^{-c'\mathsf{D}}\big].$$

The pointwise ratio passes through the positive exterior mixture in these common coordinates. This route only uses the Hessian of the flat reference in the force lemma. The actual chart, rotated readouts and selectors must still be admitted on the common product window. Removing the flat box window and comparing with the full flat marginal use the Gaussian tail and Schur estimates above.

6.3.0.14. Admission on the real conditional window. For each positive string entering the exterior mixture, use the completed label of its averaging step before $\mathbf{R}$ at that level. Keep the actual stored fields, frames and cut rows of that label. In particular a component that will be treated later by an exterior operation is still counted in this exponent, at the stage where the fluctuation integral is performed.

At a point of the support of this step, put $\mathcal{A}_k=\widehat{g}_k(y,y_O)$ on the nonpivot bonds that touch Ω_{k+1}. In the strip use the corresponding cut datum, background and shifted fluctuation. For every carrier Y the step field facts give

$$(U_{k+1},0,J(U_{k+1}))|_Y \in \widetilde{\mathcal{U}}^{1/2}_{\sigma^{\mathbf{T}}}(Y).$$

Here $\sigma^{\mathbf{T}}$ is the graded structure of the completed label. In addition the free variable is in the half-radius version of the step box

$$\begin{cases} \widehat{g}_k^{-1}|\mathcal{A}_k(b)|<3\mathfrak{b}_k & \text{on free bonds touching } \Lambda_{k+1},\\ \widehat{g}_k^{-1}|\mathcal{A}_k(b)|<2C_1^{\mathrm{fl}}\mathfrak{b}_k & \text{on the other free bonds of } \Omega_{k+1}. \end{cases}$$

In this display the bond types are those of the step's integration and exterior sets. The full product of this box with the graded field domain is the domain used by the old-origin substitution. The bound uses $|\mathcal{A}_k| < \delta_k = \widehat{g}_k \mathfrak{b}_k$ on the integration bonds and the bound by $\mathsf{c}_{\mathrm{fl}} \widehat{g}_k \mathfrak{b}_k$ on the other free bonds, or $\mathsf{c}_{\mathrm{fl}}^{\sharp} \widehat{g}_k \mathfrak{b}_k$ after the strip change. Choose C_1^{fl} above these two constants.

The first factor has four requirements. The passed plaquette and fluctuation tests, and the retained tests on the older or prepared rows, give the regularity of the completed datum layer by layer. The bound includes the prescribed shell factor at a prepared component. Near Ω_{k+1} that factor is one, and its far contribution to the profile estimate is bounded by $C(\log x_k)^r e^{-cLM\check{R}_{k+1}}$. The layer estimates of the regular critical field then give the pointwise plaquette and current bounds in their own units. The current is that of the restricted action, including its prescribed boundary stencil. The complex potential slot is zero. On each addressed gauge cube the local transport estimate gives the required real gauge with potential and first difference bounded by the same layer size times the fixed cube-size constant. For each addressed tower, restrict the real critical configuration with its own averages. The restriction identity and the inherited layer bounds give the tower and its plaquette and current estimates in the tower units. On a core the same restriction with the core scale gives its two radius bounds. These are the four clauses of the step membership criterion. Their half-radius form uses $C\varepsilon_i^{[r]} \le c_1 \check{\alpha}_{0,i}$ at each layer. Here $\varepsilon_i^{[r]}$ includes its actual layer factor, $\check{\alpha}_{0,i}$ is the minimum of the two adjacent radii (the single radius at level zero), and $2c_1$ is below the fixed lower bound on the graded coefficients. The test thresholds and radii are chosen in that order. This also admits the structure of any earlier member addressed by the label.

On the clean interior the exact product-window identity supplies these support points when y ranges over $\mathcal{W}_I$. Its old-test implication uses the same coarse datum on full double blocks, the margin from δ_k to the approximate test at $2\delta_k$, and the old plaquette bound from the factors L^{-2} and δ_k/ε_k. Exterior conditions are those of the chosen compatible string. The reference branch retains the same step strings and tests. At a fixed output its normalized weight relative to the clean kernel is bounded above and below by positive constants. Thus the test-support properties carry to that branch under disintegration. For a conditional oscillation estimate the resulting almost-everywhere admission suffices. A bound for a larger complex product of varying exterior data is a different assertion.

Finally the actual step substitution on this domain has the pivots of B' solved before it is used in any older carrier. At complete parameters its averages are $e^{iB'} V_k^{\mathrm{bg}}$, its second member is the actual current of $U^{\sharp}$, and it preserves the prescribed transports at sites with stored data. The older datum induced by the literal fluctuation is regular with half the margin on the support of the tests. This is the regular evaluation clause for the outgoing background of the fluctuation integral. The identity by origins therefore applies on this domain to both the old exponent and its local evaluated potentials.

6.3.0.15. Which remainder is counted in a window. An ordinary $R^{(i)}(X)$ enters the old remainder sum only at its declared action-region place. The remainder of the fluctuation integral is assigned there when the entire domain X is at least one level-i cell inside the corresponding small-field region. The remainder produced by healing is assigned there on the same one-cell interior of its output action region. The term is a function of the core pair at that place. A remainder of the fluctuation integral in the rim, and a term of the healing exponentiation outside its prescribed interior, are filed as boundary terms. Membership in a larger clean box at a later time does not change that filing. An earlier term can enter the ordinary sum after healing only through the actual identity for the refiled term.

For an ordinary $R^{(i)}(X)$, apply the window function of its admitted old core, subtracting its value at $(\mathbf{1}, 0)$. If the window is at scale $m \ge i$, write $\sigma = L^{-(m-i)}$ and ρ for the ratio of output to old radii. Its contribution is bounded by

$$C r_i e^{-\kappa d_i(X)} (2 + d_i(X))^2 \rho^2 \sigma^4.$$

This is the vacuum subtraction estimate. At a fixed old base the rooted domain sum absorbs the polynomial. The $C\sigma^{-4}$ possible old bases in the current window cancel the scale factor. Thus the contribution per window is $C\rho^2 r_i$, with no additional geometric gain in the age. The far members stay at their original places with their rooted decay, as in the step's remainder potential bound. Summation in i is the flow sum eq. 4.ccv. Neither a remainder at the rim nor an exponent with stored colour data enters this sum. Their actual boundary carriers, with the hull family of the label at evaluation, have the separate boundary and stored-factor bounds.

6.3.0.16. Removing the old interaction at fixed exterior data. For the generating function it suffices to bound the oscillation of each old contribution on the real conditional window. Use the reference branches of the clean coupling, after removing the separate restriction weights. Fix a compatible exterior e of the output ω, including its retained datum and all stored spectators. Write $k = j - 1$ and put

$$\vartheta_k = \frac{\delta_k}{\alpha_k} \asymp (\log x)^{\mathfrak{p}_0 - q}, \qquad \delta_k = \widehat{g}_k b_j.$$

Use the complete evaluated potentials of the fluctuation step. The input field in each potential is the pair of the critical background and its current, with the physical free coordinates $\mathcal{A} = \widehat{g}_k(y, y_O(e))$. Its output field $U^\sharp$ is the actual solution at the new datum $e^{iB'} V_k^{\mathrm{bg}}$; B' includes the solved pivot entries. At the complete parameters the levelled substitution reads its actual current and preserves the stored variables. Thus the sum over a given origin equals the difference of that origin evaluated at $U^\sharp$ and at the unfluctuating $U^\flat$.

For the regular family after the pointed counterterm subtraction, the old remainders and the Wilson weight difference, the step estimates on the admitted real box give

$$|V_e^o(Y; y)| \le C\vartheta_k \, S_k^o \, e^{-\lambda d_k(Y)}. \tag{6.xvi}$$

The bound also holds for an ordinary defect if present, with its separate size. In this formula the full fluctuation box has width at most a fixed multiple of b_j, including the fixed exterior coordinates. The normalization constant from $U^\flat$ depends on e alone. The sizes are

$$S_k^E = \sum_{i \le k} \omega_{k+1-i} e_i, \qquad S_k^R = \sum_{i \le k} \rho_i^2 r_i,$$
$$S_k^c \le C M^4 \sup_m \alpha_{0,m}^2 \, \mathsf{b}_\star.$$

Here c denotes the Wilson lag origin, $\mathsf{b}_\star$ bounds the increments of inverse coupling, and the source in the generating function is carried as an insertion in the unsourced step. The regular sum is at most CE_0 by eq. 4.cxcix. For the spectator-free remainders with $r_i \le C x_i^{-s}$ and $s > 2$, eq. 4.ccv bounds S_k^R by Cx^{2-s}. The Wilson size is bounded uniformly. In its formation the level-m Wilson members have size at most $C\alpha_{0,m}^2 (k - m + 1)\mathsf{b}_\star$; the spatial and layer sum is already taken in the displayed bound for S_k^c. Replacing it by the global supremum of $x_k(\cdot) - x_k$ would lose uniformity.

The source of the lag in the unsourced density is $\sum_{i \le k} b_i(1 - \varphi_i)$. When the profiles of healed regions are redrawn, their changes are compensated at each bare plaquette in the Wilson sum. The remaining lag is supported in the standing large-field region. On the clean box, including its trace window, every lag potential whose full carrier stays there vanishes, by the whole-lattice identification of the step potentials. An exterior lag can still vary with y through the background substitution. Use eq. 6.xvi for that localized origin. Its contributing carriers reach the nonempty trace, so the spatial rate can also pay for that distance. The bound without this extra distance gain already suffices here. With profiles kept before compensation, the same bound for the evaluated lag origin is used wherever the step estimate is admitted. A bound on the volume-weighted lag of an individual history cannot be attributed to a resummed class unless the lag is common to that class.

On the positive history resolution before this compensation, the weighted lag can be controlled without excluding all old creations under the box. Let n_j be the size of the level-j window. Count the older level-i cells under it whose profile φ_i is less than one somewhere. Each enters with weight $(j-i+1)L^{-4(j-i)}$. There are at most $Cn_jL^{4(j-i)}$ cells to test, and a profile can differ from one only next to a live or newly created cell at that level. The one-cell probability bound therefore gives the first moment of the weighted count:

$$\mathbb{E}\,\mathfrak{S}_j^{\mathrm{lag}} \le Cn_j \sum_{i<j}(j-i+1)e^{-cp_0(g_i)}.$$

Below the witness level n, the running lower bound $x_i \ge x_n+\lambda_\sharp(n-i)-C$ makes this series summable. Use half the exponent at x_n-C, and use the other half to dominate any fixed inverse power of x_n+n-i. Between n and the end of the fluctuation segment the couplings are comparable to that of the witness. Its logarithmic number of levels contributes only a polynomial prefactor. Markov's inequality at the threshold $\tau_\star n_j$, followed by the sum over the segment, gives an exceptional weight $Ce^{-c'p_0(g_n)}$ for fixed $\tau_\star>0$. This uses the volume of each fine cell in the window units. A count of all older test failures with unit weight would lose that factor. The bound concerns the positive refinement on which the lag is recorded. In the compensated class use the refiled exponent. A restriction by the finer lag event must use its own joint law.

On this finer resolution, fix the exterior and keep the original profiles in the Wilson exponent. On the admitted complex box for both matched fields, the curvature estimate bounds the difference of their plaquette actions per unit volume in window units by $Cg^2b_j^2$. A level-i cell occupies $L^{-4(j-i)}$ of a level-j cell. The running bound on the increments of inverse coupling bounds the missing profile coefficient there by $C(j-i+1)$ in the lag count. Summing the action differences over the lagging cells therefore gives

$$|\mathbb{P}_j^{\mathrm{lag}}| \le Cg^2b_j^2\,\mathfrak{S}_j^{\mathrm{lag}} \le Cg^2b_j^2\,\tau_\star n_j.$$

On a smaller concentric box the Cauchy estimate in two directions spends Cb_j^{-2}, so the Hessian has size $Cg^2\tau_\star n_j$. For its spatially weighted estimate the decay of the two matched minimizer responses is used on the same profile cells. These estimates read the lag at fixed exterior on the finer resolution.

At fixed exterior, subtract the value at one point y_* of the product window. A term independent of the interior coordinates then cancels. Each other full carrier meets a current cube of the box, with its prescribed fixed enlargement for pivot reads. After summing its old origins, root that carrier at such a cube. The strict rate reserve in eq. 6.xvi pays for the rooted count. This gives

$$\sup_{y\in\mathcal{W}_I}|P_{e,\mathrm{reg}}(y)-P_{e,\mathrm{reg}}(y_*)| \le Cn_j\vartheta_k(S_k^E+S_k^R+S_k^c),$$

with the ordinary defect size added if present. This is a current-scale count. The old base points of a regular activity have already been summed in its window, after the counterterm of that base point has been subtracted.

For surviving boundary and kept factors, apply the ordinary step estimates on the admitted support just described. The actual support point, including the cut strip point, lies in the half-radius domain of the substitution. The pinned levelling map uses the actual output datum and its transformed current. It preserves the stored arguments. Thus the identities for the two evaluated exponents use the same spectators, and their estimates apply at the original fixed exterior.

For the filed boundary system, apply the one-term-per-slot bound of Theorem 10(e) by origin, with its stored-field and dial domains. Its amplitude is $C\mathsf{B}\vartheta_k$ at the retained hull rate. Its carrier crosses the small-field boundary, with hull length at least $c_2L\check{R}_j-2$. For any fixed a the bound is $C_a\mathsf{B}\vartheta_k(\log\theta_k)^{-a}$ times the hull decay at a smaller rate. Spend a fixed part of the available rate on the crossing length and retain a rate above the rooted entropy. For a kept factor use its

inherited carrier oscillation bound. The factor form gives $C_a\mathsf{B}_\Phi\vartheta_k e^{-L\check{R}_j}$ times the same decay. In the difference at y and y_*, all terms depending only on the fixed exterior cancel.

The root cubes for the remaining terms lie outside the alive exempt hulls by the clean padding. The rooted sum eq. 6.xxxix thus gives, on labels with these inherited bounds,

$$Cn_j\vartheta_k(S_k^E + S_k^R + S_k^c + C_a\mathsf{B}(\log\theta_k)^{-a} + C_a\mathsf{B}_\Phi e^{-L\check{R}_j})$$

for the old oscillation, including the ordinary defect size when present. This application is to the real support. The induction of the inherited bounds on all surviving histories is a separate input to the exterior mixture.

6.3.0.17. Terms attached to healed regions. In the native positive history representation, a boundary term produced at healing is filed at its healing level. Its localization box can reach the read after the region has disappeared, or when the region lies outside the padded read. To use the estimate on attached terms, test the terms themselves. At read level j, an attached term X filed at $i' < j$ has weight $L^{-4\nu}x_{i'}^{2q+2}M_X d_{i'}(X)^2$, where $\nu = j - i'$, M_X bounds the term and $d_{i'}(X)$ is the size of its localization box in level-i' units. Sum over boxes meeting the read. The native localization estimate bounds the expectation per fine anchor by $CL^{-4\nu}x_{i'}^{2q+2}q_{i'}^{\mathrm{pk}}$, where $q_{i'}^{\mathrm{pk}}$ bounds the mass of the creation or healing event that supplies a term at that position. This uses the sum of $M_X d_{i'}(X)^2$ at a fixed anchor and the spatial decay for terms attached to regions away from the read. The fine-anchor count $Cn_jL^{4\nu}$ cancels the factor $L^{-4\nu}$. The per-bond version uses the same bound with the localization overlap constant.

With $q_{i'}^{\mathrm{pk}} \le Ce^{-c_{\mathrm{cr}}p_0(g_{i'})}$, the resulting level sum is bounded by $Cn_je^{-c_{\mathrm{cr}}p_0/2}$. For $i' < k_0$ use both running bounds on $x_{i'}$. Half the exponent controls the sum of the polynomial weights in $x + B_\sharp(k_0 - i')$, since $\mathfrak{p}_0 > 1$. The levels of the fluctuation segment have comparable coupling and logarithmic cardinality. Their polynomial prefactor is absorbed by the reserve in the exponent since $p_0(g_{i'})/p_0 \to 1$ uniformly in that segment. Markov's inequality at $e^{-c_{\mathrm{cr}}p_0/4}$ gives a failure mass at most $Cn_je^{-c_{\mathrm{cr}}p_0/4}$. This estimates the budget with all filing levels.

For the weighted derivative estimate on the older list $i' < k_0 - \mathfrak{l}$, use its axial-gauge representative and the vanishing first jet at the flat field. The Schwarz bound uses the fine fluctuation $CL^{-2\nu}g_jb_j$ and $(g_j/R_{i'}^{\mathrm{an}})^2 \le C(1 + B_\sharp\nu)$. Thus the term has second-order size at most $CM_X\kappa_{\mathrm{ax}}(X)^2L^{-4\nu}(1 + B_\sharp\nu)b_j^2$, where $\kappa_{\mathrm{ax}}(X)$ bounds the axial representative on the box. Apply Cauchy's estimate on the admitted tube for the Hessian. The weighted row sum contributes $(d_{i'}(X)L^{-\nu}+C)^4e^{c_P(d_{i'}(X)L^{-\nu}+C)}$. For the localized boundary terms the exponential uses part of their decay. For the frozen-coupling term the older-box bound $d_{i'}(X) \le 100M\check{R}_{i'} + C$ and the choice of the lag depth bound $d_{i'}(X)L^{-\nu}$ uniformly. The remaining factors are polynomial in the old inverse coupling, so the same first-moment argument applies with an enlarged fixed power. On this per-bond event the native gradient bound is $C\widehat{b}_j(b_j^2 + p_0(g_j))e^{-cp_0}$, with the pivot-map norm included in C. Integrating on the product window gives an oscillation at most $Cn_jb_j\widehat{b}_j(b_j^2 + p_0(g_j))e^{-cp_0}$, which can be added to the old oscillation when this decomposition is used. We must use the localization and derivative estimates for the actual terms of the conditional density. The all-filings mass estimate alone does not extend the older-list derivative bound to terms filed later.

For the native ordinary remainder, retain the localization of each term in the gradient estimate. The volume factor of a level-i' remainder cancels the number of its fine placements. The remaining old-level sum in the gradient is bounded by $Cg_jx_j^{(3-\kappa_0)/2}\,\mathrm{polylog}(x_j)$, with $x_j = g_j^{-2}$. At fixed background apply Cauchy's estimate in the second coordinate, including a coordinate of the exterior, on the joint window tube. Let m_j be the available complex coordinate margin there. Only terms whose read contains both coordinates can contribute. Their localization reserve pays the weighted

rooted sum, giving

$$\sup_b \sum_{b'} e^{c\,d(b,b')} |\partial_b \partial_{b'} P_j^{\mathbf{R}}| \le \frac{C}{m_j}\, g_j x_j^{(3-\kappa_0)/2} \operatorname{polylog}(x_j).$$

For the bound with b_j^{-1} one needs a complex margin proportional to b_j. An absolute or inverse-logarithmic margin still gives a small Hessian for the chosen $\kappa_0 > 4$. This estimate is for the ordinary remainder with its native localization and chart. The terms from marked or retained spectators need their own mixed bounds.

The per-bond event for this comparison is imposed on the incoming list of formed terms. At a compatible exterior keep its filing levels, localization boxes and recorded coupling lags, along with the spectators and the history data that determine this list. The geometric clean guard fixes the free-bond mask and each dependence shell. The bound M_X is a supremum on the admitted domain of the formed term, including its recorded lag factor where present. It is fixed as the real interior coordinate varies. The axial factor and the distance and count weights also depend only on this exterior record and the fixed geometry. The pass indicator for the budget is therefore an exterior factor on the whole product window. At a merge sum the positive incoming terms with their own list and indicator. A test on a list filed after this step must be imposed at its own incoming comparison or justified by the later-record kernel on the actual retained state.

Let $P_{e,\mathrm{old}}$ denote the sum of the admitted contributions just bounded. Suppose the resulting bound for $\sup_{\mathcal{W}_I} |P_{e,\mathrm{old}}(y) - P_{e,\mathrm{old}}(y_*)|$ is $\epsilon_j^{\mathrm{old}}$, uniformly over the exterior data. For each e, keep the same domain, quadratic extraction, intrinsic terms, stored variables and readout, and remove $P_{e,\mathrm{old}}$ only in an auxiliary normalized interior law E_e^{int}. Then

$$e^{-2\epsilon_j^{\mathrm{old}}} \le \frac{dE_e}{dE_e^{\mathrm{int}}} \le e^{2\epsilon_j^{\mathrm{old}}}.$$

Indeed the ratio is the remaining exponential divided by its mean under E_e^{int}. The estimate costs $(e^{2\epsilon_j^{\mathrm{old}}} - 1) \sup |G|$ for a bounded insertion, uniformly in ω and e. Integrate this bound against the original exterior mixing measure. The intrinsic box comparison and the flat read-set approximation are performed next, for each exterior, and have the same flat target.

The loss $C n_j (\log x)^{\mathfrak{p}_0 - q}$ uses one power of the window-to-radius ratio. It suffices for the generating function route with any fixed number of insertions by choosing q after the polynomial logarithmic losses in the source radii. A Hessian at fixed exterior cannot supply a derivative with respect to a different retained datum or a stored variable. Such a derivative would require one common analytic domain for the two complete evaluations. The normalized removal uses the real admission just proved on the conditional support, with its retained rows and margins. Each surviving boundary or stored factor must also retain its declared carrier and oscillation majorant at that evaluation.

Adding $a^{\mathsf{T}} y$ to P_e leaves its Hessian unchanged and changes its force by a. It translates the Gaussian mean even on all of $\mathbb{R}^n$. Centering a quadratic observable removes its scalar mean, but not the linear term caused by that field translation. We retain this term below.

Integration by parts with its boundary. Suppress e, let Q be real symmetric and invertible, and set $C = Q^{-1}$. Define

$$\mathcal{B}_j(F) = Z^{-1} \int_{\partial D} n_j(y) F(y) e^{-V(y)}\, dS(y). \tag{6.xvii}$$

The divergence theorem, with $\partial_j V = (Qy)_j - r_j$, gives

$$\mathbb{E}[(QY)_j F] = \mathbb{E}[\partial_j F + r_j F] - \mathcal{B}_j(F). \tag{6.xviii}$$

On a rectangle this is the difference of its two face integrals. The boundary has not been discarded.

The auxiliary linear-source function $M(z) = \mathbb{E}e^{z^{\mathsf{T}}Y}$ is entire on a bounded window. Since $M(0) = 1$, its logarithm $W(0) = 0$ is defined near zero. There put

$$\mathbb{E}_z F = \frac{\mathbb{E}(Fe^{z^{\mathsf{T}}Y})}{M(z)}, \qquad \beta_j(z) = \frac{\mathcal{B}_j(e^{z^{\mathsf{T}}Y})}{M(z)}. \tag{6.xix}$$

Apply eq. 6.xviii to the exponential and multiply by C. This proves the exact connected identity

$$\partial_i W(z) = \sum_j C_{ij}\{z_j + \mathbb{E}_z r_j - \beta_j(z)\}. \tag{6.xx}$$

The source here is an auxiliary linear field source. It is not an identification with a physical $\mathrm{tr}(F^2)$ numerator.

Let $m = \mathbb{E}Y$, let Σ be the covariance and let κ denote joint cumulants. Differentiation gives

$$\begin{aligned}
m_i &= \sum_j C_{ij}\{\mathbb{E}r_j - \beta_j(0)\},\\
\Sigma_{ia} - C_{ia} &= \sum_j C_{ij}\{\kappa(r_j, Y_a) - \partial_a\beta_j(0)\},\\
\kappa(Y_i, Y_a, Y_b) &= \sum_j C_{ij}\{\kappa(r_j, Y_a, Y_b) - \partial_a\partial_b\beta_j(0)\},\\
\kappa(Y_i, Y_a, Y_b, Y_c) &= \sum_j C_{ij}\{\kappa(r_j, Y_a, Y_b, Y_c) - \partial_a\partial_b\partial_c\beta_j(0)\}.
\end{aligned} \tag{6.xxi}$$

Each derivative differentiates the numerator and $1/M$. The first produces a covariance; the next remove the disconnected partitions and give the mixed cumulants. Equivalently, compare the convergent local power series in eq. 6.xx.

Put $Z_a = Y_a - m_a$. The boundary derivatives are explicitly

$$\begin{aligned}
\beta_{j,a}(0) &= \mathcal{B}_j(Z_a),\\
\beta_{j,ab}(0) &= \mathcal{B}_j(Z_aZ_b) - \Sigma_{ab}\mathcal{B}_j(1),\\
\beta_{j,abc}(0) &= \mathcal{B}_j(Z_aZ_bZ_c) - \Sigma_{ab}\mathcal{B}_j(Z_c) - \Sigma_{ac}\mathcal{B}_j(Z_b)\\
&\quad - \Sigma_{bc}\mathcal{B}_j(Z_a) - \kappa(Y_a, Y_b, Y_c)\mathcal{B}_j(1).
\end{aligned} \tag{6.xxii}$$

These follow by differentiating the quotient. In particular an unnormalized face-moment estimate is not automatically the same estimate for a connected boundary derivative.

Replacing traces by weighted collar moments. On the product window $D = \prod_b K_b$, let $b(j)$ be the bond carrying the coordinate j. Choose ψ_j depending only on $y_{b(j)}$, vanishing near $\partial K_{b(j)}$, equal to one off its collar of width δ_j, with $|\partial_j\psi_j| \le c/\delta_j$. Integration by parts in the j direction has no boundary contribution for $\psi_j e^{z^{\mathsf{T}}y}$: on the $b(j)$ face the cutoff vanishes, and the other faces have zero j-normal component. Equivalently, use Fubini and integrate only in the factor $K_{b(j)}$. Comparing it with eq. 6.xviii proves

$$\mathcal{B}_j(e^{z^{\mathsf{T}}Y}) = -\mathbb{E}\left[e^{z^{\mathsf{T}}Y}\{\partial_j\psi_j + (1-\psi_j)((QY)_j - r_j(Y) - z_j)\}\right]. \tag{6.xxiii}$$

Indeed the compactly supported formula equates $\mathbb{E}[\psi_j(QY - r)_j e^{zY}]$ with $\mathbb{E}[(\partial_j\psi_j + z_j\psi_j)e^{zY}]$. Adding the part with $1 - \psi_j$ gives the sign and terms above.

Thus moments of the form

$$\mathbb{E}\Big[1_{\mathrm{collar}}(1 + |Y|_{\mathrm{loc}})^q\{\delta_j^{-1} + |(QY)_j| + |r_j(Y)| + 1\}\Big] \tag{6.xxiv}$$

control the corresponding numerator derivatives, with the collar of the single bond $b(j)$. The local norm means the finite tested coordinate list with its specified weights. The derivatives of $1/M$ also use its ordinary moments.

Up to order three there are only finitely many product and quotient terms. If their ordinary moments are uniformly bounded and the weighted collar moments are $O(\epsilon)$, the boundary derivatives in eq. 6.xxi are $O(\epsilon)$ with the resulting finite moment factors. This follows directly by differentiating eq. 6.xxiii and eq. 6.xix. An unweighted collar probability does not prove eq. 6.xxiv; polynomial losses in the force and cutoff remain.

For a bond in the buffered interior the normalized box comparison supplies one way to bound this moment. Suppose the marginal at that bond has density ratio at most e^{Ξ} relative to the reference on the same product window. At the reference, the Gaussian is centered, the coordinate variances are uniformly bounded, the full window has Gaussian probability at least $1/2$, and the tilt has uniformly bounded oscillation. If the bond window contains the Euclidean ball of radius $c_0 b$, a collar of Euclidean width at most $c_0 b/2$ is contained in $\{|y_{b(j)}| \geq c_0 b/2\}$. The Gaussian one-bond tail, divided by the full window probability and multiplied by the exponential of the tilt oscillation, is at most Ce^{-cb^2}. The density ratio transfers this bound at the same bond with factor e^{Ξ}.

On the product window, the uniform precision row bound gives $|(QY)_j| \leq Cb$. The retained linear force and the perturbation gradient use their admitted row bounds. When these, the tested coordinate sizes and the inverse collar width are bounded by fixed powers of $1 + b$, eq. 6.xxiv is bounded by a polynomial in $1+b$ times $e^{\Xi - cb^2}$. This uses the density comparison at the differentiated bond, with its full read margin. The bound is uniform over exterior data for which these constants are uniform, and passes to their positive mixture.

In eq. 6.xxi, the boundary derivatives are contracted against a row of the Gaussian inverse. Take a tested coordinate at depth at least $2D_0$ from the edge after accounting for its read. For bonds at distance at most D_0 from this coordinate, use the collar bound with the common buffer. On the remaining bonds use the deterministic polynomial bound in eq. 6.xxiv from the full window and the uniform force and gradient bounds. The weighted row estimate for the inverse makes the contribution of these remaining bonds at most $C\,\mathrm{poly}(1 + b)e^{-cD_0}$. The quotient derivatives use only moments of the fixed tested list, so they retain the same split.

When e varies, the bound must be uniform in e or integrated in the order specified by the actual exterior law. A fixed-exterior bound is not a uniformly integrable envelope. This matters for a clean restriction formed by healed components.

The covariance of quadratic insertions. Let

$$O_i = Y^{\mathsf{T}} A_i Y + b_i^{\mathsf{T}} Y + c_i, \qquad A_i^{\mathsf{T}} = A_i, \qquad d_i = b_i + 2A_i m. \tag{6.xxv}$$

Only the symmetric part contributes to a scalar quadratic form. Expansion at $Y = m + Z$ gives $O_i - \mathbb{E}O_i = Z^{\mathsf{T}} A_i Z - \operatorname{tr}(A_i\Sigma) + d_i^{\mathsf{T}} Z$. Multiplication yields

$$\begin{aligned}\operatorname{Cov}(O_1, O_2) = {} & 2\operatorname{tr}(A_1\Sigma A_2\Sigma) + d_1^{\mathsf{T}}\Sigma d_2 \\ & + \sum_{a,b,c} (A_1)_{ab}(d_2)_c \kappa(Z_a, Z_b, Z_c) \\ & + \sum_{a,b,c} (A_2)_{ab}(d_1)_c \kappa(Z_a, Z_b, Z_c) \\ & + \sum_{a,b,c,d} (A_1)_{ab}(A_2)_{cd} \kappa(Z_a, Z_b, Z_c, Z_d).\end{aligned} \tag{6.xxvi}$$

The fourth centred moment is its fourth cumulant plus three pairings. Subtracting the quadratic means removes $\Sigma_{ab}\Sigma_{cd}$. The other two pairings contract to the trace above. The mixed terms give the third cumulants, and the two linear terms give $d_1^{\mathsf{T}}\Sigma d_2$. This accounts for every term.

The centred Gaussian reference with covariance C_0 and purely quadratic insertions is $2\operatorname{tr}(A_1 C_0 A_2 C_0)$. Its identification needs the mean term, covariance discrepancy and third and fourth cumulants in the actual tested contractions.

For one sufficient dimension-explicit estimate put

$$a_i = \sum_{a,b} |(A_i)_{ab}|, \quad v_i = \sum_a |(d_i)_a|, \qquad \|\Sigma\|_{\max}, \|C_0\|_{\max} \le K. \tag{6.xxvii}$$

If $\|\Sigma - C_0\|_{\max} \le \epsilon_2$ and the tested third and fourth cumulants are bounded by ϵ_3, ϵ_4, then

$$\begin{aligned} &|\operatorname{Cov}(O_1, O_2) - 2\operatorname{tr}(A_1 C_0 A_2 C_0)| \\ &\quad \le 4K\epsilon_2 a_1 a_2 + K v_1 v_2 + \epsilon_3(a_1 v_2 + a_2 v_1) + \epsilon_4 a_1 a_2. \end{aligned} \tag{6.xxviii}$$

Expand one covariance factor at a time in the trace. Each product differs by at most $2K\epsilon_2$, and the prefactor two gives the first term. Absolute summation gives the others. Weighted localized variants use the same actual contractions.

If $a_i \le Cr^4 \|f_i\|_\infty$ and $r \le C(\log x)^{p_r}$, the first and fourth errors cost $(\log x)^{8p_r}$. They require $\epsilon_2, \epsilon_4 = o((\log x)^{-8p_r})$ to be $o(\|f_1\|_\infty \|f_2\|_\infty)$. A claim that errors merely tend to zero does not suffice. The other rates are read from the mean and third-moment terms.

Each physical quadratic insertion ordinarily carries g^2, so the reference covariance carries g^4. Its errors and the physical remainders must be small relative to that signal. A fixed source-disc estimate cannot replace a missing potential normalization by an inverse power of g.

Exterior averaging adds the conditional means. Suppose the resummed representation has a positive probability realization with exterior variable E, clean event A and correct observable pullbacks. Conditional expectation gives

$$\begin{aligned} \operatorname{Cov}(O_1, O_2 \mid A) = \mathbb{E}\{&\operatorname{Cov}(O_1, O_2 \mid E, A) \mid A\} \\ &+ \operatorname{Cov}(\mathbb{E}(O_1 \mid E, A), \mathbb{E}(O_2 \mid E, A) \mid A). \end{aligned} \tag{6.xxix}$$

Add and subtract the product of conditional means to prove it. It applies to a positive conditional law, not separately to signed expansion terms.

Choose one deterministic number a_i^0 per observable and prove

$$|\mathbb{E}(O_i \mid e, A) - a_i^0| \le \delta_i \quad \text{for every admitted clean } e. \tag{6.xxx}$$

Then the last covariance in eq. 6.xxix has absolute value at most $2\delta_1\delta_2$. Choosing a different reference for every exterior would not prove this. The backgrounds, insertion coefficients and conditional moments need one common reference.

Put $q = \mathbb{P}(A^c)$, assume $0 < q < 1$ and $|O_i| \le B_i$ on the whole positive probability space. Decomposing by A gives

$$\begin{aligned} \operatorname{Cov}(O_1, O_2) = (1-q)\operatorname{Cov}(O_1, O_2 \mid A) + q\operatorname{Cov}(O_1, O_2 \mid A^c) \\ + q(1-q)(m_1^A - m_1^{A^c})(m_2^A - m_2^{A^c}). \end{aligned} \tag{6.xxxi}$$

If every clean conditional covariance differs from a fixed Γ by at most ϵ, this implies

$$|\operatorname{Cov}(O_1, O_2) - \Gamma| \le \epsilon + 2\delta_1\delta_2 + q(6B_1B_2 + |\Gamma|). \tag{6.xxxii}$$

The bad covariance is at most $2B_1B_2$ and the product of mean differences is at most $4B_1B_2$. These prove the constants. At $q = 0$ use the clean formula directly; at $q = 1$ there is no clean estimate to use.

For unbounded insertions retain the marked bad-event moments. For instance Cauchy–Schwarz bounds $|\mathbb{E}[1_{A^c} O_1 O_2]|$ by $(\mathbb{E}[1_{A^c} O_1^2])^{1/2} (\mathbb{E}[1_{A^c} O_2^2])^{1/2}$. Centering also requires the corresponding first moments. A bad-event probability alone does not bound them.

An unnormalized clean sum has to be divided by its actual mass. Source derivatives of that scalar contribute unless the exact numerator and denominator have already been realized as this conditional probability. A normalizer from another volume or resolved class cannot be substituted.

Uniform shapes and the remaining model estimates. The required positive shapes have $f_i \geq 0$, support diameters $O(d)$, separation between d and $6d$, and

$$\int f_i \geq \vartheta d^4 \|f_i\|_\infty, \qquad \|\nabla f_i\|_\infty \leq C_{\mathrm{shape}} d^{-1} \|f_i\|_\infty. \tag{6.xxxiii}$$

The integral against $|x-y|^{-8}$ has a lower bound $c_\vartheta \|f_1\|_\infty \|f_2\|_\infty$. The maximum distance is a fixed multiple of d and the two masses supply d^8. The free comparison theorem gives the lattice version at sufficiently fine compatible mesh, with this uniform derivative bound. In fact, partition into mesh cells of side $a \leq d$. The oscillation on each cell is at most $Ca\|\nabla f_i\|_\infty$. Only cells in the support enlarged by Ca contribute, whose total volume is $O(d^4)$ by the diameter condition. Therefore the Riemann mass error is at most $CC_{\mathrm{shape}}(a/d)d^4\|f_i\|_\infty$, uniformly in the position of the support. Taking $a/d \leq c\vartheta/C_{\mathrm{shape}}$ gives sampled mass at least $(\vartheta/2)d^4\|f_i\|_\infty$. The actual source class permits $C_{\mathrm{shape}} = \vartheta^{-1}$, in which case a sufficient floor is $a/d \leq c\vartheta^2$. Alternatively the sampled mass itself can be imposed. Smoothness and continuum mass without a uniform derivative bound do not supply this floor.

All errors in eq. 6.xxxii, with physical remainders, must be $o(g^4\|f_1\|_\infty\|f_2\|_\infty)$ uniformly on the whole shape class, positions and required reference volumes. The fixed $\vartheta = 1/12000$ allows dependence on that value followed by one uniform cutoff floor.

A reference estimate uniform along arbitrarily large tori at each fixed datum and test pair passes to a reference infinite-volume state and uses common-normalizer transfer. An estimate only on one prescribed finite torus needs the separate finite-reference and vacuum comparison. These are alternatives; neither follows from a local kernel.

The first remaining task is the literal identity in eq. 6.xi, with the actual exterior sigma-field, domain, numerator and normalizer. Next bound the complete Hessian and the individual forces. Then bound the tested connected force and boundary quantities in eq. 6.xxi, using either the trace or collar identity. The common-reference mean comparison in eq. 6.xxx and marked bad moments are separate. Their rates must dominate the window and coefficient losses in eq. 6.xxviii.

These estimates would supply the interacting covariance on the run route. The proved free, remainder and state-transfer implications then have their needed inputs. The alternative averaging-fibre route additionally requires its measure and carried-weight identification; it is not an extra conjunct once the run route closes.

6.3.1. *A clean collar and the actual local filing.* A local term made inside a sufficiently clean collar uses the whole-lattice recipe. The collar must contain the actual trace window, which includes a layer of cells of side $M\check{R}_j\xi_j$. A layer of $M\xi_j$-cubes is smaller and does not suffice for that assertion. We first prove the geometric and finite-filing statements, then sum the boundary tails. The whole-lattice comparison keeps the same input list; in particular it does not erase regular marked members produced by healed histories.

6.3.2. *The two grids and the trace window.* Use physical spacings $\xi_j = L^j\xi_0$. Let π_j be the grid of cubes of side $M\xi_j$, and let $\mathcal{P}_j$ be the cell grid of side $M\check{R}_j\xi_j$. The grids and all labels are the ones fixed by the run. Assume the actual cube ratio

$$\check{R}_j \leq L\check{R}_{j+1}, \qquad j < n. \tag{6.xxxiv}$$

Thus the physical cell size is nondecreasing: $\check{R}_j\xi_j \leq \check{R}_n\xi_n$. Distances in current cube units mean physical distance divided by $M\xi_n$, using the periodic graph metric when needed.

For a region X, its trace window X^{+1} rounds it out, at each level j, to all cells of $\mathcal{P}_j$ that meet it, and adds one cell layer. Include the fixed finite additional layers used by the actual step in this definition. Let c_{tr} be a bound for their number. Rounding and adding these layers gives the explicit inclusion

$$X^{+1} \subset \{x : \mathrm{dist}_\infty(x, X) \leq C_{\mathrm{tr}} M\check{R}_n\xi_n\}, \qquad C_{\mathrm{tr}} = C(1 + c_{\mathrm{tr}}). \tag{6.xxxv}$$

Indeed rounding to one cell moves each coordinate by at most one cell side; every additional layer costs at most one more. Apply eq. 6.xxxiv at each level. No sum over the number of levels occurs, because the window is the union of these levelwise neighborhoods, not their successive enlargement.

Let $\mathcal{S}_n$ be a standing label and put $Z_n = \Lambda_n^c$. For W, a set of current cubes, write W_R for its R-neighborhood in current cube units. The clean-collar condition used below is

$$W_R \subset \Lambda_n, \qquad s := R - C_{\mathrm{tr}}\check{R}_n - C_0 > 0. \tag{6.xxxvi}$$

Here C_0 covers the fixed cube collars of the local potential and integration formulas. They are specified as part of the recipe, rather than changed after a bound is proved.

6.3.3. *What remains in a standing history.* The standing part deletes the entire cluster of each healed component. All data which are still stored belong to an island, a drop-out or an unhealed component. The following conclusion uses this actual deletion rule.

Lemma 6.5 (The standing trace in the clean region)**.** Every retained date, mark and stored variable of a standing history of level n lies in Z_n, with at least one endpoint there for a stored bond. Outside Z_n, the action and determining sequences have no remade layers and coincide with the all-small-field sequences. Consequently the standing trace and its reading on X^{+1} are empty when $X^{+1} \subset \Lambda_n$. ■

Proof. Induct on the moves of a step. A new large-field outcome is recorded only on the component where its test fails; it is contained in that step's large-field region. At a subsequent step, an old component and all its standing contents are either carried, merged into another live component, or treated by the large-field operation. Carrying and merging retain the contents inside the new live component. An island or a drop-out retains its contents inside its own component. Healing deletes that component's entire cluster, including its older dates, fields, frames and marks; none of those deleted variables remains as a free integration variable in the standing part.

The only modifications of an earlier label sequence take place inside a component of a later operation. If the component is healed, its old regions are replaced by the healed output. If it remains standing, it lies in Z_n. The remade levels in eq. 2.xxii are modified inside precisely such a standing drop-out. Hence no remade layer survives outside Z_n. The nested unmodified label regions give the all-small-field sequence there. This proves the induction. An empty trace follows by restriction to X^{+1}. □

An alive island I has a hull $[I]_j$, the union of the closed level-j cubes meeting I. At birth this gives the one-layer enlargement. The nested partitions give

$$([I]_j)^{\uparrow n} = [I]_n, \qquad [I]_n \subset Z_n^{\sim c_I}, \tag{6.xxxvii}$$

where c_I is the fixed hull collar. The first identity uses the same standing island on both sides; an island absorbed before level n is no longer in this family. The second follows from seating of an alive island in the final live region and from the definition of its hull. Thus an alive exempt hull cannot enter the interior of a collar which excludes $Z_n^{\sim c_I}$. The possible failure of a finer place condition inside a remade drop-out occurs in Z_n and does not change this conclusion.

The hulls have a bounded corner multiplicity. Write u_j for the physical side of a level-j localization cube and b_i for the physical side of a level-i history cell. An island born at i has sides between $21b_i$ and $100b_i$. Its level-j hull has sides at most $100b_i + 2u_j$, hence at most $100\check{R}_j + 2$ cubes per direction since $b_i \le b_j$. Use the torus margin $204b_j < \ell$ for the following count. If a hull contains a corner v, its island meets the box of radius u_j about v, and both lift into the box of radius $102b_j$ about the lifted corner. When $21b_i \ge u_j$, the island contains a box of side u_j within the box of radius $2u_j$ about that corner. Distinct such islands are disjoint, so volume comparison gives at most 4^4 of these boxes. When $21b_i < u_j$, each island side is shorter than $5u_j$ and each hull side contains at most six cubes. An aligned interval of length nu_j containing the corner has at most

$n+1$ positions. Summing over $1 \le n \le 6$ gives at most 27^4 distinct small hulls containing the corner. The exempt family consists of geometric hulls, so coincident hulls count once here. Thus $m_H \le 4^4 + 27^4$, also for the surviving subfamily or its hulls on the next grid with the same torus margin.

6.3.4. *Equality of the filed recipes.* We use the actual local representation of the step: walk terms are filed at their full carriers; pivot charts, means and Jacobians carry their defining double blocks; Mayer selections retain the whole selected potential domain; a cutoff selection retains its bond collar; and a connected logarithmic term is filed at the union of its polymer domains. The normalized Gaussian functions are restricted by their prescribed hereditary rules. These are the literal recipes of § 4.5, not merely numerical bounds on a gas. Every dependency must be included in the carrier before this convention is applied.

Proposition 6.6 (The whole-lattice recipe on an empty trace)**.** Fix the reference numbers, the physical action weights and one coherent input list. Let $E_h(X,\cdot)$ be a filed term made from a standing history h, and let $E_\emptyset(X,\cdot)$ be the term made by the whole-lattice step with that same input. If $X^{+1} \subset \Lambda_n(\mathcal{S}_n)$, then

$$E_h(X,P) = E_\emptyset(X,P) \tag{6.xxxviii}$$

on every common admitted local pair domain. The assertion applies to the local Gaussian normalizer, the mismatch leg, the interaction terms, and their declared pointing. It asserts equality of functions at the same pair P, rather than equality of two generally different global backgrounds. ■

Proof. By Lem. 6.5, the trace on the entire set of cells used by a carrier in X is empty. The local regions, tiers and integration-bond types therefore coincide with the whole-lattice ones. In particular a carrier contained in X has no external or crossing integration bond. Its cutoff has the ordinary full threshold. A mean term whose full carrier is contained in X cannot reach an external bond, so that term is zero. The unlocalized global Gaussian mean can still contain walks from the exterior; their full carriers are not contained in X.

Each local differential coefficient and each walk term depends only on the pair, regions and bonds in its full carrier. At the same P, these data agree.

For the axial Gaussian, include the multiplier in this carrier check. The second variation of the pivot row is local to its double block, but it is paired at the pivot with the restricted value of $\mathsf{H}_1^{\mathsf{T}}\mathbf{J}$. Expand this multiplier into its own walk terms before filing the pivot contribution. Attach each such walk at the pivot and retain its padded hull and current read. For the same indexed tree in the two axial kernels, match every layer on that hull and the admitted pair at its inner bonds. The active mask is the same on bonds with both endpoints in the hull. The extensions by zero and restrictions therefore give the same matrix entries in the two settings, term by term. This gives equality for the native axial covariance and precision terms after the free-coordinate and mask identifications. If every term shorter than m_0 matches, the two remaining native tails give a kernel difference bounded by

$$C2^{-m_0} e^{-\delta d_{\mathrm{ax}}(b,b')},$$

where d_{ax} is the distance between bond origins in the axial lattice units. Indeed the absolute sum at length m has the bound $C2^{-m-1}$ times this spatial exponential. Summing the geometric series and then the rows and columns with a smaller spatial weight gives the weighted Schur bound $C2^{-m_0}$. An escaping multiplier branch is part of this same tail.

A local pivot chart and its coarea factor agree by uniqueness of their admitted local solution. The contour gauge and its normalizer use the same contours and reference weight. Coherence of the input identifies each old activity and its own counterterm used in X. Hence all individual potentials agree, including the fields and current produced by their prescribed local substitutions. This last assertion is on their common admitted domain; it does not enlarge either domain.

Now apply the finite expansion. A Mayer term is a product of the same selected potentials and the same cutoff indicators. Its local Gaussian functional has the same coefficients and the same real integration variables. Every coarse-parameter derivative and integral in its polymer activity therefore agrees. A logarithmic term on X uses only polymers contained in X, evaluated by hereditary restriction, so every summand in its connected series agrees. Absolute convergence, or equality at each finite truncation followed by the same absolute majorant, proves eq. 6.xxxviii. Bond roots and midpoint tents are the same in both recipes, so the conclusion also passes to their actual pointing. □

The same proof shows that a nonzero difference between the two recipes must have a carrier whose trace window meets the nonempty standing trace. It cannot be filed on an interior domain and then assigned a different, smaller carrier.

6.3.5. *Hull entropy rooted outside the exempt regions.* We supply the geometric sum needed for old boundary terms. On the grid of level j, let H_j be the hulls of the islands still alive at level n. Their multiplicity at a cube corner is at most m_H. Define $d_j^\natural(X)$ by minimizing the length of a tree of cube edges in X, which meets every cube outside a selected subfamily of complete hulls and meets every selected hull. Edges inside a hull still cost their ordinary length; only the requirement to visit all its cubes is removed.

Lemma 6.7 (A root sum independent of island sizes)**.** If the cube q is contained in no exempt hull, then for $\kappa > c_E$,

$$\sum_{X \ni q} e^{-\kappa d_j^\natural(X)} \le C_H \sum_{m \ge 0} e^{-(\kappa - c_E)m}, \qquad c_E = 2\log 8 + (16 + m_H)\log 2. \tag{6.xxxix}$$

The same count with a given root vertex v holds for domains whose chosen minimizing tree contains v, including vertices in an exempt hull. It also bounds the sum restricted to tree lengths $m \ge D$ by starting the series at D. The constants are independent of the side lengths and volumes of the hulls, the torus size and the number of levels. ■

Proof. Choose, for each X, a minimizing tree and an exempt subfamily by a fixed ordering. Its length in cube-edge units is an integer m. Since q is not exempt, the tree meets one of its at most sixteen corners. Root it at the first such corner. A tree with m edges has a depth-first tour of length $2m$; the lattice graph has degree at most eight. There are at most $16 \cdot 8^{2m}$ choices for this rooted tree, with an overcount which only helps.

Every nonexempt cube of X meets a tree vertex, and at most sixteen cubes meet one vertex. Every selected hull also meets a tree vertex, and at most m_H hulls pass through that vertex. Thus X is recovered by at most $16 + m_H$ binary choices per vertex: choose the incident cubes and the full hulls. There are at most $m+1$ vertices. This gives at most $16 \cdot 8^{2m} 2^{(16+m_H)(m+1)}$ encoded domains. The description is permitted to count disconnected or inadmissible choices as well. Summation with $e^{-\kappa m}$ proves eq. 6.xxxix. For a specified vertex root the same encoding starts at that vertex, and the factor sixteen for its choice is unnecessary. Large hulls add one choice, rather than their volume. □

Lemma 6.8 (A carrier crossing the clean collar)**.** Suppose a level-j carrier meets W, and its trace window meets the standing trace. Under eq. 6.xxxvi and eq. 6.xxxvii, after increasing C_0 by the fixed hull collar,

$$d_j^\natural(X) \ge c_* L^{n-j} s - C_*. \tag{6.xl}$$

The constants depend on the fixed grids and collars only. ■

Proof. The trace padding eq. 6.xxxv shows that the carrier reaches to current distance at least s from W. All current coarsenings of its exempt hulls lie outside the clean interior by eq. 6.xxxvii. An admissible tree must therefore meet a cube near W, which is not exempt, and either a second

nonexempt cube at distance at least s, or a selected hull outside that interior. In the latter case the tree still has to reach that hull. Its connecting path pays ordinary geometric length, including every portion inside a hull.

In physical units that path has length at least $cM\xi_n s - CM\xi_j$, allowing for the two touched cube corners. Division by $M\xi_j$ gives eq. 6.xl. The same argument on the periodic graph uses its intrinsic distance. It does not assume that the whole torus has one nonwrapping chart. □

6.3.6. *Summing old boundary origins in their actual units.* Let the observation region contain N_W current cubes. It meets at most $CL^{4(n-j)}N_W$ cubes at level j. Allow a fixed-origin multiplicity A_j, and suppose the actual local boundary majorants satisfy

$$b_j(X) \le B_j e^{-\kappa d_j^{\natural}(X)}, \qquad A_j B_j \le B_*(1+n-j)^p L^{q(n-j)}. \tag{6.xli}$$

In this hypothesis $d_j^{\natural}$ uses only hulls still alive at the final level n. This is an explicit admission condition on the surviving boundary filing, not a consequence of a creation-time bound using a larger exempt family. A term whose carrier contains no island absorbed between j and n has the same two lengths, so its old bound suffices. At an absorbed hull use the refiling described below.

A simple example shows the necessity. Let H be a large exempt box and q an adjacent cube. The old hull length of $H \cup q$ is zero. After H is removed from the exempt family, a covering tree must visit its many cubes and has length tending to infinity with their number. A bounded nonzero function filed on $H \cup q$ can satisfy the old majorant and fail every proposed bound with the same amplitude and the new length. Deleting the hull from the norm without refiling the function is therefore invalid.

6.3.6.1. Boundary terms at an absorbed island. If a carrier X of origin level j contains the level-j hull of an absorbed island, X meets the treated region and enters the near list of that operation. Consume the old member in the localized interaction. Fill its slot from the reduced history obtained by erasing the past of the treated components, and subtract that same replacement in the localized interaction. The erased history is a genuine history by the reduction rule. The two changes preserve the sum of the exponents.

For an old boundary slot its donor has the same surviving hulls in X as the completed label, so its hull length equals the required output length. At the new level the donor's length is at least the required length. Carry the actual donor member with its birth core and its own level and origin constant. Members made by the current operation use their new bounds, and the pointed regular entries are formed anew with the output base points. Each slot holds one term, and at most four boundary origins occur at one level and carrier. This transfers the decay to the output length without using the old member's discount for the absorbed hull.

At the new level t there is also a change of slot for a domain disjoint from the treated region. Put $A = \Lambda_t(\mathcal{S}^+)$ and write Z_1, Z_2 for the unions of treated components of the first and second classes. The two output action regions are $A \cup Z_1$ and $A \cup Z_1 \cup Z_2$. The one-layer window X_t^{+1} can reach one of the treated components even when X does not. The window criterion tests the new filing by inclusion of X_t^{+1} in these regions. For a former $\mathbf{T}$-boundary member with X disjoint from the treated region, if an outside cell of its window survives, the member remains in the $\mathbf{T}$ slot. If all those cells are treated and at least one is in Z_2, the member goes into the island remainder slot H. If all are in Z_1, it goes into the regular remainder range.

The unpointed contribution supplied by $\mathbf{T}$ occupies exactly one of these places. The change of filing gives no second copy of the function. The rule that treats a carrier as near whenever its window meets the treated region supplies the same member as the rule by slots, from the reduced history. In particular a member in the regular remainder range is supplied on that range in the donor's pre-healing label. On the narrower carry region we must identify the passed function with that member before applying its regular remainder bound. Use the comparison of the unfiled functions under erasure of the deleted histories, with its carrier and stage hypotheses. For the

pointed sum, split the old exterior base points into the still exterior points and the points newly in the one-layer erosion of $A \cup Z_1 \cup Z_2$. The latter points enter the regular sum once.

Apply the carriage bound to the standing list of an output label. At a level and carrier the bound is per origin. A carried or donor member occupies that slot with its own bound. A member formed at this step occupies its new slot. The bounds for the nonpointed origins are therefore returned with amplitude

$$\max\{\mathsf{B}_{\mathrm{in}}, \mathsf{B}^{\mathbf{T}}, \mathsf{B}^{\mathbf{S}}, \mathsf{B}^{\mathbf{R}}\}$$

in the output hull length. For the pointed origin use the new sum of regular members over its output base points. Its bound is the pointed norm summed over those points.

For the ordinary formation the localized Gaussian normalizer has amplitude B_{N}. The other three boundary kinds have amplitude at most one each on the declared step box once the coupling ceiling makes their fluctuation factor times the inherited sizes small. Thus $\mathsf{B}^{\mathbf{T}}$ can be taken as $\mathsf{B}_{\mathsf{N}} + 3$, with the ceiling chosen after the inherited bounds. The stage and main-step origins require their own formation amplitudes on their actual domains.

For the interaction part of the stage amplitude, factor the old term evaluated at the new stage background with zero collar field out of the stage integral. The integrated field's switch is removed at that evaluation. The remaining potential is its difference from that evaluation. Each cluster of the input-dependent logarithm therefore contains such a difference vertex. The stage Cauchy bound gives it a factor $CB_*(\log \theta_t)^{-e}$, where B_* bounds the inherited entries on the admitted collar charts. Sum the rooted cluster bounds over the performed stages. Even when the collars overlap, the count is at most $C(\log \theta_t)^r$, and $e > r$ gives a uniform bound at the stage rate. The input-independent normalizers use their own summability estimate, with the field-independent scalars kept outside the carrier logarithms. For a fixed domain, the sum of the stage terms formed on it occupies one stage slot. The Wilson profile differences enter the action profile sum separately.

The identity on the retained variables of a standing list is the sum over the real histories that return it. The resulting measure uses these filed terms and keeps the stored variables of that list. Hence a uniform bound over the actual output lists gives the bound at the next exterior disintegration, which uses this positive measure. There is no separate exponent of each history in that sum.

The same filing applies at source w and at zero. A carried or refilled member keeps its birth function and field space. The output read uses the cut old list and the restriction of the stored tuple to the carrier. At the fields already integrated by a stage, the old function is read at zero and the associated parameters are omitted. This restriction is independent of w.

On the fixed source class of radius r_{s} at a stop k, the sourced step bounds the difference of a boundary member from its zero-source value by

$$2r_{\mathrm{s}}^{-1}\|w\|_{\flat,K-k}\, B_{j,o} e^{-\kappa d_j^{\natural}(\mathcal{S};X)}.$$

Here $B_{j,o}$ is the boundary majorant's amplitude at origin o and $\mathcal{S}$ is the label at which the member is read. The difference reads w on $X^{\sim}$. At a refilled slot the donor length is at least the required output length, so apply the same bound to the restriction on the output list. Apply the sourced formation estimate to each newly formed boundary member on its own domain. The pointed origin uses its new sum of pointings, with the spare decay paying their count. Repeating the step yields the bound in the surviving hull norm at the witness, on the same source class. This uses the sourced induction with its frozen frame, tube room and constant-source data. The output evaluation must lie in the native restricted field space.

A polynomial in $\log \theta_n$ can be included in B_*. The factor A_j counts the actual origins and slot multiplicities; a fine-origin incidence is not counted as one coarse incidence. Suppose every term being summed has a boundary carrier as in Lem. 6.8.

Proposition 6.9 (The old boundary tail)**.** If $\kappa/2 > c_E$, there are $s_*, c, C > 0$, depending on the displayed rates and powers but not on n, such that for $s \geq s_*$,

$$\sum_{j\leq n} A_j \sum_{\substack{X \text{ meeting } W \\ X \text{ has a boundary carrier}}} b_j(X) \leq CB_* N_W e^{-cs}. \tag{6.xlii}$$

The same estimate bounds the oscillation when $b_j(X)$ is a bound on the complete evaluated local term on one common chart; subtraction of two values costs a factor two. ■

Proof. Root a domain at a fine cube meeting W. None of these cubes is contained in an exempt hull. Spend half its decay on eq. 6.xl, and sum the remaining half with Lem. 6.7. The level-j contribution is bounded by

$$CB_j A_j N_W L^{4(n-j)} e^{-c\kappa L^{n-j} s}.$$

Put $a = n - j$. Equation eq. 6.xli leaves the scalar sum $\sum_{a\geq 0}(1+a)^p L^{(q+4)a} e^{-c\kappa L^a s}$. Factor out $e^{-c\kappa s/2}$. The remaining sum is uniformly bounded for $s \geq s_*$: its ratio at successive integers is bounded by a fixed power times $e^{-c\kappa s(L-1)L^a/2}$, which is at most one half once s_* is fixed sufficiently large. The finite initial factor is harmless. This proves eq. 6.xlii without a cutoff-dependent sum over old levels. □

For example, choose

$$R \geq C_{\mathrm{tr}} \check{R}_n + C_0 + s_* + C_1 \log x. \tag{6.xliii}$$

Then the tail is bounded by $CB_* N_W x^{-cC_1}$. If $\check{R}_n \leq C(\log x)^r$, the enlarged window still has only $O((\operatorname{diam} W + R)^4)$ current cubes, hence a polylogarithmic number of retained coarse link variables. The cell margin and the exponential margin are paid separately in eq. 6.xliii.

6.3.7. *The input which the clean region retains.* Equation eq. 6.xxxviii compares two recipes with the same coherent input list. A regular marked member generated from a previously healed region belongs to that list even when the standing trace is empty. Its small norm is estimated as a marked input, rather than set to zero. Likewise, the complementary Gaussian cutoff factors used in the finite expansion of a passed sharp test can have their roots inside the clean region. Their size is the rooted Gaussian tail of eq. 4.cxxxix; they are not boundary-history carriers.

Thus the local complete exponent separates into the whole-lattice Gaussian and regular interaction recipe, the retained small marked input, the cutoff correction, and the boundary tail eq. 6.xlii. To identify a conditional law in retained coarse coordinates one must in addition identify its physical background substitution and its coarea/domain image on one admitted chart. A bound for $E_h(X, P)$ as a function of P does not prove that two physical substitutions have the same arguments. The geometric proof here establishes the local recipe and its boundary-carrier tail before that separate analytic step.

The generating function on the fluctuation segment. Write $\mathsf{r} = \hat{\mathsf{d}}$, $g = x^{-1/2}$ and $\bar{v} = gp_0$. Let $\phi_a = \widetilde{f}_a$, $a = 1, 2$, and let X_a be the two bounded, windowed observables of the witness field. The tents move a support by at most CMa_s, so the enlarged supports are still separated by at least $\mathsf{d}/2$ when the room constant is large. Use the union of their bare plaquette sets in the readout construction. Each set has at most $C\mathsf{r}^4 \eta_{k_0}^{-4}$ plaquettes.

For step j, let γ_j^0 be the flat Gaussian marginal on the free read bonds and let $\mathcal{W}_j$ be their product of balls. Denote by T_j a uniform bound for the change of expectation of a function of these bonds of supremum at most one, from the rotated actual law at a compatible exterior to $\gamma_j^0(\cdot \mid \mathcal{W}_j)$. The bounds above give, on the admitted reference branches,

$$T_j \leq C\left[e^{2\epsilon_j^{\mathrm{old}}} - 1 + e^{\Xi_j} - 1 + n_j \widehat{g}_{j-1} b_j^3 + t_j + n_j \varpi_j\right], \qquad \Xi_j \leq C n_j b_j^2 e^{-c\mathsf{D}}.$$

Here $t_j \le Cn_j e^{-cb_j^2}$ also bounds the Gaussian error from the box and read-set cutoffs. For this bounded generating function remove both the old-origin tilt and the intrinsic remainder at each original fixed exterior e. If P is a removed part, the density ratio on the product window is $e^P/\langle e^P\rangle$, where the expectation uses the normalized law after that removal. Thus the ratio lies between $e^{-\operatorname{osc} P}$ and $e^{\operatorname{osc} P}$. The old-origin bound gives the first term in T_j. The full intrinsic oscillation at the original stored values is at most $Cn_j\widehat{g}_{j-1}b_j^3$ by §6.3.0.4. This is the third term in T_j at weak coupling. Both removals use the same product window and the same physical background.

The resulting quadratic law on the box has precision Q^e_{II} and linear term $Q^e_{IO}y_O + (\ell^e_E)|_I$. Compare it with the centered law on the same window whose precision is $K_e = (((Q^e)^{-1})_{II})^{-1}$. The force difference is exactly

$$(Q^e_{II} - K_e)y + Q^e_{IO}y_O + (\ell^e_E)|_I.$$

The first term is the Schur correction. All three terms are estimated with the quadratic weighted row bounds at e. The gap and marginal-density argument give the term with Ξ_j, without a comparison of nonlinear evaluations at different exterior values. Remove the centered Gaussian box window, compare its read covariance with the flat one, and impose the flat read window. The two window changes are included in t_j. Use the same Wilson ratio x_{j-1}/θ_{j-1} in the flat precision, as in the Gaussian comparison in the rotated coordinates. The final flat read law is the same for every compatible exterior. Average the normalized estimates against the original positive exterior mixture.

Take the source radii

$$|\lambda_a| \le \Lambda_a = \frac{c_* x}{2\mathsf{r}^4 p_0^2 \|\phi_a\|_\infty} \quad (a = 1, 2), \qquad z_p = \sum_{a=1}^{2} \lambda_a \phi_a(x(p)).$$

Zero profiles may be omitted. The constants below hold with a fixed reserve in these radii. Let ξ_j be independent flat read variables with the windowed law just specified. Put

$$M_{\le j}(p) = i \sum_{k_0 < l \le j} \widehat{g}_{l-1}(H^{\square}_{l-1}\mathsf{C}^0\xi_l)(p), \qquad Z_j(P) = \mathbb{E}\exp\left(\tfrac{1}{2}\sum_p z_p |M_{\le j}(p) + P(p)|^2\right).$$

The norm in the exponent is a norm of real-field matrices. The complex variables are the source coefficients. The row bounds of the linear readout, $b_l \le Cp_0$ and the geometric sum of η_{l-1}^2 give $\sup_p |M_{\le j}(p)| \le C\eta_{k_0}^2\bar{v}$. The same size holds for the remaining plaquette backgrounds and the intermediate arguments in a one-step replacement. Together with the count of plaquettes this gives $|Z_j| \le C$ and

$$|Z_j(P) - Z_j(P')| \le C\frac{\sup_p |P(p) - P'(p)|}{\eta_{k_0}^2\bar{v}}.$$

Indeed one integrates the change of the exponent along the segment between P and P'. Both bounds hold on the same source polydisc.

At each remaining level use one prescribed complete axial tree on the common read box, with its root and all paths included in the read. Gauge-transforming the field before putting it in this fixed gauge changes the resulting field by one constant rotation. Use the tower frames of the localized readouts within this gauge. Simultaneous rotation of all arguments of Z_j leaves it unchanged, since the flat laws and their balls are colour invariant and the flat maps act separately on each colour. Hence

$$Y_j(V_j) = Z_j(P^{(j)}(A^{\mathrm{ax}}(V_j)))$$

is a bounded gauge-invariant function on the admitted readout domain. It can be set to one outside that domain. The read sets contain the entire dependence on the tree and the old readouts. In particular an operation on an exterior component of a clean string leaves that read unchanged. At $j = k_0$ take $Y_{k_0} = e^{\lambda_1 X_1 + \lambda_2 X_2}$ on the whole space. On the clean branch it is Z_{k_0} of the localized

plaquette defects. The equality uses $a_p(U) = \frac{1}{2}|U(\partial p) - 1|^2$ in the normalized SU(2) norm and the fact that the witness tests pass there.

The one-step identity for the localized defects replaces the argument of Z_{j-1}, on the actual fluctuation window, by

$$i\widehat{g}_{j-1}H_{j-1}^{\square}\mathsf{C}^0\widetilde{y} + P^{(j)}(A^{\mathrm{ax}}(V_j)).$$

Its pointwise error is bounded by $C\eta_{j-1}^2[(\mathsf{r}gp_0)^2 + gp_0e^{-c\Delta_j}]$, with Δ_j the native readout margin. This comparison uses one colour convention for both supports. The residual constant rotation drops out of Z_{j-1}. The remaining expression depends only on the free read coordinates and the retained V_j. The T_j bound and one integration with $\gamma_j^0(\cdot \mid \mathcal{W}_j)$ now give

$$\left|\mathbb{E}_j^{\mathrm{ref}}Y_{j-1} - Y_j\right| \le C\left[L^{-2(j-1-k_0)}(\mathsf{r}^2gp_0 + e^{-c\Delta_j}) + T_j\right].$$

For the unconditioned comparison below, $\mathbb{E}_j^{\mathrm{ref}}$ is the box law obtained from the original adjacent-level law after summing the standing parts and holding the compatible exterior fixed. Its good current selector is then constant on the product window. The comparison to γ_j^0 is included in T_j. The last integration is exactly the independent addition of the j-th slice in the definition of Z_j. No change to the exterior weights is made.

For the unconditioned two-point function use the positive joint law of each adjacent pair of levels. Let μ_j be the standing law with its stored variables retained, and let π_j be the joint law of the original step from μ_{j-1} to μ_j, including the string of moves. Its marginals give the exact telescoping identity

$$\mathbb{E}_{\mu_{k_0}}Y_{k_0} - \mathbb{E}_{\mu_{k_1}}Y_{k_1} = \sum_{j=k_0+1}^{k_1}\mathbb{E}_{\pi_j}(Y_{j-1} - Y_j).$$

In the j-th term sum the earlier histories over their standing parts in both the inserted and uninserted measures. Use the good current condition on the complete read box when it selects an exterior weight of the resulting integrals. At fixed exterior, the indicator comparison for that step makes it constant on the product window, with the redundant interior flags summed out. Disintegrate at the ordinary output before the large-field moves. On the good current part those moves are exterior to the read and preserve Y_j, including under the gauge changes. The coarea integral with the insertion has the same weight as the integral without it. After normalization the box expectation is mixed with the exterior law weighted by the uninserted box integral. If d_j denotes the bound for the box comparison and p_j the mass of the excluded current part, the j-th term has modulus at most $d_j + 2Cp_j$, using the bounded extensions of both Y's. For a good condition defined on finer strings, we must verify this factorization after the standing-part sum.

Thus this comparison uses the summed one-step exceptional mass. It allows the earlier healed histories in the incoming standing law. On the prescribed reference torus the age and creation bounds control the probability of a bad current part by summing the cells that meet the padded read, with the lag estimate where the reference requires it. A comparison conditioned on a terminal exterior and on the full string uses the same-exterior estimates separately. If a finer class changes this box law by a normalized Radon–Nikodym factor in $[e^{-\epsilon}, e^{\epsilon}]$, the expectation of the bounded insertion changes by at most $(e^{\epsilon} - 1)\|Y_{j-1}\|_\infty$. In that comparison charge the class restriction at the step where it enters.

6.3.7.1. The top field and the Gaussian windows. To bound the last field, first use the native level-k_1 plaquette tests. The top read of the comparison uses its own localized minimizer. Its box need not be a test cube. Include the complete backward corner blocks for every top plaquette in its determining read. Assign each coarse plaquette to its native test cube by its barycenter. One test layer is wider than the complete corner stencil. At a passed native test the tested background has bare plaquette defect at most $\varepsilon_{k_1}\eta_{k_1}^2$ on those blocks. It has the prescribed level-k_1 averages on the four rows of the plaquette. The local averaging estimate of Prop. 3.4 therefore gives $|\partial V_{k_1} - 1| \le 2\varepsilon_{k_1}$ there.

The localized Landau curvature estimate on the top comparison box then gives

$$\sup_p |P^{(k_1)}(p)| \le C\eta_{k_1}^2 \varepsilon_{k_1} \le C\eta_{k_1}^2 g p_0.$$

The last inequality uses the running coupling bound over the segment. The transfer from the native test uses the scalar curvature of the block datum.

A failed or undefined native test is a creation. A skipped test lies in the margin of an earlier live component. An operation at the top touching a complete read has a live predecessor. Thus the terminal exception is covered by the live and creation cells of levels $k_1 - 1, k_1$ meeting the padded reads and operation margins, before the terminal field is formed. On the clean part, subsequent exterior moves do not read or change the determining data of these plaquettes. The same finite-band rarity estimate bounds p_{top}, with the top stencils included in its cell count. On the part of the original terminal law where this test fails, set the top argument P to zero. The bounded extensions allow this replacement at cost Cp_{top}, where p_{top} is the mass of that part. Keep the original terminal law in the expectation of the resulting $Z_{k_1}(P)$.

Write $Z_\infty(P)$ for the unwindowed flat read expectation and C_{loc} for its one-colour covariance. Set $F_a = \mathrm{diag}(\phi_a(x(p)))$ and $h = \lambda_1 F_1 + \lambda_2 F_2$. Decompose the real matrix field P orthogonally into its component in the three-colour Gaussian subspace, with coordinates p_c, and its perpendicular component $P^\perp$. Then

$$\frac{Z_\infty(P)}{Z_\infty(0)} = \exp E_P(\lambda), \qquad E_P(\lambda) = \frac{1}{2}\sum_{c=1}^{3} p_c^{\mathsf{T}} h(1 - C_{\mathrm{loc}}h)^{-1} p_c + \frac{1}{2}\sum_p h_{pp}|P^\perp(p)|^2.$$

To obtain this identity, write each colour as $C_{\mathrm{loc}}^{1/2}$ times a standard Gaussian and complete the square for real sources. This also works for singular C_{loc}. The weighted trace bound gives convergence and continuation to the source polydisc. More explicitly, put $D_\lambda = \sum_a |\lambda_a||F_a|$ and write $h = D_\lambda^{1/2} S D_\lambda^{1/2}$ with $\|S\| \le 1$. The trace of $D_\lambda^{1/2} C_{\mathrm{loc}} D_\lambda^{1/2}$ is at most a fixed constant less than one, also for the doubled radii after reducing c_*. The Neumann series therefore bounds $|E_P|$ by $C\sum_p (D_\lambda)_{pp}|P(p)|^2$. The plaquette count, the radii and the top-field bound make this $O(L^{-4\mathsf{n}})$.

Let $t = \sum_j C n_j e^{-cb_j^2}$. The joint flat window conditions the full Gaussian on an event of complement probability at most t. At each fixed P the determinant and the bound for E_P, applied to the doubled real sources, bound the second moment of the insertion uniformly. Cauchy–Schwarz bounds the deleted integral by $C\sqrt{t}$, and the conditioning denominator costs Ct. Consequently the terminal mixture

$$Z_{\mathrm{term}} = Z_\infty(0)\, \mathbb{E}_{\mathrm{term}} e^{E_P}$$

approximates the windowed mixture within $C\sqrt{t}$. Here $\mathbb{E}_{\mathrm{term}}$ is expectation under the original terminal law with the argument P defined above. The Gaussian integral is evaluated at each fixed terminal datum before taking that expectation.

Finally, the local/global flat comparison replaces the centered determinant $Z_\infty(0)$ by the whole-torus one, with error $Cp_0^{-2}e^{-cd_*}$. Write Z_{free} for this determinant. Its covariance in one colour is $C^x = \sum_{j=k_0+1}^{k_1} x_{j-1}^{-1} \mathcal{C}_{(j)}$. The trace series gives a fixed positive lower bound for $|Z_{\mathrm{free}}|$ on the polydisc.

For the unconditioned law the generating function differs from Z_{term} by at most

$$C\left[\mathsf{r}^2 g p_0 + \max_j e^{-c\Delta_j} + \sum_j T_j + \sqrt{t} + \sum_j p_j + p_{\mathrm{top}}\right].$$

The joint laws and their conditional kernels can be chosen independently of λ. The bounds may first be imposed on a countable dense subset of the polydisc and then extended by analyticity of the bounded insertions. This compares the generating functions before taking logarithms.

6.3.7.2. Returning to the physical two-point function. The trace series bounds $|Z_\infty(0)|$ below. For large x, the bound on E_P also bounds $|Z_{\mathrm{term}}|$ below. The quotients of the witness generating function by Z_{term} and of $Z_\infty(0)$ by Z_{free} lie in a fixed disc about one when the corresponding errors are small. The two log differences then have supremum $C\delta$, with δ the sum of the generating-function error above and $p_0^{-2}e^{-cd_*}$. Mixed Cauchy differentiation costs $C\delta/(\Lambda_1\Lambda_2)$. Relative to $x^{-2}\|\phi_1\|_\infty\|\phi_2\|_\infty$ this is the factor $C(\mathsf{r}^4p_0^2)^2$ times δ.

The remaining mixed derivative is that of $\log \mathbb{E}_{\mathrm{term}}e^{E_P}$ at zero. Put

$$A_a(P)=\frac{1}{2}\sum_p \phi_a(x(p))|P(p)|^2.$$

Expansion of the resolvent to first order in h gives this derivative as

$$\mathbb{E}_{\mathrm{term}}\sum_{c=1}^{3} p_c^{\mathsf{T}}F_1C_{\mathrm{loc}}F_2p_c+\mathrm{Cov}_{\mathrm{term}}(A_1,A_2).$$

Indeed, $\partial_a E_P(0)=A_a(P)$ and the two orders of $F_1, C_{\mathrm{loc}}, F_2$ give equal quadratic forms by transposition. The covariance comes from differentiating the logarithm after averaging. On the union of the test supports $|C_{\mathrm{loc}}(p,p')|\le Cx^{-1}\eta_{k_0}^4$ by the diagonal bound and positivity. With at most $C\mathsf{r}^4\eta_{k_0}^{-4}$ plaquettes and $|P|\le C\eta_{k_0}^2 gp_0L^{-2\mathsf{n}}$, the two terms are bounded at scale $x^{-2}\|\phi_1\|_\infty\|\phi_2\|_\infty$ by $C\mathsf{r}^8p_0^2L^{-4\mathsf{n}}$ and $C\mathsf{r}^8p_0^4L^{-8\mathsf{n}}$, respectively.

Take $\mathsf{D}=A\log x$, with A fixed sufficiently large. This fits the test margins since $\check{R}_{k_0}/\log x\to\infty$. The witness room gives $\mathsf{r}\asymp p_0^2$, and $\mathsf{D}+\check{R}_{k_0}=O(\mathsf{r})$ in the chosen range of exponents. The box count gives $n_j\le C\mathsf{r}^4$, and $\mathsf{n}=O(\log x)$. Thus the activity contribution to the old oscillations, estimated with one power of the ratio of radii, obeys

$$\sum_j Cn_j(\log x)^{\mathfrak{p}_0-q}\le C(\log x)^{1+9\mathfrak{p}_0-q}.$$

After the mixed Cauchy loss this is $O((\log x)^{1+29\mathfrak{p}_0-q})$, so take $q>1+29\mathfrak{p}_0$ as well as the earlier lower bounds. On the admitted branches the other old terms use the power and collar bounds in the old oscillation estimate. The intrinsic and covariance terms involving $x^{-1/2}$ have only fixed logarithmic prefactors. The two collar distances and the box margin give $e^{-c\mathsf{D}}$ up to fixed constants, which also absorbs any fixed logarithmic power. The window error uses $b_j\asymp p_0$, and $L^{-4\mathsf{n}}\le Cx^{-8}$.

For the geometric exceptions, the union of padded reads fits in the level-k_1 neighborhood counted above. Its cover at level j costs at most $C(\mathsf{r}+\mathsf{D}+\check{R}_{k_0})^4L^{4(k_1-j)}$ cells. Sum the one-cell bounds for live and creation events over these covers, including the predecessors of the top tests. This bounds their contribution to $p_{\mathrm{top}}+\sum_j p_j$ by

$$C(1+\mathsf{n})(\mathsf{r}+\mathsf{D}+\check{R}_{k_0})^4L^{4\mathsf{n}}e^{-cp_0}.$$

Here $L^{4\mathsf{n}}=O(x^8)$ and $\mathfrak{p}_0>1$, so this too is negligible after the Cauchy loss. This count uses the indicated geometric exceptions. When the native decomposition with attached terms supplies the conditional box estimate, charge the failure of its per-bond budget separately. Its bound summed over the segment is $C\sum_j n_je^{-cp_0}$, also negligible after the Cauchy loss. For this native budget split the adjacent law at the incoming list of that step. The indicator is fixed at each exterior, so the box normalization on the passing part is unchanged. On its complement the bounded difference of the two insertions costs at most a constant times the failure mass. Other refinements must still use the factorization of their actual history law.

The flat covariance contribution is $\frac{3}{2}\sum_{p,p'}\phi_1(x(p))\phi_2(x(p'))C^x(p,p')^2$. In the linear combination of the slices, replacing x_{j-1}^{-1} by x^{-1} costs at most $C(B_\sharp\mathsf{n}+c_5)x^{-2}$ times the sum of the absolute slice kernels. On separated supports that sum is bounded by $C\eta_{k_0}^4\mathsf{r}^{-4}$ by the exponential slice bound and its geometric sum. Multiplying by the sum of the two covariances to compare their squares,

and then summing the plaquettes, gives a relative error $C(B_\sharp \mathsf{n} + c_5)/x$ in the smeared covariance at scale x^{-2}. The cross term and square from the omitted coarse covariance give the displayed coarse-complement error of the free calculation.

Apply this conclusion in the physical-source identity at k_0. There the small mixed-source term and the errors in the two first derivatives are the source estimates in (a) and (b). The leading covariance is ${\zeta'_{k_0}}^2\langle X_1; X_2\rangle$. This identifies the covariance of the bounded witness observables in the physical-source identity. The source remainder bounds at k_0, the nondegeneracy for the chosen class of tests, and the reference-law transfer to the stated Gibbs states keep their separate roles.

6.4. **Positive history sums and averaged removal of exceptional runs.** The passage from a run window to a connected correlation has two normalizations. One first sums the positive histories that represent the same physical event, and then normalizes their total mass. Conditioning each history separately generally gives different weights. The purpose of this section is to perform these operations in their correct order and to estimate the error from exceptional runs without a uniform lower bound on the clean probability at every exterior field. The resulting estimates concern the second and fourth connected correlations used in the short-distance argument.

All probability measures in this section are real and positive at zero source. A differentiated polymer resolution can have signed or complex terms; it must first be identified with the positive physical measure before the statements below apply. No estimate on the absolute values of a different resolution makes that identification automatically.

6.4.1. *Pushforward measures and the multiplicity of a history class.* Let H be finite or countable. For $h \in H$ let σ_h be a finite positive measure on a standard Borel space Ω_h, and let $T_h : \Omega_h \longrightarrow \Omega$ be measurable, where Ω is also standard Borel. Assume

$$0 < Z := \sum_{h\in H} \sigma_h(\Omega_h) < \infty. \tag{6.xliv}$$

The common physical measure is

$$\mu = Z^{-1} \sum_{h\in H} (T_h)_* \sigma_h. \tag{6.xlv}$$

For a nonnegative measurable F, its integral is the sum of the integrals of $F \circ T_h$. This follows first for indicators from the definition of a pushforward and then for general F by monotone convergence. For an integrable complex F, apply this result to its absolute value before taking real and imaginary parts.

Suppose H is partitioned into classes $\mathcal{C}$. Define the unnormalized measure of a class by

$$\Sigma_C = \sum_{h\in C} (T_h)_* \sigma_h, \qquad C \in \mathcal{C}. \tag{6.xlvi}$$

Then $Z\mu = \sum_C \Sigma_C$. This is an equality of positive measures, including all Jacobians and all tests present in the individual histories. Rearrangement of the sum is justified by positivity. It does not require a choice of one representative configuration for the class.

Proposition 6.10 (The density of a resummed class)**.** Suppose there is a positive measure ν_C such that $(T_h)_*\sigma_h = a_h \nu_C$ for every $h \in C$, with $a_h \geq 0$ measurable. Then

$$\Sigma_C = a_C \nu_C, \qquad a_C = \sum_{h\in C} a_h. \tag{6.xlvii}$$

In particular the multiplicity can be taken outside an integral over the class variables only if a_C is constant almost everywhere in those variables. ■

Proof. For every nonnegative F, monotone convergence gives $\sum_h \int F a_h \, d\nu_C = \int F \sum_h a_h \, d\nu_C$. This proves the equality of measures. A constant factor outside all such integrals is equivalent to a constant Radon–Nikodym density. □

Equality of the coordinate domains, or independence of the histories from the source parameter, does not imply constancy of a_C. For example the two measures dy and $(1+y^2)\,dy$ on $[-1,1]$ have the same domain and no source dependence, but their sum has density $2+y^2$. Both densities contribute to a source integral $\int e^{zX(y)}\,d\Sigma_C(y)$. If an exact change of variables shows that all the pushforwards are equal to the same measure, the finite cardinality of the class is a constant multiplicity. For an infinite class of identical nonzero positive finite measures, eq. 6.xliv would fail. Thus an infinite counting factor cannot be discarded using a formal cancellation of infinite normalizers.

When $a_C > 0$ is differentiable, $\log a_C$ belongs in the complete conditional exponent of § 6.3. There is an additional derivative contribution even if every summand has a simple Hessian. For a finite class write $a_h = e^{p_h}$ and $w_h = e^{p_h}/\sum_j e^{p_j}$. Direct differentiation yields

$$\nabla \log a_C = \sum_h w_h \nabla p_h, \tag{6.xlviii}$$

$$\nabla^2 \log a_C = \sum_h w_h \nabla^2 p_h + \sum_h w_h (\nabla p_h - \bar{p})(\nabla p_h - \bar{p})^{\mathsf{T}}, \quad \bar{p} = \sum_h w_h \nabla p_h. \tag{6.xlix}$$

For a countable class, a sufficient condition is that, on every compact subset K of the coordinate chart,

$$\sum_{h\in C} \sup_K a_h(1 + |\nabla p_h|^2 + \|\nabla^2 p_h\|) < \infty, \qquad a_h = e^{p_h},$$

and that $a_C = \sum_h a_h$ stays positive. These bounds justify differentiation and each separate weighted sum in eq. 6.xlviii and eq. 6.xlix. Uniform convergence of $\sum_h a_h$ and its first two derivative series alone does not justify separating two divergent terms in the logarithmic Hessian.

The second term in eq. 6.xlix is the covariance of the slopes of the summands. For $p_\pm(y) = \pm My$, each individual Hessian vanishes, whereas $(\log(2\cosh My))''$ equals M^2 at zero. Control of individual Hessians consequently does not control the Hessian after a positive history sum. The slopes or the complete summed density must also be controlled.

6.4.2. *The exterior law at zero source.* Let $\pi : \Omega \longrightarrow E$ be the exterior variable and let $\lambda = \pi_*\mu$. Standard Borel spaces admit a probability kernel $e \mapsto \mu_e$ with

$$\int F\,d\mu = \int_E \left(\int F\,d\mu_e \right) \lambda(de) \tag{6.l}$$

for every integrable F. Equalities involving this kernel are understood outside a λ-null set, on which any fixed version may be used. At a finite lattice cutoff all spaces used here are finite products of compact Lie groups, Euclidean spaces and discrete history sets, so this measurability setting applies.

The weights of separate histories in μ_e involve their conditional masses at e. In particular they are not in general the unconditional weights $\sigma_h(\Omega_h)/Z$. One way to see the distinction is to retain the history label on the disjoint union $\bigsqcup_h \Omega_h$, push it to the pair (h, e), and then disintegrate over e. The resulting conditional law of h supplies exactly the required weights. Summing first and disintegrating first give the same joint integrals when these conditional weights are retained, by eq. 6.l.

For bounded real physical insertions $X_1, \dots, X_n$, put

$$F(z) = \int_E \mu_e\Big(e^{\sum_i z_i X_i}\Big)\,\lambda(de). \tag{6.li}$$

The exterior law λ in this formula is the law at zero source and stays fixed during differentiation. This follows by inserting the exponential in eq. 6.l; no approximation is being made. All changes of exterior weights induced by a source are already present in the conditional generating functions. Factoring out an e-dependent source normalizer from those functions would require retaining that factor inside the outer integral. Dividing it out before exterior averaging would change F and its connected derivatives.

6.4.3. *What an unconditional rarity estimate implies.* Let $C \subset \Omega$ be the clean event, measurable in the joint physical and history space. Enlarge Ω to that joint space when the event is not determined by the physical field alone. Write

$$q(e) = \mu_e(C), \qquad p = \mu(C^c) = \int_E (1 - q(e))\lambda(de). \tag{6.lii}$$

The number p can be exponentially small although $q(e)$ is zero on a set of exterior fields of positive measure. For example take $E = \{0, 1\}$, $\lambda(\{1\}) = p$, and let cleanliness be exactly the event $e = 0$. Then $q(1) = 0$. Thus no positive lower bound on all the conditional clean probabilities follows from small p.

For $0 < \eta < 1$, define

$$G_\eta = \{e : q(e) \geq \eta\}. \tag{6.liii}$$

Since $1 - q > 1 - \eta$ on its complement, integration gives

$$\lambda(G_\eta^c) \leq \frac{p}{1 - \eta}. \tag{6.liv}$$

More generally the set where $q < 1 - \delta$ has mass at most p/δ. The point is that the exceptional exteriors must be retained in the error estimate; they do not disappear from a conditional statement.

For $q(e) > 0$, define the clean conditional kernel

$$\mu_e^C(F) = q(e)^{-1}\mu_e(F1_C). \tag{6.lv}$$

This kernel is a probability measure regardless of how small $q(e)$ is. Its existence says nothing about a uniform bound on its density or its derivatives. Such bounds require the actual complete conditional law. The next comparison uses only positivity.

6.4.4. *A resampling with the same exterior marginal.* It is convenient to compare laws on the feature space $\mathbb{R}^n$. Let $X = (X_1, \ldots, X_n)$ be measurable and let $\rho = X_*\mu$. Let $G \subset \{q > 0\}$ be a measurable admitted set of exteriors. For $e \in G$, use the law of X under μ_e^C; for $e \notin G$, use the point mass at $0 \in \mathbb{R}^n$. Their mixture with respect to the unchanged λ is a probability measure ν_G.

We use the total variation convention $\|\rho - \nu\|_{\mathrm{TV}} = \sup_A |\rho(A) - \nu(A)|$ for probabilities. For bounded f, the corresponding integral bound is $|\rho(f) - \nu(f)| \leq 2\|f\|_\infty \|\rho - \nu\|_{\mathrm{TV}}$. This convention is fixed to avoid an ambiguous factor of two.

Proposition 6.11 (Averaged clean resampling)**.** With the preceding definitions,

$$\|\rho - \nu_G\|_{\mathrm{TV}} \leq p + \lambda(G^c). \tag{6.lvi}$$

If $G = \{q > 0\}$, the right hand side can be improved to p. If $G = G_\eta$, the bound $p + p/(1 - \eta)$ is valid. ∎

Proof. At a fixed e with $q > 0$, the full conditional probability is $q\mu_e^C + (1 - q)\mu_e^{C^c}$, with the second term omitted when $q = 1$. Its distance from μ_e^C is at most $1 - q$. Pushforward under X does not increase total variation, since preimages of feature events are physical events. At $e \notin G$ the distance from the chosen point mass is at most one. Integrate these bounds and take the supremum over feature events to obtain $\int_G (1 - q)\, d\lambda + \lambda(G^c) \leq p + \lambda(G^c)$. When $G = \{q > 0\}$, the integral of $1 - q$ on G^c is exactly $\lambda(G^c)$, so the first displayed expression equals p. The last assertion follows from eq. 6.liv. □

Global conditioning on C gives another probability law, $\mu(\cdot \mid C)$. Its exterior marginal is $q(e)\lambda(de)/(1 - p)$ when $p < 1$. Thus global conditioning and clean conditional resampling have different exterior marginals. The latter is useful when a run-window estimate is to be integrated against the original exterior law. This is the comparison that Prop. 6.11 supplies.

6.4.5. *Weighted exceptional moments.* A small exceptional probability alone does not control an unbounded insertion. The estimate needed for a product of insertions can be stated without global moment bounds on every physical field. For each nonempty $S \subset \{1, \dots, n\}$ let

$$d_S = \mu\left(1_{C^c} \prod_{i\in S} |X_i|\right), \qquad M_S = \prod_{i\in S} M_i, \tag{6.lvii}$$

where $M_i > 0$. Assume these numbers are finite and that $|X_i| \le M_i$ on C, up to a μ-null set. The clean bound can use insertions from which fixed deterministic constants have been subtracted. It cannot subtract an exterior-dependent random constant without changing the global connected correlations.

Proposition 6.12 (Mixed moment error with weighted tails)**.** For every nonempty S,

$$\left|\rho\left(\prod_{i\in S} x_i\right) - \nu_G\left(\prod_{i\in S} x_i\right)\right| \le d_S + [p + \lambda(G^c)]M_S, \tag{6.lviii}$$

$$\left|\rho\left(\prod_{i\in S} x_i\right)\right| \le M_S + d_S, \qquad \left|\nu_G\left(\prod_{i\in S} x_i\right)\right| \le M_S. \tag{6.lix}$$

When $G = \{q > 0\}$ the term $p + \lambda(G^c)$ in the first bound can be replaced by p. ■

Proof. Write $X_S = \prod_{i\in S} X_i$. On G the difference between a full conditional moment and a clean conditional moment is

$$\mu_e(X_S 1_{C^c}) - \frac{1 - q(e)}{q(e)} \mu_e(X_S 1_C). \tag{6.lx}$$

The absolute value of the second term is at most $(1 - q(e))M_S$, because $|\mu_e(X_S 1_C)| \le q(e)M_S$. This cancellation of $q(e)$ is the reason that a uniform clean probability floor is unnecessary here. On G^c the comparison moment is zero. The full moment there has a bad part controlled by the corresponding portion of d_S, and a clean part at most $q(e)M_S$. Integrating these estimates gives

$$d_S + M_S \left[\int_G (1 - q)\, d\lambda + \int_{G^c} q\, d\lambda\right]. \tag{6.lxi}$$

The bracket is at most $p + \lambda(G^c)$. If $G = \{q > 0\}$, its second integral is zero and its first is at most p. Finally, the full absolute moment is at most $M_S + d_S$ and the comparison law is supported in the clean feature box together with the origin. This proves the remaining bounds. □

The defect d_S is precisely where the Gaussian marks and unspent reserves of § 4.18 are used. If the history construction only bounds p, the weighted defects still require proof. If it bounds the marked mass in the actual normalized positive law, Prop. 6.12 converts that estimate directly into a mixed moment error. An unnormalized mass estimate must first be divided by a valid partition floor; the proposition does not provide that floor.

For comparison, suppose $q_0 > 1$ and $\|X_i\|_{L^{nq_0}(\mu)} \le B_i$. Hölder's inequality, first on the exceptional event and then on the product, gives

$$d_S \le p^{1-1/q_0} \prod_{i\in S} B_i, \qquad 1 \le |S| \le n. \tag{6.lxii}$$

Indeed the product has L^{q_0} norm at most the product of the $L^{|S|q_0}$ norms of its entries, and those norms are bounded by the stated L^{nq_0} norms on a probability space. In a fourth connected correlation, uniform eighth moments therefore give a square-root gain from rarity. A direct marked-mass estimate can give a stronger gain and does not need these global eighth moments.

6.4.6. *Connected correlations as polynomials in mixed moments.* For nonempty S, write $m_S = \mathbb{E}\prod_{i\in S} X_i$. The joint cumulant is the polynomial

$$\kappa_S(X) = \sum_{\pi\in\Pi(S)} (-1)^{|\pi|-1}(|\pi|-1)! \prod_{B\in\pi} m_B, \tag{6.lxiii}$$

where $\Pi(S)$ is the set of set partitions of S into nonempty blocks. The indices distinguish repeated insertions as well as different ones. Consequently the same formula gives diagonal moments and derivatives in repeated directions.

For bounded variables, eq. 6.lxiii follows by expanding $\log(1+u) = \sum_{k\ge1}(-1)^{k-1}u^k/k$ in a neighborhood of the origin and extracting the coefficient of $\prod_{i\in S} z_i$ in $\log \mathbb{E}e^{\sum z_i X_i}$. An unordered partition with k blocks arises in $k!$ orders in u^k, and the factor $1/k$ leaves $(k-1)!$. For variables with the finite mixed absolute moments occurring in the formula, use this polynomial as the definition; bounded truncations and dominated convergence recover it from the usual moment definition. No moment generating function is asserted to exist for an unbounded variable.

Let $\left\{ {n \atop k} \right\}$ denote the number of partitions of $\{1,\dots,n\}$ into k blocks. Define

$$b_n(D) = \sum_{k=1}^{n} k! \left\{ {n \atop k} \right\} (1+D)^{k-1}, \qquad D \ge 0. \tag{6.lxiv}$$

In particular

$$b_2(D) = 1 + 2(1+D), \tag{6.lxv}$$

$$b_4(D) = 1 + 14(1+D) + 36(1+D)^2 + 24(1+D)^3. \tag{6.lxvi}$$

Thus $b_2(0) = 3$ and $b_4(0) = 75$.

Proposition 6.13 (Connected error from weighted exceptional runs)**.** Assume $d_S \le DM_S$ for every nonempty $S \subset \{1,\dots,n\}$. Put $r_G = p + \lambda(G^c)$. Then

$$|\kappa_\rho(x_1,\dots,x_n) - \kappa_{\nu_G}(x_1,\dots,x_n)| \le (D + r_G) b_n(D) \prod_{i=1}^{n} M_i. \tag{6.lxvii}$$

For $G = \{q > 0\}$ one may use $r_G = p$. ■

Proof. For each partition with k blocks, subtract the product of its comparison moments from the product of its physical moments. Use the telescoping product identity, replacing one factor at a time. The replaced factor has error at most $(D + r_G)M_B$ by Prop. 6.12; every other factor has modulus at most $(1+D)M_{B'}$. Since the blocks partition all indices, the product of these bounds is $k(D+r_G)(1+D)^{k-1}\prod_i M_i$. Multiply by $(k-1)!$ from eq. 6.lxiii, sum over partitions, and group them by k. This is exactly eq. 6.lxiv. □

The same proof gives a useful comparison for two arbitrary bounded feature laws with coordinate bounds M_i. If their total variation distance is at most δ, each mixed moment differs by at most $2\delta M_S$, and all moments have modulus at most M_S. Therefore

$$|\kappa_\rho - \kappa_\nu| \le 2\delta b_n(0) \prod_i M_i. \tag{6.lxviii}$$

The constants are 6δ for a covariance and 150δ for a fourth cumulant after the product of the bounds is factored out. These constants are explicit sufficient bounds; no optimality is needed in the application.

6.4.7. *Auxiliary source logarithms on the bounded feature box.* Bounded clean insertions also justify the connected interpretation analytically. Let ρ and ν be supported in $\prod_i[-M_i, M_i]$. For

$$t = \sum_i |z_i| M_i \le c < \log 2, \tag{6.lxix}$$

their generating functions satisfy

$$|F_\rho(z) - 1| \le e^t - 1 < 1, \qquad |F_\rho(z)| \ge 2 - e^c, \tag{6.lxx}$$

and the same inequalities hold for ν. The estimate follows from $|e^w - 1| \le e^{|w|} - 1$ and integration. The principal logarithm is therefore single valued throughout this region.

If the total variation distance is at most δ, then $|F_\rho - F_\nu| \le 2\delta e^c$. The straight segment joining their values remains in the disc $|w-1| \le e^c - 1$, where $|1/w| \le (2-e^c)^{-1}$. Integrating the derivative of the logarithm along that segment gives

$$|\log F_\rho(z) - \log F_\nu(z)| \le \frac{2\delta e^c}{2 - e^c}. \tag{6.lxxi}$$

For a polydisc with radii $c/(nM_i)$, Cauchy's formula bounds the derivative with one occurrence of every variable by the right hand side times $n^n c^{-n} \prod_i M_i$. The polynomial bound in eq. 6.lxviii is usually smaller for $n = 2, 4$, but the logarithmic estimate explains the absence of a normalization singularity.

These auxiliary sources are inserted into a fixed positive law at zero source. Their region of holomorphy is not a claim that the renormalization charts extend to sources of size M_i^{-1}. One may use this elementary generating function to estimate a real-law comparison without analytically continuing any history map to that larger source domain. If the physical insertion itself has been replaced by a derivative of a source-dependent effective action, its higher source derivatives must be retained separately.

6.4.8. *The law of total cumulance.* The clean resampling still averages over the exterior field. The conditional means cannot be discarded. The exact expression for all the resulting terms is useful at order four.

Let $e \mapsto \xi_e$ be a probability kernel on $\mathbb{R}^n$, let α be an exterior probability, and let $\xi = \int \xi_e \, \alpha(de)$. For nonempty S set $c_S(e) = \kappa_{\xi_e}(x_i : i \in S)$. Suppose the coordinates are bounded, or that all moments and integrals used below are finite with an integrable dominating function. Then

$$\kappa_\xi(x_1, \dots, x_n) = \sum_{\pi \in \Pi_n} \kappa_\alpha(c_B(e) : B \in \pi). \tag{6.lxxii}$$

An outer cumulant of one entry means its expectation.

To prove the formula for bounded coordinates, write $K_e(z) = \log \xi_e(e^{\sum_i z_i x_i})$ on a common small polydisc. Its coefficient with distinct indices in S is $c_S(e)$. Expand

$$\log \int e^{K_e(z)} \, \alpha(de) = \sum_{k \ge 1} \frac{1}{k!} \kappa_\alpha(K_e(z), \dots, K_e(z)). \tag{6.lxxiii}$$

The series converges near zero because $K_e(0) = 0$ and its supremum tends to zero there. To obtain the coefficient of $z_1 \cdots z_n$, distribute the distinct indices among k nonempty entries. These distributions are ordered partitions. The factor $1/k!$ removes their ordering, giving eq. 6.lxxii. For finite moments one can instead perform the same computation in the algebra of polynomials with $z_i^2 = 0$. Every series truncates at degree n, so the proof uses only the assumed moments and integrability.

At orders two and three the identity reads

$$\kappa_{12} = \mathbb{E}_\alpha c_{12} + \mathrm{Cov}_\alpha(c_1, c_2), \tag{6.lxxiv}$$

$$\kappa_{123} = \mathbb{E}_\alpha c_{123} + \mathrm{Cov}_\alpha(c_1, c_{23}) + \mathrm{Cov}_\alpha(c_2, c_{13}) + \mathrm{Cov}_\alpha(c_3, c_{12}) + \kappa_\alpha(c_1, c_2, c_3). \tag{6.lxxv}$$

At order four it reads

$$\begin{aligned}\kappa_{1234} = \mathbb{E}_\alpha c_{1234} &+ \sum_{i=1}^{4} \mathrm{Cov}_\alpha(c_i, c_{\{1,2,3,4\}\setminus\{i\}}) \\ &+ \sum_{\{ij\}\{k\ell\}} \mathrm{Cov}_\alpha(c_{ij}, c_{k\ell}) \\ &+ \sum_{\{ij\},\{k,\ell\}=\{1,2,3,4\}\setminus\{i,j\}} \kappa_\alpha(c_{ij}, c_k, c_\ell) \\ &+ \kappa_\alpha(c_1, c_2, c_3, c_4). \end{aligned} \tag{6.lxxvi}$$

The second sum has the three pair partitions 12|34, 13|24, 14|23. The third has six choices of the pair $\{i, j\}$. The displayed terms account respectively for partitions with one, two, three and four blocks.

A mixture of centered Gaussian linear laws already illustrates one essential term: its conditional fourth cumulants vanish, but covariance of the conditional covariances can give a nonzero global fourth cumulant. Similarly, for quadratic Gaussian insertions the conditional one-point functions need not be constant when the covariance depends on e. Subtracting the global one-point function does not remove their exterior variation. The mixed outer cumulants in eqs. 6.lxxiv and 6.lxxvi must be estimated.

6.4.9. *A fixed reference and quantitative exterior errors.* For $k \geq 1$ define

$$a_k = \sum_{j=1}^{k} (j-1)! \left\{ {k \atop j} \right\}. \tag{6.lxxvii}$$

The first four values are $1, 2, 6, 26$. The moment polynomial implies $|\kappa(Y_1, \dots, Y_k)| \leq a_k \prod_i \|Y_i\|_\infty$. For $k \geq 2$ this cumulant is unchanged if a deterministic constant is added to any one entry. For bounded variables the invariance follows because such an addition changes the logarithm of the generating function only by a linear term. The polynomial identity extends it to finite moments.

Proposition 6.14 (Exterior averaging around a deterministic reference)**.** In the setting of eq. 6.lxxii, suppose constants γ_S and nonnegative ϵ_S satisfy

$$|c_S(e) - \gamma_S| \leq \epsilon_S \tag{6.lxxviii}$$

for every nonempty S, almost everywhere under α. Then

$$|\kappa_\xi(x_1, \dots, x_n) - \gamma_{\{1,\dots,n\}}| \leq \epsilon_{\{1,\dots,n\}} + \sum_{\substack{\pi \in \Pi_n \\ |\pi| \geq 2}} a_{|\pi|} \prod_{B \in \pi} \epsilon_B. \tag{6.lxxix}$$

■

Proof. The one-block term of eq. 6.lxxii has error at most $\epsilon_{\{1,\dots,n\}}$. In every other term subtract γ_B from each entry, using invariance of an outer cumulant of order at least two under deterministic translations. Its entries now have suprema at most ϵ_B. The bound following eq. 6.lxxvii and the triangle inequality prove the result. □

For two insertions the bound is

$$\epsilon_{12} + 2\epsilon_1\epsilon_2. \tag{6.lxxx}$$

For four insertions it is

$$\begin{aligned}\epsilon_{1234} + 2\sum_i \epsilon_i \epsilon_{\{1,2,3,4\}\setminus\{i\}} + 2 \sum_{\{ij\}\{k\ell\}} \epsilon_{ij}\epsilon_{k\ell} \\ + 6 \sum_{\{ij\},\{k,\ell\}=\{1,2,3,4\}\setminus\{i,j\}} \epsilon_{ij}\epsilon_k\epsilon_\ell + 26\epsilon_1\epsilon_2\epsilon_3\epsilon_4. \end{aligned} \tag{6.lxxxi}$$

This form identifies exactly how accurately the conditional means and the lower connected correlations must be controlled. It is not necessary to demand the same absolute accuracy from quantities that appear only as products. Conversely, a bound on the conditional covariance alone is not enough for the fourth connected correlation.

6.4.10. *Discarding unadmitted exteriors before reference comparison.* Suppose the conditional reference estimates hold only on G, with $\lambda(G) > 0$. Define the probability $\widehat{\nu}_G = \lambda(G)^{-1} \int_G X_* \mu_e^C \, \lambda(de)$. This removes the artificial point mass used in ν_G. Both measures are supported in the clean feature box, and

$$\|\nu_G - \widehat{\nu}_G\|_{\mathrm{TV}} \le \lambda(G^c). \tag{6.lxxxii}$$

Indeed $\nu_G = \lambda(G)\widehat{\nu}_G + \lambda(G^c)\delta_0$. The comparison with a deterministic reference can now be made under the genuine exterior probability $\lambda(\,\cdot \mid G)$.

Combining the preceding propositions gives the complete estimate

$$\begin{aligned} |\kappa_\rho - \gamma_{\{1,\dots,n\}}| \le{}& (D + p + \lambda(G^c)) b_n(D) \prod_i M_i \\ &+ 2\lambda(G^c) b_n(0) \prod_i M_i \\ &+ \epsilon_{\{1,\dots,n\}} + \sum_{\substack{\pi \in \Pi_n \\ |\pi| \ge 2}} a_{|\pi|} \prod_{B \in \pi} \epsilon_B. \end{aligned} \tag{6.lxxxiii}$$

Here $d_S \le D M_S$ and the conditional cumulants on G are within ϵ_S of γ_S. The first line compares the physical law to clean resampling, the second removes the exceptional exterior mass, and the remaining lines average the conditional reference estimates. Every normalization in this comparison is a normalization of a positive probability.

If a chart-admission set $A \subset E$ is also required, take $G = A \cap G_\eta$. Its exceptional mass obeys

$$\lambda(G^c) \le \lambda(A^c) + \frac{p}{1 - \eta}. \tag{6.lxxxiv}$$

A model proof must supply the first term when admission is not automatic. It cannot infer admission solely from the existence of a conditional probability. The useful point is that a lower bound on q is only needed on the retained exteriors, and their discarded mass is explicitly accounted for.

6.4.11. *Short-distance powers and the marked reserve.* We apply eq. 6.lxxxiii with fixed order $n = 2$ or $n = 4$, inverse running coupling $x \longrightarrow \infty$, and $N_i = \|f_i\|_\infty$. Suppose the admitted clean readouts satisfy

$$M_i \le C_i x^{-1} (\log x)^{A_i} N_i, \qquad A_i \ge 0. \tag{6.lxxxv}$$

For the two-point readout bound used in § 6.2, one can take a fixed exponent after substituting the permitted polylogarithmic window radius. No optimization of that exponent is required; it must be recorded before spending the rarity reserve.

Suppose the normalized marked mass gives, for fixed $c, b > 0$,

$$D + p + \lambda(A^c) \le C \exp[-c(\log x)^b]. \tag{6.lxxxvi}$$

Then for fixed $\eta \in (0,1)$ the first two lines of eq. 6.lxxxiii are

$$o\left(x^{-n} \prod_i N_i \right). \tag{6.lxxxvii}$$

To check the assertion, $D \to 0$, so $b_n(D)$ stays bounded. The remaining factor, after $x^{-n} \prod_i N_i$ is removed, is at most a constant times $\exp[-c(\log x)^b + (\sum_i A_i) \log\log x]$. Its exponent tends to $-\infty$ for every $b > 0$. The same conclusion follows from a power bound $O(x^{-a})$ with $a > 0$. A logarithmic rarity bound $O((\log x)^{-P})$ instead requires $P > \sum_i A_i$.

The estimate is a consequence of the normalized, marked hypothesis eq. 6.lxxxvi. The unnormalized unmarked sum of histories does not imply it. The distinction between a stored volume mark and a field moment mark remains exactly the one in § 4.18; the present argument uses the field moments in d_S rather than replacing them by volume moments.

For the conditional errors put $L_S = \prod_{i\in S} x^{-1}N_i$. If the bounds on G have the form $\epsilon_S \le \delta_S(x)L_S$, then the last two lines of eq. 6.lxxxiii, divided by $L_{\{1,\dots,n\}}$, are at most

$$\delta_{\{1,\dots,n\}} + \sum_{\substack{\pi\in\Pi_n \\ |\pi|\ge 2}} a_{|\pi|} \prod_{B\in\pi} \delta_B. \tag{6.lxxxviii}$$

Thus it suffices that the displayed products tend to zero. In particular conditional mean errors that are bounded at their natural scale and actually tend to zero make every partition containing a singleton negligible, provided the other conditional errors remain bounded at their natural scales. A conditional two-point error $o(x^{-2}N_iN_j)$ controls its pair-pair contribution to order four, provided the second pair error stays bounded on its natural scale. The one-block fourth-order error must itself be $o(x^{-4}\prod_i N_i)$; averaging cannot improve it.

6.4.12. *The estimates still required from the interacting model.* The comparison just proved removes an unnecessary demand for a uniform conditional clean-probability floor. It gives a rigorous way to spend the positive history reserve in connected correlations. Its remaining inputs are concrete.

First, the history sum and its class identifications must be equalities for the zero-source physical measure, with their pushforward densities retained as in Prop. 6.10. Second, the complete conditional exponent and the physical readout must be identified on the admitted clean chart. Third, the marked normalized mass must give the d_S bounds. Fourth, the conditional cumulants, including their means and their source contact terms, must obey eq. 6.lxxviii against one fixed reference. These are the places where the background inverse, formation and interacting force estimates enter.

For $n = 2$, the reference coefficient is the free-curvature two-point coefficient, and the errors in eq. 6.lxxx must be small relative to its positive lower bound for the permitted shapes. For $n = 4$, the reference is the connected four-point kernel and the errors are those in eq. 6.lxxxi. The free kernel and its sign calculation do not prove the conditional interacting estimate. The running-coupling conversion is applied only after the comparison at scale x^{-n} has been proved.

These observations also specify a useful order for closing the short-distance argument. The conditional one-block errors and the marked normalization come first. Quantitative shape and grid errors are then compared with the established leading coefficient. Exceptional exteriors and lower conditional cumulants are controlled by the explicit products above. No additional conditional clean-mass theorem is needed for this averaged route.

6.5. **Effective source derivatives and separated contact terms.** Integrating a subset of the fields turns an affine physical source into a nonlinear effective source action. Its mixed derivatives contribute to connected correlations even at zero source. This section derives the exact finite-order formula and estimates the mixed terms from their spatial carriers. It explains when the covariance of the first source responses suffices, and when additional contact insertions must be retained.

6.5.1. *A fixed integration domain and its source derivatives.* Let μ be a probability on a measurable space. Suppose $A(z, y)$ is holomorphic in $z = (z_1, \dots, z_n)$ near zero, measurable in y, and $A(0, y) = 0$. Assume that $e^{A(z,y)}$ and the source derivatives used below have a common integrable bound on a smaller polydisc. These hypotheses justify differentiation under the integral. Put

$$F(z) = \mu(e^{A(z,\cdot)}), \qquad W(z) = \log F(z), \quad W(0) = 0. \tag{6.lxxxix}$$

Since $F(0) = 1$, the logarithm exists on a neighborhood of zero. For nonempty $B \subset \{1, \dots, n\}$ define the distinct-index jet

$$A_B(y) = \prod_{i \in B} \partial_{z_i} A(z, y)\Big|_{z=0}. \tag{6.xc}$$

The integral in eq. 6.lxxxix is on a fixed measurable domain and with a fixed zero-source measure. A source-dependent change of variables must first be written on such a domain with its complete Jacobian. Differentiating a sharp indicator of a moving domain is not justified by holomorphy of the action alone.

Proposition 6.15 (The partition formula for effective source jets)**.** Under these assumptions,

$$\partial_{z_1} \cdots \partial_{z_n} W(0) = \sum_{\pi \in \Pi_n} \kappa_\mu(A_B : B \in \pi). \tag{6.xci}$$

An outer cumulant with one entry is its expectation. ■

Proof. For the coefficient with each index appearing once, work in the commutative algebra in which $z_i^2 = 0$. Every power series then truncates at degree n, so no interchange of infinite series is required. In this algebra $A(z, y) = \sum_{\varnothing \neq B} z_B A_B(y)$, where $z_B = \prod_{i \in B} z_i$. The cumulant expansion of $\log \mu(e^A)$ is $\sum_{k=1}^n \kappa_\mu(A, \dots, A)/k!$. To obtain $z_1 \cdots z_n$, the k entries must use disjoint nonempty index sets whose union is all indices. These are the ordered partitions into k blocks. The factor $1/k!$ removes their ordering, proving the formula. The dominated analytic assumptions identify this finite coefficient with the indicated derivative of W. □

At order two,

$$W_{12}(0) = \mu(A_{12}) + \mathrm{Cov}_\mu(A_1, A_2). \tag{6.xcii}$$

At order three,

$$\begin{aligned} W_{123}(0) = \mu(A_{123}) &+ \mathrm{Cov}_\mu(A_{12}, A_3) + \mathrm{Cov}_\mu(A_{13}, A_2) \\ &+ \mathrm{Cov}_\mu(A_{23}, A_1) + \kappa_\mu(A_1, A_2, A_3). \end{aligned} \tag{6.xciii}$$

At order four,

$$\begin{aligned} W_{1234}(0) = \mu(A_{1234}) &+ \sum_i \mathrm{Cov}_\mu(A_i, A_{\{1,2,3,4\}\setminus\{i\}}) \\ &+ \sum_{\{ij\}\{k\ell\}} \mathrm{Cov}_\mu(A_{ij}, A_{k\ell}) \\ &+ \sum_{\{ij\},\{k,\ell\}=\{1,2,3,4\}\setminus\{i,j\}} \kappa_\mu(A_{ij}, A_k, A_\ell) \\ &+ \kappa_\mu(A_1, A_2, A_3, A_4). \end{aligned} \tag{6.xciv}$$

The sums have respectively four, three and six terms. Thus controlling only A_i does not control either $\mu(A_{12})$ or the additional fourth-order terms.

6.5.2. *A quantitative bound for all contact contributions.* Let $M_i > 0$ and suppose $\|A_i\|_\infty \le M_i$. For each block B of size at least two suppose

$$\|A_B\|_\infty \le \eta_B \prod_{i \in B} M_i. \tag{6.xcv}$$

Using the cumulant constants a_k defined in eq. 6.lxxvii, the partition formula gives

$$|W_{1\cdots n}(0) - \kappa_\mu(A_1, \dots, A_n)| \le \prod_i M_i \sum_{\substack{\pi \in \Pi_n \\ \pi \neq \{\{1\},\dots,\{n\}\}}} a_{|\pi|} \prod_{\substack{B \in \pi \\ |B| \ge 2}} \eta_B. \tag{6.xcvi}$$

Every term in the sum contains at least one mixed block. The proof is to apply $|\kappa(Y_1,\dots,Y_k)| \le a_k \prod \|Y_j\|_\infty$ to each term of eq. 6.xci. It applies also to complex-valued jets, since the moment polynomial and its absolute-value bound are algebraic.

For example, the second-order error is at most $\eta_{12} M_1 M_2$. At order four it is at most

$$\prod_i M_i \Big[\eta_{1234} + 2 \sum_i \eta_{\{1,2,3,4\}\setminus\{i\}} + 2 \sum_{\{ij\}\{k\ell\}} \eta_{ij}\eta_{k\ell} + 6 \sum_{\{i,j\}\subset\{1,2,3,4\}} \eta_{ij} \Big]. \tag{6.xcvii}$$

In this formula the third-order jets occur paired with one first-order jet. There is no isolated third-order coefficient missing from the estimate.

If $A_i = Q_i + I_i$ with $\|Q_i\|_\infty \le M_i$ and $\|I_i\|_\infty \le \rho_i M_i$, multilinearity gives

$$|\kappa(A_1,\dots,A_n) - \kappa(Q_1,\dots,Q_n)| \le a_n \left[\prod_i (1+\rho_i) - 1 \right] \prod_i M_i. \tag{6.xcviii}$$

This follows by expanding in the nonempty subset of entries where I_i is used. Combining eqs. 6.xcvi and 6.xcviii accounts separately for the first response error and for every mixed response. The latter cannot be absorbed into the former without a bound on the mixed jets.

6.5.3. *Local carriers and a common source polydisc.* Let $\mathcal{D}$ be a family of finite domains in a graph with cells v. Let $d(X) \ge 0$ be a connected-size function. For each X suppose $H_X(z,y)$ is holomorphic on the same closed source polydisc $|z_i| \le r_i$, measurable in y on one admitted field domain, and obeys

$$\sup_{z,y} |H_X(z,y)| \le h_X. \tag{6.xcix}$$

Assume H_X is independent of z_i when its physical carrier $X^\sim$ misses $\operatorname{supp} f_i$. All source parameters here are held independently; a single bound for a source in one direction would not justify this mixed Cauchy estimate.

Suppose $H = \sum_X H_X$ converges normally on smaller polydiscs. For a nonempty B its mixed jet is

$$H_B(y) = \sum_{X:\, X^\sim \cap \operatorname{supp} f_i \neq \varnothing \text{ for all } i\in B} \partial_B H_X(0,y). \tag{6.c}$$

Multivariate Cauchy estimates give

$$\|H_B\|_\infty \le \left(\prod_{i\in B} r_i^{-1} \right) \sum_{X \text{ meeting every support in } B} h_X. \tag{6.ci}$$

There is no factorial for distinct variables. Repeated directions can be introduced as distinct source variables; the usual factorial for a single-variable derivative then follows from coefficient multiplicities.

The preceding statement requires a common field domain for all H_X after the actual substitution. If the norm in eq. 6.xcix is established only before substitution, the substituted family must be shown to stay inside that domain. Cauchy's formula does not repair a failure of domain admission.

6.5.4. *Exponential suppression of separated mixed jets.* Assume that a nonnegative local weight has the incidence bound

$$\sup_v \sum_{X\ni v} e^{\kappa d(X)} h_X \le E_0. \tag{6.cii}$$

Suppose every carrier that meets a selected support has an assigned root in a finite set W, and that assigning a root never reduces the estimate on the right: more explicitly, the sum over such domains is bounded by $\sum_{v\in W} \sum_{X\ni v}$ with the same h_X and $d(X)$. Assume also that if $X^\sim$ meets two of the

separated supports, then $d(X) \geq D_*$. These are the geometric root and carrier properties needed in the estimate. Then

$$\sum_{X \text{ meeting every support in } B} h_X \leq |W| E_0 e^{-\kappa D_*}, \qquad |B| \geq 2. \tag{6.ciii}$$

Indeed factor $e^{-\kappa d(X)}$ out of the weighted incidence norm and use $d(X) \geq D_*$ in each contributing term. The root count is paid once by $|W|$. This proves

$$\|H_B\|_\infty \leq |W| E_0 e^{-\kappa D_*} \prod_{i \in B} r_i^{-1}, \qquad |B| \geq 2. \tag{6.civ}$$

A localization carrier may be an enlargement of X. If its enlargement has radius r_{loc} and the supports are separated by d_*, then the size lower bound must use $d_* - 2r_{\mathrm{loc}}$ in the appropriate units. In particular it is not enough to say that the original domains are disjoint. The separation has to survive the actual enlargement used in the source dependence.

If there are several origin levels, apply eq. 6.civ with their own incidence bound, root count, carrier units and source radii, and sum those numerical estimates. A coarse root count cannot be used for fine-origin terms without the filing estimate that transfers their incidence weights. This is the same bookkeeping requirement as in eq. 6.cxcii.

6.5.5. *The short-distance contact budget.* Let $x \to \infty$ and $N_i = \|f_i\|_\infty > 0$. Suppose the first responses satisfy

$$\|A_i\|_\infty \leq C x^{-1} (\log x)^P N_i, \tag{6.cv}$$

and all mixed jets of the regular effective source arise from families satisfying eq. 6.civ. Suppose their summed numerical bound is

$$\|A_B\|_\infty \leq C_n (\log x)^Q e^{-c(\log x)^b} \prod_{i \in B} N_i, \qquad |B| \geq 2, \tag{6.cvi}$$

with $b > 1$. This follows, for example, when $D_* \geq c'(\log x)^b$, the root and norm factors are polylogarithmic, and $r_i^{-1} \leq C_n N_i$.

For a partition in eq. 6.xci with s singleton blocks and at least one mixed block, its cumulant is bounded by

$$C_n x^{-s} (\log x)^{Q'} e^{-c'(\log x)^b} \prod_i N_i. \tag{6.cvii}$$

For fixed $n \leq 4$ this is $o(x^{-n} \prod_i N_i)$. In fact after division by $x^{-n} \prod_i N_i$, the exponent has the form $(n-s)\log x - c'(\log x)^b + Q' \log\log x$, which tends to $-\infty$ because $b > 1$. Summing the finitely many partitions proves

$$W_{1\cdots n}(0) = \kappa_\mu(A_1, \ldots, A_n) + o\left(x^{-n} \prod_i N_i \right), \qquad n = 2, 4. \tag{6.cviii}$$

This establishes the regular separated contact estimate with the actual source radius loss retained.

The condition $b > 1$ in this argument is stronger than the $b > 0$ sufficient for rare-history errors in eq. 6.lxxxvii. Here the mixed jets were not assumed to have the natural factor $x^{-|B|}$, so the exponential must overcome a fixed positive power of x. If the geometric decay is only $e^{-c \log x} = x^{-c}$, its coefficient must exceed the missing source powers. If the mixed jets already carry their full natural powers, $b > 0$ suffices. These are different uses of the same exponential reserve and should not be conflated.

6.5.6. *Normalizer derivatives and the order of averaging.* The formulas also fix the effect of a chosen analytic normalizer. If $\widetilde{F}(z) = e^{-E(z)}F(z)$ with deterministic E, then

$$\partial_B \log F(0) = \partial_B E(0) + \partial_B \log \widetilde{F}(0). \tag{6.cix}$$

A bound on $\widetilde{F}$ alone does not bound the left side until the required mixed derivatives of E are estimated. If E is a sum of terms each depending on only one source variable, its mixed distinct-index derivatives vanish for $|B| \geq 2$. For local terms involving several source variables, the carrier estimate above supplies the needed bound.

For a conditional normalizer $E_e(z)$, the identity must first be kept inside the exterior average:

$$F(z) = \int e^{E_e(z)} \widetilde{F}_e(z)\, \lambda(de). \tag{6.cx}$$

Replacing this by $\int \widetilde{F}_e(z)\lambda(de)$ would remove all the source derivatives of E_e and their exterior fluctuations. Apply the partition formula to the full conditional logarithm, and then the law of total cumulance of § 6.4. This order retains both the source contact terms and the conditional means.

At an actual clean run the remaining verification is therefore precise. The original positive physical source integral must equal the fixed-domain effective integral. Its first responses must have the stated readout and irrelevant remainder. Every mixed response must retain its own carrier and source radius. The marked history reserve controls the exceptional contributions. Under these inputs, eq. 6.cviii and the averaged comparison prove the connected extraction step without discarding any differentiated normalizer.

Physical source derivatives at the four-support witness. Use the sourced density of §5.20.1.1 at level $k_0 = K - s$. The fixed-domain representation in the two-point strategy applies with $w = \sum_{i=1}^{4} z_i f_i$. Use the exponent of each resummed standing class, including the exponents of its integral operations. The measures of the classes carry the unsourced gauge, averaging and test factors on the joint space with stored fields. In particular, an averaging delta can make the conditional measure in the block field singular at fixed stored fields. Exactness of both operations for the sourced total gives $Z(w)/Z(0) = \mathbb{E}e^{\Phi(w)}$, with Φ the complete exponent minus its zero-source value. If the representation extracts deterministic local source energies as a separate factor, include them in Φ in this identity.

The contact of a live component with a support and the age of its lineage are already functions of the standing class. For an event involving an individual history and the block field together, let τ_h^0 and $\tau_{[h]}^0$ denote their zero-source block-field marginals before normalization. Multiply the class joint measure by $d\tau_h^0/d\tau_{[h]}^0(V)$ on the sheet for $h \in [h]$. These weights are independent of w and sum to one almost everywhere. The lift gives the required individual zero-source joint marginal and leaves the sum of the sourced integrals unchanged. The exponent on a sheet is still the exponent of the resummed class.

6.5.6.1. Mixed derivatives on island carriers. Separate the differences of regular activities, remainders and boundary terms with no islands, together with the label's pointed shares of the source energies. The boundary terms involving islands form a second sum. In the remaining sum keep the coupling pieces and the exponents of the integral operations. Each nested operation exponent enters once, in the operation that contains it. The carrying Wilson and boundary terms enter in their own sums when a drop-out has no exponent for them in its integral. All differences use the same stored tuple at source w and at zero.

Write $\rho_{\mathsf{d}} = \mathsf{d}L^s$ for the support separation in witness lattice units. At origin level $j \leq k_0$ the separation in localization cubes is $n_j = (\rho_{\mathsf{d}}/M)L^{k_0-j}$. The rooms ensure $n_j \geq C\check{R}_j$ and give source radii $c\varrho/\|f_i\|_\infty$ at the witness. At fixed fields, the running shift and each counterterm weight are sums of functions of single plaquette source values, with fixed profiles and tents. By linearity of the

Wilson action in the weight, this also applies to the separate carrying Wilson terms of a drop-out. Their mixed derivatives vanish at disjoint supports regardless of the size of the carrying region. An elementary operation whose source dependence lies in its component of diameter $C\check{R}_j$ misses at least one of any two of the separated supports. Apply this criterion to the actual carrier of each sourced operation exponent, including any subtraction from its normalizer.

For a formed operation the fixed-variable source formula uses the twice-enlarged component, with the already formed inner exponents included in the same read. At level j the component at formation is in a cube of side $100M\check{R}_j$ in its own units. Its enlarged physical diameter is at most $CM\check{R}_j a_{K-j}$, below the support separation by the witness room. Thus the mixed derivative of this complete exponent vanishes. This applies also to the executed operations retained inside a drop-out. The Wilson and boundary factors never integrated by those operations keep their own carriers. The calculation uses the exponent at fixed stored fields and zero-source reference measure throughout. In particular it involves no division by a complex sourced operation mass.

For the regular activities and local energies, use the enlarged carrier in eq. 6.ciii. An island boundary term uses the tree length through the cells outside the exempt hulls, with the tree also meeting each selected hull as in Lem. 6.7. By the hull geometry at eq. 6.xxxvii, every source contact in an enlarged carrier is within $C(1+\check{R}_j)$ cells of a vertex of this tree. The two contacts of an active carrier therefore give length at least $n_j - C - C\check{R}_j$. Edges inside a hull still count in the original lattice metric. For the root pin the tree at a vertex near the first contact. There are at most Cn_j^4 such vertices. The rooted walk and hull incidence count in that lemma apply at fixed history, before taking the essential supremum. The exempt hulls are those in the surviving filing at the witness. For a term whose old bound discounted an absorbed hull, apply the donor refiling after eq. 6.xli on the admitted source box before using the incidence estimate.

For the boundary differences use the sourced bound on the retained list at its actual field values. The witness room and monotonicity of the depth norms give $\|w\|_{\flat,K-j} \le \varrho/2$ for every origin on $|z_i| \le \varrho/(8\|f_i\|_\infty)$, after choosing the fixed source radius ϱ within the sourced class. Cauchy differentiation uses this common disc in the sources at fixed stored fields. If an estimate holds almost everywhere for each source separately, impose it first on a countable dense set and extend it there by holomorphy of the actual read. With the exponential incidence bound for the actual island and regular terms, Cauchy's estimate thus costs $Cn_j^4 e^{-cn_j}\prod_{i\in B}(\|f_i\|_\infty/\varrho)$ for a mixed derivative in B, $|B|\ge 2$. Sum the levels using $n_j = n_{k_0}L^{k_0-j}$ to obtain

$$\|\Phi_B\|_\infty \le C(\rho_{\mathsf{d}}/M)^4 e^{-c\rho_{\mathsf{d}}/M}\prod_{i\in B}(\|f_i\|_\infty/\varrho). \tag{6.cxi}$$

This estimate uses the source localization on the resummed standing classes, with the relative incidence bound on the same source polydisc. For an operation that has a larger source carrier one must include it in the mixed-jet estimate with its actual size.

6.5.6.2. First derivatives on live histories. Let B_i be the event that a live component at the witness meets the fixed neighbourhood of support i. On this event let a_i be the greatest lineage age among those components. Each of its a_i+1 stored levels can increase the spatial count in the first source derivative. Write its upper weight as $y_i = \mathbf{1}_{B_i}(a_i+2)^C L^{4(a_i+1)}$. A renewal of the label does not reset the count of retained levels. For a nonempty set of indices I, $\prod_{i\in I} y_i \le \sum_{i\in I} y_i^4$, since every nonzero y_i is at least one. On B_i an attaining component meets one of at most $C\rho_{\mathsf{d}}^4$ witness cells. Summing over these cells and then the ages gives

$$\mathbb{E}\prod_{i\in I} y_i \le C\rho_{\mathsf{d}}^4 Q_{17}(k_0), \qquad Q_b(k_0) = \sum_{a\ge 0} L^{ba}\sup_{\mathfrak{c}}\mathbb{P}(\text{lineage age } a \text{ at } \mathfrak{c}). \tag{6.cxii}$$

The four powers cost L^{16a} and the remaining power pays for the polynomial in the age. This is a normalized history estimate, with the volume and depth range of the age bound in force.

For a first derivative keep the witness, the class, the guards, the background and the stored tuple fixed and restrict the source to $w = tf_i$. This is the one-direction derivative of the very same exponent used in eq. 6.cxi. The source terms on the regular domain depend on the function w, so restricting the other three parameters to zero changes no integration domain or zero-source law. The derivative of the full source energy of the empty standing label is a deterministic constant c_i. For another standing label $\mathcal{S}$ the difference is the first derivative of $\sum_j[\mathsf{T}_j(\mathcal{S};w) - \mathsf{T}_j(\mathcal{S}_\emptyset;w)]$, with T_j the label's share of the source energy. Only a missing term near Z_j^+ whose enlarged carrier meets the source can contribute. This includes a missing one-point gauge term if it is included in the source energy. The small-field regions are nested in the reduced standing label, so the earlier missing sites lie in the witness live footprint. The padding at level j has physical width at most $CM\check{R}_j a_{K-j} \le CM\check{R}_{k_0} a_s$ by eq. 2.xx. Off B_i the padded missing sites are therefore separated from the source by a fixed fraction of d. A contributing carrier has $d_j(X) \ge c\rho_{\mathsf{d}} L^{k_0-j}/M$. Rooting the sum near the source, the weighted carrier count and Cauchy's estimate at the fixed source radius give a bound $C\|f_i\|_\infty \sum_{j\le k_0} m_j^4 e^{-cm_j}$, where $m_j = \rho_{\mathsf{d}} L^{k_0-j}/M$. This is at most $C\|f_i\|_\infty \rho_{\mathsf{d}}^4 e^{-c'\rho_{\mathsf{d}}/M}$. On B_i the missing share belongs to the live error.

Off contact, the counterterm identity for the running weight gives the profile of the insertion,

$$\partial_{z_i}\zeta_{k_0}(p;w)|_0 = f_i(x(p)) + \sum_{j\le k_0} b_j'(0) \sum_y h_y^{(j)}(p) f_i(x(p_y)) = \zeta_{k_0}' \widetilde{f}_i(p).$$

Here $b_j'(0)$ differentiates the whole running increment with respect to the input source. At constant input the tent sum is one and the coefficient is ζ_{k_0}'. The tents have range at most CMa_s, so the bounded sum of $|b_j'(0)|$ and the lower bound on $|\zeta_{k_0}'|$ give $|\widetilde{f}_i - f_i| \le CMa_s \operatorname{Lip}(f_i)$. Use $\widetilde{f}_i$ as the profile of the bounded readout G_i in the four-insertion comparison below. Its window tests all cubes needed to read the enlarged support. Include these padded carriers in the neighborhood defining B_i. On the actual zero-source joint law, the witness characteristic functions imply passage of the individual cube tests off B_i. This is a statement about the same retained fields and the localized witness chart.

On the admitted complete regular carriers the ordinary one-direction bounds eq. 4.clxxvii and eq. 4.clxxx–eq. 4.clxxxi apply to this restriction pointwise. After subtraction of the vacuum value and the tent action, the quadratic coefficient is bounded by $C\delta_{k_0}/\alpha_{k_0}$, using the formed source slope. At age $a = k_0 - j$, the quadratic estimate retains a geometric factor $L^{-\alpha_H a}$ after the fine-site count. The cubic term retains L^{-2a}, up to a polynomial in a. Summing gives $C\delta_{k_0}^3/\alpha_{k_0}$ per witness window and per unit source norm. For an old ordinary remainder the quadratic field factor pays the fine-site count and the extra factor $x_j^{-\kappa_0/2}$ is summed with $\alpha_j^{-2} \le Cx_j$ by the lower flow bound. This gives the additional $x^{2-\kappa_0/2}$ below. For the localized readout off B_i, the four-layer enlargement of the test cube lies in the ordinary region. The history background restricted there is the local minimizer at its own averages by the nested-minimizer property. In a common gauge compare it with the test minimizer on this enlargement. The logarithmic difference of their averages is zero on the common interior rows and is bounded by $C\varepsilon_{k_0}$ on the outer layer. The stored fields enter through these actual boundary averages. The collar response gives a bound $C\varepsilon_{k_0} e^{-c\check{R}_{k_0}}$ for the change of the local potential and its first lattice derivatives in the plaquette read. In bare plaquette units, with $\eta = \eta_{k_0}$, the plaquette change is bounded by $C\varepsilon_{k_0}\eta^2 e^{-c\check{R}_{k_0}}$. Both plaquette defects have size at most $C\varepsilon_{k_0}\eta^2$, so

$$\tfrac{1}{2}\big|\|U_p - \mathbf{1}\|^2 - \|U_p' - \mathbf{1}\|^2\big| \le C\varepsilon_{k_0}^2 \eta^4 e^{-c\check{R}_{k_0}}.$$

The separate contribution from the distant live region uses the same curvature scale with decay $e^{-c\rho_{\mathsf{d}}}$. Summing with the witness profile cancels η^4 against the bare plaquette count and gives the action bound below. These bounds use complete ordinary charts. Long or wrapping carriers that leave those charts use the far bound, or the live estimate if they reach a local contact.

6.5.6.3. Matching the windowed insertions. Let J_i denote the main Wilson response in the physical derivative on B_i^c, before replacing its background by the witness minimizer. Extend $J_i\mathbf{1}_{B_i^c}$ by zero on B_i. On the same joint law put $O_i = \zeta'_{k_0} G_i(V)$, using the witness window even on B_i. Write $F_i = \|f_i\|_\infty$. On the witness window the localized minimizer passes its own plaquette test and there are at most $C\rho_{\mathsf{d}}^4\eta_{k_0}^{-4}$ plaquettes in the enlarged support. Off that window $G_i = 0$. Thus $\|O_i\|_\infty \le Cx^{-1}\rho_{\mathsf{d}}^4 p_0^2 F_i$ on the entire joint law. Then

$$J_i\mathbf{1}_{B_i^c} - O_i = (J_i - O_i)\mathbf{1}_{B_i^c} - O_i\mathbf{1}_{B_i}.$$

The two-radius comparison above bounds the first term on the actual off-contact window, uniformly in the stored fields. It has size at most $Cx^{-1}\rho_{\mathsf{d}}^4 p_0^2 F_i(e^{-c\check{R}_{k_0}} + e^{-c\rho_{\mathsf{d}}})$. The second term is bounded by the windowed supremum times $\mathbf{1}_{B_i}$. This term occurs because the witness window can pass on a live history. Expand the difference of the fourth cumulants by multilinearity. A term containing a deleted slot $O_i\mathbf{1}_{B_i}$ costs its L^1 bound times the suprema of the other slots, by the moment formula for the cumulant. With $B = \bigcup_i B_i$, the total deletion cost is at most

$$C\,\mathbb{P}(B)\,x^{-4}\rho_{\mathsf{d}}^{16}p_0^8\prod_i F_i.$$

Here $\mathbb{P}(B) \le C\rho_{\mathsf{d}}^4 Q_{17}(k_0)$. The off-contact defect costs the same prefactor with $\mathbb{P}(B)$ replaced by $e^{-c\check{R}_{k_0}} + e^{-c\rho_{\mathsf{d}}}$. Thus the replacement of the physical main entries uses the actual joint law and the localized comparison on B_i^c. The age-weighted bound below is still needed for the live parts of the physical derivatives.

The off-contact ordinary error has size at most $Cx^{-1}\rho_{\mathsf{d}}^4 F_i$ times $(\log x)^{3\mathfrak{p}_0-q} + p_0^2 x^{2-\kappa_0/2}$, where the last term pays the ordinary remainders. The far error costs a polynomial in ρ_{d} times $F_i e^{-c\rho_{\mathsf{d}}}$. For the live estimate, differentiate the outermost standing operation exponents. An operation can contribute only when its twice-enlarged carrier meets the source. By the diameter bound above and eq. 2.xx, its entire stored stock is then in the witness source neighborhood of diameter $C\mathsf{d}$. Its lineage is among those counted by a_i, and the oldest retained level is at least $k_0 - a_i$. This also covers the additional waiting-window stock of a drop-out, since its predecessor already belongs to the lineage at the start of the window. At a fixed level j the stocks of distinct outermost operations are disjoint. Nested stocks enter their outer exponent once. A site can occur once more through a drop-out, since intersecting standing marks have disjoint active level windows. The total site count at that level, with this multiplicity, is bounded by $C\rho_{\mathsf{d}}^4 L^{4(k_0-j)}$. Apply the Cauchy bound for the sourced excess exponent, which is bounded by a fixed constant times its stored site count on the fixed source disc. The derivative sum is at most

$$C\varrho^{-1}F_i\rho_{\mathsf{d}}^4\sum_{j=k_0-a_i}^{k_0} L^{4(k_0-j)} \le C\varrho^{-1}F_i\rho_{\mathsf{d}}^4 L^{4a_i}.$$

For the separate carrying Wilson terms, a level-j site has $O(\eta_j^{-4})$ bare plaquettes, each with action bounded by $C\eta_j^4$ on the corresponding regular layer. At the bare layer use boundedness of the plaquette action. This gives a fixed cost per site. The boundary terms use their own rooted carrier estimates. With the source footprint and nested storage bounds above, the live error has bound $s_i y_i$ with $s_i = C(\log x)^C\rho_{\mathsf{d}}^8 L^{C\check{R}_{k_0}}F_i$. This includes the differentiated operation exponent. The joint law throughout is the one used for the mixed jets, and the law of the four G_i is its block-field marginal.

The lineage estimate of Prop. 5.71 with $b = 17$ gives $Q_{17}(k_0) \le Ce^{-cp_0}$ on its admitted runs. The fixed-torus alternative uses the same age exponent at the witness depth where its terminal bound applies. In particular the L^4 error is at most $Cs_i\rho_{\mathsf{d}}e^{-cp_0/4}$. Here $\check{R}_{k_0} = o(p_0)$ and $p_0/\log x \to \infty$, so it is $o(x^{-1})F_i$. In every partition with at least two blocks subtract the deterministic constant from each first jet, using invariance of the cumulant under those translations. The one-block partition

has only the four-source mixed jet. Hölder's inequality in the moment formula bounds each of the fourteen partitions containing a mixed source derivative by the product of its mixed-jet bounds and the L^4 bounds for its first jets. Relative to $x^{-4}\prod_i F_i$ this costs at most $x^4(\log x)^C e^{-c\rho_{\mathsf{d}}/M}$. In the partition into singletons expand the centered entries. Each cumulant term with a live factor costs at most $C\prod_i s_i\,\rho_{\mathsf{d}}^4 Q_{17}(k_0)$ by eq. 6.cxii in the corresponding moments. No independence between contacts is needed. The relative cost is bounded by $Cx^4\rho_{\mathsf{d}}^{36}(\log x)^C L^{C\check{R}_{k_0}}e^{-cp_0}$. In the prescribed room $\check{R}_{k_0}=o(p_0)$ and p_0 is of order $(\log x)^{\mathfrak{p}_0}$ with $\mathfrak{p}_0>1$, so this tends to zero. An ordinary error replacing one of the four main terms costs $C\rho_{\mathsf{d}}^{16}(\log x)^{9\mathfrak{p}_0-q}$ relative to the same scale, apart from the exponentially small pieces. The ordinary remainder has an extra inverse power of x that absorbs every fixed logarithmic power. In the prescribed room $\rho_{\mathsf{d}}\asymp(\log x)^{2\mathfrak{p}_0}$ this requires $q>41\mathfrak{p}_0$. The far error is negligible by the same separation as in eq. 6.cxi. This reduces the physical fourth derivative to the fourth cumulant of the bounded readouts, with the four running source factors retained.

6.5.6.4. Counting the near reads on a finite torus. In the native four-source decomposition there is a second bound for the near first derivatives. It uses the cells actually read by each slot. For source i let T_i count the cells of each stratum $\Omega_n\setminus\Omega_{n+1}$, $n<k_0$, in its enlarged support, measured in units of level n. Include the internal strata of pocket strips with their own units. The action costs a constant on each such cell and on the level-k_0 portion, whose volume is $O(\rho_{\mathsf{d}}^4)$. In counting localization and volume terms, a stratum of level n measured at level $j\ge n$ contributes $L^{-4(j-n)}$ times its own count. The sum over reading levels therefore costs $C(\rho_{\mathsf{d}}^4+T_i)$. For the regular source terms the fine-anchor factor $L^{4(n-j)}$ cancels the same volume power in their decay, leaving the summable $L^{-\alpha(n-j)}$. The boundary, potential and remainder bounds are summed on their admitted native carriers. Together these give, on the i-th live-contact event,

$$|\lambda_i^{\mathrm{near}}|\le C\mathfrak{p}_\flat(\bar{x}_s)(A_i+2)^{c_\flat}(\rho_{\mathsf{d}}^4+T_i)u_i,$$

where A_i is the greatest age read by that source and u_i its source norm in this decomposition.

For a live component Z let $D(Z)$ sum $M^4\check{R}_j^5 d_j'(Z_j\cap Z)$ over its history, including the internal pocket sequences. Here d_j' is the geometric size in the history weight. Pack the cells at level j by a maximal family whose block indices are at least four apart in the max norm. The family has at most d_j' members, and each covers at most 7^4 cells of the original region. The pocket strip costs a further factor at most 2^4, and the level conversion costs at most L^4. Consequently T_i is bounded by a fixed multiple of the sum of the charges of the live components meeting that read. Each surviving level contributes at least one, so $D(Z)\ge\mathrm{age}(Z)+1$.

Sum the charge of the live component of each read block, counting it again if the block occurs in another window. Call this sum D_{read}. It dominates A_i+1 on a live contact and controls every T_i. A product of at most four near derivatives, divided by their deterministic factors, is bounded on its contact event by CD_{read}^p for $p\ge4(1+c_\flat)$. If each window meets at most N_{read} blocks, the power-mean inequality bounds its expectation by $C(4N_{\mathrm{read}})^p$ times the largest rooted p-th charge moment.

On the prolonged finite torus the dialled history bound pays $e^{-c_a n}$ for charge at least n. If the component heals at k, restrict the healed sum to charge at least $n+k-k_0$ and use the healed-block bound. This yields a geometric sum over $k>k_0$. A component still live at $\hat{K}$ has charge at least $n+\hat{K}-k_0$. Use the terminal modulus and partition-function lower bound with the charge dial. The additional decay in $\hat{K}-k_0$ pays the terminal volume under the source's depth condition $c_a(\hat{K}-k_0)\ge\mathsf{B}(g^\dagger)\hat{N}^4$, or the below-horizon bound applies. In this range the resulting rooted moment is bounded by

$$Ce^{-\theta_q p_0(g_{k_0})}\sum_{n\ge1}(n+1)^p e^{-c_a n}.$$

This gives the near-slot moment estimate where the actual four-source members have these own-scale bounds and the dialled mass estimates apply. A volume-uniform terminal charge estimate would be needed for the same argument outside that range.

6.6. **Sharp cutoff boundaries in the classical Gaussian law.** The boundary term in the conditional integration-by-parts identity need not be small merely because a Gaussian precision has a gap. The event that every bond is small can have a probability tending to zero with the volume. Dividing a whole-space tail estimate by that probability would therefore give no uniform conditional estimate. In the centered Gaussian reference law the symmetry and convexity of all the other cutoffs give a different argument: their conditional probability decreases on every radial ray. A radial boundary density can then be compared with an inner radial integral in the same direction. The normalization cancels before directions or bonds are summed.

This section proves that comparison for possibly singular physical bond covariances. It derives the resulting second through eighth moment errors, including the covariance and third and fourth connected errors of localized quadratic curvature observables. The actual flat pivot chart and contour gauge supply a concrete fixed-step application. The measure here is classical Gaussian. Haar and coarea factors, old activities, nonlinear action weights and conditional exterior forces are additional terms in the complete conditional law of § 6.3.

Physical blocks, actual covariance entries and the cutoff law. Let Y be a centered Gaussian vector in a finite-dimensional real space, with covariance $G \geq 0$, and let $Z = CY$. The blocks Z_b belong to $\mathbb{R}^3$; repeated or linearly dependent blocks are allowed. All covariances in this section are the actual matrix entries

$$\Gamma_{bc} = \mathbb{E}[Z_b Z_c^{\mathsf{T}}] = C_b G C_c^{\mathsf{T}}, \qquad \Gamma = CGC^{\mathsf{T}}. \tag{6.cxiii}$$

For every tested block choose $b_b > 0$, put

$$\mathcal{A} = \bigcap_b \{|Z_b| < b_b\}, \qquad \nu(P) = \frac{\mathbb{E}[P(Z)1_{\mathcal{A}}]}{\mathbb{P}(\mathcal{A})}, \qquad d_b = \operatorname{rank}\Gamma_{bb} \leq 3, \tag{6.cxiv}$$

and choose an upper marginal scale $\sigma_b > 0$ with $\Gamma_{bb} \leq \sigma_b^2 I$. There is no lower eigenvalue assumption. A sufficiently small neighborhood of zero in the latent Gaussian support is contained in $\mathcal{A}$, so its probability is positive. If $d_b = 0$, then $Z_b = 0$ almost surely and that constraint has no boundary contribution. All blocks occurring in a polynomial to be bounded below are included among the tested blocks.

For a finite volume no lower bound on $\mathbb{P}(\mathcal{A})$ uniform in the volume is assumed or needed. The estimates concern these normalized finite-volume laws. They do not define conditioning on a simultaneous infinite collection of cutoff events, whose intersection could have probability zero.

Marginal log-concavity from one-dimensional transport. We first prove the integration fact needed for the conditional cutoff probability. Suppose nonnegative integrable functions f, g, h on $\mathbb{R}$, positive in the interiors of their interval supports, satisfy, for $0 < t < 1$,

$$h((1-t)x + ty) \geq f(x)^{1-t} g(y)^t. \tag{6.cxv}$$

It is enough initially that the functions be continuous and the positive densities be smooth on their supports, as will hold in the application. Write $F = \int f$, $G_1 = \int g$, and assume both are positive. The increasing quantile map T from density f/F to g/G_1 is continuously differentiable in the interior and satisfies $T'(x) = f(x)G_1/[Fg(T(x))]$. The increasing map $T_t(x) = (1-t)x + tT(x)$ has derivative at least $T'(x)^t$, by the weighted arithmetic-geometric mean inequality. Changing

variables on its image and using eq. 6.cxv gives

$$\begin{aligned}\int h &\geq \int h(T_t(x))T_t'(x)\,dx \\ &\geq \int f(x)^{1-t}g(T(x))^t T'(x)^t\,dx = F^{1-t}G_1^t.\end{aligned} \tag{6.cxvi}$$

One first integrates over compact subintervals of the positive support and then lets them exhaust it. All terms are nonnegative. This also handles unbounded interval endpoints and densities vanishing at the boundary. If either integral is zero the conclusion is immediate.

The same assertion holds in $\mathbb{R}^q$. Here is the induction needed to avoid importing a stronger integration theorem. Split $x = (x', u)$, $y = (y', v)$. For fixed x', y', apply the one-dimensional assertion in u, v, with the slice of h at $(1-t)x' + ty'$. The resulting marginals obey the same inequality in $q-1$ dimensions. Apply the induction hypothesis to those marginals and use Tonelli. Slices of zero integral cause no problem. In the application all positive supports are open convex sets and all slices have these interval supports. Products of smooth compact cutoffs with a Gaussian have integrable dominating functions for their derivatives on every compact set of external parameters. Their marginals are therefore continuous, smooth where required, and positive on the interiors of their convex supports. These facts justify each induction step directly in this class of functions.

In particular, if $k(z, w)$ is log-concave jointly in z, w, and its w slices are of the preceding integrable class, then

$$w_0(z) = \int k(z, w)\,dw \quad \text{is log-concave in } z. \tag{6.cxvii}$$

Indeed use the joint log-concavity inequality for the slices at z, z' and $(1-t)z+tz'$, then integrate by eq. 6.cxvi and its induction. The function k need not be integrable over the external variable z. If $k(-z, -w) = k(z, w)$, its marginal is even. An even log-concave function satisfies $w_0(rn) \leq w_0(sn)$ whenever $0 \leq s \leq r$: write sn as a convex combination of rn and $-rn$. The argument below uses this ray monotonicity and requires no volume estimate for the complete cutoff probability.

Smooth compact approximants with an inner plateau. For $0 < \delta \leq 1/2$, construct a radial cutoff as follows. Put $\phi(t) = 0$ for $t \leq 0$, and on $0 < t < 1$ set

$$\begin{aligned}\phi''(t) &= \frac{e^{-1/t^2}}{(1-t)^4}, \qquad \phi(t) = \int_0^t (t-s)\frac{e^{-1/s^2}}{(1-s)^4}\,ds, \\ \psi_{b,\delta}(z) &= \begin{cases} e^{-\phi((|z|/b-1+\delta)/\delta)}, & |z| < b, \\ 0, & |z| \geq b. \end{cases}\end{aligned} \tag{6.cxviii}$$

The function ϕ is convex, nondecreasing, flat at zero and diverges at least as a positive multiple of $(1-t)^{-2}$ near one. Consequently $\psi_{b,\delta}$ is smooth on all of $\mathbb{R}^3$, including the sphere $|z| = b$, is even and log-concave, and equals one on $|z| \leq (1-\delta)b$. The smoothness at zero follows because it is constant near zero; the smoothness at the outer sphere follows from the exponential decay of $e^{-\phi}$ faster than every inverse power of $1-t$. Convexity of $z \mapsto \phi((|z|/b - 1 + \delta)/\delta)$ follows from convexity of the norm and monotonic convexity of ϕ, extended by $+\infty$ at and beyond one.

As $\delta \downarrow 0$, these cutoffs increase pointwise to $1_{\{|z|<b\}}$. To check monotonicity inside the ball, the argument of ϕ is $1 - (1 - |z|/b)/\delta$, which decreases as δ decreases. Define

$$\chi_\delta(Z) = \prod_b \psi_{b_b,\delta}(Z_b), \qquad \nu_\delta(P) = \frac{\mathbb{E}[P(Z)\chi_\delta(Z)]}{\mathbb{E}\chi_\delta(Z)}. \tag{6.cxix}$$

Every denominator is positive, and Gaussian dominated convergence gives $\nu_\delta(P) \to \nu(P)$ for every polynomial P. No independence of the tested coordinates enters this statement.

The plateau in eq. 6.cxviii is essential to the estimate: the derivative is supported in the outer annulus $[(1-\delta)b, b]$. A smooth cutoff whose derivative remained nonzero close to zero would not by itself yield the exponential boundary tail established next.

Conditional Gaussian support and monotonicity on rays. Fix a block b of positive rank and let $V_b = \operatorname{ran}\Gamma_{bb}$, of dimension $d = d_b$. Orthogonal decomposition of a whitened latent Gaussian gives, when conditioning on $Z_b = z \in V_b$,

$$Z_a = \Gamma_{ab}\Gamma_{bb}^{+}z + D_aW \quad (a \neq b), \qquad w_{b,\delta}(z) = \mathbb{E}_W \prod_{a\neq b} \psi_{b_a,\delta}(\Gamma_{ab}\Gamma_{bb}^{+}z + D_aW). \tag{6.cxx}$$

Here W is a standard Gaussian independent of Z_b, possibly in dimension zero, and Γ_{bb}^{+} is the inverse on V_b, extended by zero. For completeness, write the latent standard Gaussian as its orthogonal projection onto the row space of the map defining Z_b and the perpendicular projection. The first projection is determined by z, and the second is an independent standard Gaussian on its subspace. This proves eq. 6.cxx, including singular full covariances. There is no bound asserted on $\Gamma_{ab}\Gamma_{bb}^{+}$.

The integrand defining $w_{b,\delta}$, multiplied by the Gaussian density of W, is jointly log-concave in (z, W) and unchanged under $(z, W) \mapsto (-z, -W)$. The formula in eq. 6.cxvii therefore proves that $w_{b,\delta}$ is even and log-concave on V_b. Its value decreases along every ray. It is positive near zero, although it may vanish elsewhere because of exact dependencies between blocks. Such zeros strengthen the inequalities below and require no separate boundary trace convention.

A normalized boundary flux with no lower marginal variance. Define the normalized smooth flux

$$\beta_{b,\delta} = \frac{\mathbb{E}[|\nabla\psi_{b_b,\delta}(Z_b)| \prod_{a\neq b}\psi_{b_a,\delta}(Z_a)]}{\mathbb{E}\chi_\delta(Z)}. \tag{6.cxxi}$$

For $d_b = 0$, set $\beta_b^* = 0$; the flux is zero because the cutoff is constant near zero. In positive rank the radial gradient lies in V_b, so the ambient Euclidean norm in eq. 6.cxxi is also its intrinsic gradient norm. Set $B = b_b$, $a = (1-\delta)B$, and use polar coordinates $z = rn$ in V_b. Up to a constant independent of r, n, the intrinsic Gaussian density is $\exp[-q(n)r^2/2]$, with $q(n) = n^{\mathsf{T}}(\Gamma_{bb}|_{V_b})^{-1}n \geq \sigma_b^{-2}$.

For a fixed direction let

$$\begin{aligned} D_n &= \int_0^B \psi_{B,\delta}(rn)w_{b,\delta}(rn)r^{d-1}e^{-q(n)r^2/2}\,dr, \\ I(q,a) &= \int_0^a s^{d-1}e^{-qs^2/2}\,ds. \end{aligned} \tag{6.cxxii}$$

For every $r \in [a, B]$, ray monotonicity and the inner plateau give $D_n \geq w_{b,\delta}(rn)I(q(n), a)$. The integral of the nonnegative radial derivative $-\partial_r\psi_{B,\delta}$ on $[a, B]$ is one. Thus the corresponding numerator in direction n is at most

$$D_n \frac{B^{d-1}e^{-q(n)a^2/2}}{I(q(n), a)}. \tag{6.cxxiii}$$

This inequality remains true if $D_n = 0$, because the preceding pointwise inequality then forces the numerator to vanish. In particular it does not divide by a possibly zero directional weight.

There are constants depending only on $d \leq 3$ such that $I(q, a) \geq c_d \min(a^d, q^{-d/2})$. If $a \leq q^{-1/2}$, integrate over $[0, a]$, where the exponential is at least $e^{-1/2}$. Otherwise integrate over $[0, q^{-1/2}]$. Since $B/2 \leq a \leq B$, the ratio in eq. 6.cxxiii is bounded by $C_dB^{-1}[1 + (qB^2)^{d/2}]e^{-qB^2/8}$. Taking the supremum over all $q \geq \sigma_b^{-2}$ gives

$$\boxed{\beta_{b,\delta} \leq \beta_b^* := \frac{C_d}{b_b}\left[1 + \left(\frac{b_b}{\sigma_b}\right)^d\right] e^{-c_d b_b^2/\sigma_b^2}} \qquad (1 \leq d = d_b \leq 3). \tag{6.cxxiv}$$

To justify the last maximization explicitly, put $x = qB^2$, $x_0 = B^2/\sigma_b^2$. The product $(1 + x^{d/2})e^{-x/16}$ is bounded on $[0, \infty)$. For $x \geq x_0$, the remaining factor is at most $e^{-x_0/16}$; increasing the constant gives the displayed bound, with for example a smaller fixed c_d. Now integrate eq. 6.cxxiii over directions. The determinant normalization of the intrinsic Gaussian and the total integral of D_n

cancel. This proves eq. 6.cxxiv uniformly in δ, the volume, the number of other constraints, their dependencies and every lower marginal eigenvalue.

For $b_b \geq \sigma_b$ the useful simpler consequence is

$$\beta_b^* \leq C_d b_b^{d-1} \sigma_b^{-d} e^{-c_d b_b^2/\sigma_b^2}. \tag{6.cxxv}$$

The qualification is necessary. At small radius the normalized radial flux can be of order d/b_b; an estimate proportional to $b_b^{d-1}\sigma_b^{-d}$ alone would be false there. The proof has retained that regime in eq. 6.cxxiv.

Gaussian integration by parts before the sharp limit. For a polynomial P in the ambient physical blocks, ordinary Gaussian integration by parts, applied to a whitened latent vector, gives

$$\begin{aligned} \nu_\delta[Z_i P] &= \sum_j \Gamma_{ij} \nu_\delta[\nabla_j P] + \sum_b \Gamma_{ib} \mathcal{L}_{b,\delta}(P), \\ \mathcal{L}_{b,\delta}(P) &= \frac{\mathbb{E}[P(Z) \nabla \psi_{b_b,\delta}(Z_b) \prod_{a \neq b} \psi_{b_a,\delta}(Z_a)]}{\mathbb{E}\chi_\delta(Z)}. \end{aligned} \tag{6.cxxvi}$$

The gradients are column vectors and Γ_{ib} are the corresponding 3 by 3 blocks. Degeneracy of Γ does not alter the formula: in the latent variables its two chain-rule factors are exactly the factors producing CGC^{T}. Gaussian domination justifies integration by parts even when the cutoffs have no compact support in null directions of C.

Let $\|P\|_{\mathcal{B}}$ be the supremum on the product of closed balls $\mathcal{B} = \prod_b \{|z_b| \leq b_b\}$. Then

$$|\mathcal{L}_{b,\delta}(P)| \leq \beta_b^* \|P\|_{\mathcal{B}}. \tag{6.cxxvii}$$

For $L = \sum_i \ell_i^{\mathsf{T}} Z_i$, define its canonical sharp defect by

$$\mathcal{D}_L(P) = \nu[LP] - \sum_{i,j} \ell_i^{\mathsf{T}} \Gamma_{ij} \nu[\nabla_j P]. \quad |\mathcal{D}_L(P)| \leq \left(\sum_{i,b} |\ell_i| \, \|\Gamma_{ib}\| \beta_b^* \right) \|P\|_{\mathcal{B}}. \tag{6.cxxviii}$$

Indeed the left side is the limit of the left side of eq. 6.cxxvi contracted with ℓ, while eq. 6.cxxvii bounds the right side uniformly. This proves the sharp identity and its estimate without assigning a meaning to a product of a boundary delta function with another sharp indicator on the same surface.

For repeated or dependent constraints the separate sharp limits of $\mathcal{L}_{b,\delta}$ need not be intrinsic: the allocation between coincident constraint surfaces can depend on the smoothing schedule. The total defect in eq. 6.cxxviii is intrinsic, because its definition uses only sharp conditional polynomial expectations. This is the only boundary object needed for the moment estimates. When a classical smooth-boundary free-coordinate trace exists, $\nabla 1_D = -n \, dS$, so this defect is the negative of the covariance contracted with the outward boundary functional in the conditional-law identity. This also fixes the sign convention.

The actual weighted Schur accounting. Choose positive amplitude scales a_b and positive cell weights μ_b. Assume the following explicit two-sided bound, using the covariance entries of eq. 6.cxiii:

$$S = \max \left\{ \sup_i \sum_j \mu_j \frac{\|\Gamma_{ij}\|}{a_i a_j}, \sup_j \sum_i \mu_i \frac{\|\Gamma_{ij}\|}{a_i a_j} \right\} < \infty, \qquad \varepsilon_\partial = \sup_b \frac{a_b \beta_b^*}{\mu_b}. \tag{6.cxxix}$$

The two sums give the usual bounded operator on weighted counting ℓ^2 after normalizing by a_b: weighted Cauchy in each row and then the column bound give norm at most S. For the boundary estimate the more specific computation is

$$\frac{1}{a_i} \sum_b \|\Gamma_{ib}\| \beta_b^* = \sum_b \mu_b \frac{\|\Gamma_{ib}\|}{a_i a_b} \frac{a_b \beta_b^*}{\mu_b} \leq S \varepsilon_\partial. \tag{6.cxxx}$$

Thus, with $U(L) = \sum_i a_i|\ell_i|$,

$$|\mathcal{D}_L(P)| \le \delta(L)\|P\|_{\mathcal{B}}, \qquad \delta(L) = S\varepsilon_\partial U(L). \tag{6.cxxxi}$$

There is no number of ambient coordinates in this estimate. The factor μ_b^{-1} in ε_∂ cannot be dropped: coordinate Gaussian integration by parts uses the ordinary partial derivative with respect to that coordinate. A weighted kernel convention does not change that derivative.

For example, if a precision is written as a self-adjoint operator K in pairing $\sum_b \mu_b y_b \cdot z_b$, its coordinate density has Euclidean precision MK, where $M = \mathrm{diag}(\mu_b I_3)$. Its covariance matrix is $(MK)^{-1}$. If $(K^{-1}f)_i = \sum_j \mu_j \mathsf{G}(i,j) f_j$, then $K^{-1} = \mathsf{G}M$, and $(MK)^{-1} = \mathsf{G}$. Accordingly $\mathsf{G}(i,j)$, rather than $\mu_j \mathsf{G}(i,j)$, is the covariance entry used here. This calculation prevents either suppressing or inserting a second cell-volume factor during the physical coordinate conversion.

All linear marginals remain Gaussian dominated. There is a useful moment bound independent of the cutoff radii. For a real linear statistic L, put $v(L)^2 = \mathbb{E}L^2 = \ell^{\mathsf{T}}\Gamma\ell$. If this is zero then $L = 0$ almost surely. Otherwise condition the latent Gaussian on $L = x$. The argument of eq. 6.cxx, now including every cutoff, gives an even log-concave weight $w(x)$ for its one-dimensional Gaussian density, first for ν_δ and then by the sharp limit. Therefore w decreases as $|x|$ increases. For any nonnegative increasing function f of $|x|$,

$$\nu[f(|L|)] \le \mathbb{E}f(|v(L)N|), \qquad N \sim N(0,1). \tag{6.cxxxii}$$

To see the normalization explicitly, let R, R' be independent absolute Gaussian variables of this variance. The product $(f(R) - f(R'))(w(R) - w(R'))$ is nonpositive. Its expectation is twice $\mathbb{E}[fw] - \mathbb{E}[f]\mathbb{E}[w]$. Divide by $\mathbb{E}[w] > 0$, and truncate f followed by monotone convergence if necessary. This proves the assertion without a lower bound on the cutoff probability.

In particular the law is centered and, for $m \ge 1$,

$$\nu[L^{2m}] \le (2m-1)!!\, v(L)^{2m}, \qquad \nu[e^{tL}] \le e^{t^2 v(L)^2/2}, \qquad \mathrm{Cov}_\nu(Z) \le \Gamma. \tag{6.cxxxiii}$$

The exponential assertion follows by symmetry and the increasing function $\cosh(t|L|)$. The covariance ordering follows by testing every linear functional. Every joint moment of an odd number of linear statistics is zero, because the entire law is invariant under $Z \mapsto -Z$.

Covariance and fourth-order defects of linear statistics. For linear statistics L_r, write

$$\begin{aligned} &\Gamma^L_{rs} = \mathbb{E}[L_r L_s], \quad \Sigma_{rs} = \nu[L_r L_s], \quad E_{rs} = \Sigma_{rs} - \Gamma^L_{rs}, \\ &B_r = \sum_i b_i|\ell_{r,i}|, \quad \delta_r = S\varepsilon_\partial U(L_r), \quad v_r = v(L_r). \end{aligned} \tag{6.cxxxiv}$$

Here B_r bounds $|L_r|$ on the entire cutoff box, whereas v_r is its untruncated Gaussian standard deviation. These two quantities have different uses. Taking $P = L_s$ in eq. 6.cxxviii gives

$$|E_{rs}| \le \min(\delta_r B_s, \delta_s B_r), \qquad |\Sigma_{rs}| + |\Gamma^L_{rs}| \le 2v_r v_s. \tag{6.cxxxv}$$

The second estimate follows separately for its two terms from eq. 6.cxxxiii and Gaussian Cauchy–Schwarz. Every third joint moment of linear statistics is exactly zero.

Apply the same identity to $P = L_2L_3L_4$. The derivative of this product produces exactly three pairings, and hence

$$\nu[L_1L_2L_3L_4] = \sum_{j=2}^{4} \Gamma^L_{1j}\Sigma_{\{2,3,4\}\setminus\{j\}} + \mathcal{D}_{L_1}(L_2L_3L_4). \tag{6.cxxxvi}$$

In this formula $\Sigma_{\{r,s\}} = \Sigma_{rs}$. Subtracting the three Gaussian pairings gives an error at most $\delta_1 B_2 B_3 B_4 + \sum_{j=2}^{4} |\Gamma^L_{1j}||E_{\{2,3,4\}\setminus\{j\}}|$. Subtracting instead the three pairings with the actual covariance Σ gives the fourth connected moment and the explicit bound

$$\begin{aligned}|\kappa_\nu(L_1,L_2,L_3,L_4)| \le \delta_1\big(&B_2B_3B_4 + B_2v_3v_4\\ &+ B_3v_2v_4 + B_4v_2v_3\big).\end{aligned} \tag{6.cxxxvii}$$

Indeed replace $\Gamma^L_{1j} - \Sigma_{1j}$ by $-E_{1j}$, use $|E_{1j}| \le \delta_1 B_j$, and bound each remaining Σ by its two Gaussian standard deviations. Any of the four indices can be chosen as the first one. The identity proves the connected estimate without assuming a small fourth cumulant.

For example, $\mathrm{Cov}_\nu(L_1L_2, L_3L_4) = \kappa_\nu(L_1,L_2,L_3,L_4) + \Sigma_{13}\Sigma_{24} + \Sigma_{14}\Sigma_{23}$. Together with eq. 6.cxxxv this gives the covariance error of two factored quadratic observables relative to their untruncated Gaussian Wick contractions. The higher degree estimates below also control three and four such observables.

The moment recursion through degree eight. Let a collection of localized linear statistics obey

$$B_r \le R\,U_r, \qquad v_r \le v\,U_r, \qquad U_r = U(L_r), \qquad D = S\varepsilon_\partial. \tag{6.cxxxviii}$$

One may take $R = \max_{i\in\mathcal{S}} b_i/a_i$ and $v = \max_{i\in\mathcal{S}} \sigma_i/a_i$, where $\mathcal{S}$ is the union of the supports of these statistics. The variance bound follows from $\|\Gamma_{ij}\| \le \sigma_i\sigma_j$, itself a consequence of Gaussian Cauchy–Schwarz. Thus neither R nor v requires a maximum over coordinates outside their supports.

Let $M_\nu(1,\dots,n) = \nu[\prod_{r=1}^n L_r]$ and let M_0 denote the corresponding untruncated Gaussian moment. For even n, integration by parts gives the exact recurrence

$$M_\nu(1,\dots,n) - M_0(1,\dots,n) = \sum_{j=2}^{n} \Gamma^L_{1j}(M_\nu - M_0)(\{2,\dots,n\}\setminus\{j\}) + \mathcal{D}_{L_1}\Big(\prod_{r=2}^{n} L_r\Big). \tag{6.cxxxix}$$

For $n = 2$ the empty moment difference is zero. Odd moments vanish for both laws. Consequently

$$\begin{aligned}|M_\nu(1,\dots,2m) - M_0(1,\dots,2m)| &\le d_{2m}\prod_{r=1}^{2m} U_r,\\ d_2 = DR, \qquad d_n &= DR^{n-1} + (n-1)v^2 d_{n-2}.\end{aligned} \tag{6.cxl}$$

This is a direct induction: each derivative pairing contributes at most $v^2U_1U_j$, and the boundary defect contributes at most $DU_1\prod_{r=2}^n B_r$. In particular

$$\begin{aligned}d_2 &= DR,\\ d_4 &= D(R^3 + 3v^2R),\\ d_6 &= D(R^5 + 5v^2R^3 + 15v^4R),\\ d_8 &= D(R^7 + 7v^2R^5 + 35v^4R^3 + 105v^6R).\end{aligned} \tag{6.cxli}$$

All constants are independent of the total number of Gaussian coordinates. The factors U_r retain the actual localization and scale of each inserted statistic.

Absolute mixed moments have a second bound useful when subtracting products of moments. Hölder with $2m$ equal exponents and eq. 6.cxxxii gives, for either law,

$$\Big|\mathbb{E}_*\prod_{r=1}^{2m} L_r\Big| \le (2m-1)!!\prod_{r=1}^{2m} v_r \le (2m-1)!!v^{2m}\prod_{r=1}^{2m} U_r, \qquad \mathbb{E}_* \in \{\nu,\mathbb{E}\}. \tag{6.cxlii}$$

No independence of the L_r is used. The simultaneous use of the support bound in the defect and the variance bound in unaffected moment factors avoids an unnecessary cutoff radius in every term.

Localized quadratic observables and their connected errors. Write each real quadratic observable in a finite factored form

$$Q_j = \sum_\alpha c_{j,\alpha} L_{j,\alpha,1} L_{j,\alpha,2}, \qquad \mathcal{A}(Q_j) = \sum_\alpha |c_{j,\alpha}| U(L_{j,\alpha,1}) U(L_{j,\alpha,2}). \tag{6.cxliii}$$

Choose common R, v for this finite list as in eq. 6.cxxxviii. Every product of $p \le 4$ quadratic observables is a sum of words of degree $2p$. eq. 6.cxli and eq. 6.cxlii can therefore be summed with absolute coefficients, with factor $\prod_j \mathcal{A}(Q_j)$. This step counts the inserted coefficients, not all coordinates of the integration space.

For clarity define the joint cumulant by the finite partition formula

$$\kappa_*(Q_1, \dots, Q_p) = \sum_{\pi \in \mathfrak{P}_p} (-1)^{|\pi|-1} (|\pi| - 1)! \prod_{A \in \pi} \mathbb{E}_* \prod_{j \in A} Q_j. \tag{6.cxliv}$$

Write $\Delta_p = \kappa_\nu(Q_1, \dots, Q_p) - \kappa_0(Q_1, \dots, Q_p)$. The following explicit estimates result:

$$\begin{aligned} |\nu Q_1 - \mathbb{E} Q_1| &\le d_2 \mathcal{A}(Q_1), \\ |\Delta_2| &\le (d_4 + 2v^2 d_2) \mathcal{A}(Q_1) \mathcal{A}(Q_2), \\ |\Delta_3| &\le (d_6 + 3v^2 d_4 + 15 v^4 d_2) \prod_{j=1}^{3} \mathcal{A}(Q_j), \\ |\Delta_4| &\le (d_8 + 4v^2 d_6 + 30 v^4 d_4 + 156 v^6 d_2) \prod_{j=1}^{4} \mathcal{A}(Q_j). \end{aligned} \tag{6.cxlv}$$

Here the subscript zero always refers to the original untruncated Gaussian with covariance Γ. In particular its quadratic third and fourth cumulants are generally nonzero. They are the Gaussian Wick values, not quantities being set equal to zero.

We give the product bookkeeping in eq. 6.cxlv. By multilinearity it is enough to use one factored monomial for each Q_j. For covariance the full moment difference is bounded by d_4; replacing the product of its two means costs $2v^2 d_2$. At order three the three terms of partition type $(2,1)$ cost at most $3(v^2 d_4 + 3v^4 d_2)$. The product of three means, with coefficient two, costs at most $6v^4 d_2$. Together with d_6, these give the third line. At order four, the four partitions of type $(3,1)$ cost $4(v^2 d_6 + 15 v^6 d_2)$; the three of type $(2,2)$ cost $18 v^4 d_4$. The six of type $(2,1,1)$, with coefficient two, cost $12 v^4 d_4 + 72 v^6 d_2$. The final product of four means, with coefficient six, costs $24 v^6 d_2$. Their sum gives exactly the fourth line. Each estimate uses the telescoping difference of products, bounding unchanged factors by eq. 6.cxlii. This establishes the constants without an assumed connected-moment estimate.

Substituting eq. 6.cxli, the three connected error polynomials multiplying D are respectively

$$\begin{aligned} \mathcal{P}_2(R, v) &= R^3 + 5v^2 R, \\ \mathcal{P}_3(R, v) &= R^5 + 8v^2 R^3 + 39 v^4 R, \\ \mathcal{P}_4(R, v) &= R^7 + 11 v^2 R^5 + 85 v^4 R^3 + 411 v^6 R. \end{aligned} \tag{6.cxlvi}$$

The same method covers mixed linear and quadratic observables: expand each quadratic into its two factors, use eq. 6.cxxxix for each resulting word, and then the finite partition formula. An odd total linear degree vanishes before taking absolute values. No additional probabilistic assumption is required for this mixed case.

The reference Gaussian Wick values themselves can be calculated without a nonsingular physical covariance. If $Q_j = Z^{\mathsf{T}} A_j Z$ with real symmetric A_j, whitening the latent Gaussian gives, for $p \ge 1$,

$$\kappa_0(Q_1, \dots, Q_p) = \frac{2^{p-1}}{p} \sum_{\pi \in S_p} \mathrm{tr}(\Gamma A_{\pi(1)} \cdots \Gamma A_{\pi(p)}). \tag{6.cxlvii}$$

Indeed, near zero the logarithm of the Gaussian exponential generating function is

$$\frac{1}{2}\sum_{k\geq 1}\frac{2^k}{k}\operatorname{tr}\left[\left(\Gamma\sum_j t_j A_j\right)^k\right].$$

Taking the coefficient of $t_1\cdots t_p$ gives eq. 6.cxlvii. This also identifies precisely the contractions to which the sharp-cutoff cumulants are compared.

The fixed-step flat chart realizes the covariance hypothesis. We now specialize to the actual first plain-average fibre at the identity, with fixed odd block size L, in current unit-spacing coordinates. Let P_L be the plain derivative of the nonlinear average, C_0 its pivot inclusion with identity free restriction, and $\mathcal{T}$ the internal contour matrix. The definitions and the actual first-step precision are

$$\begin{aligned}&\operatorname{ran}\mathsf{C}_0=\ker P_L,\qquad (\mathsf{C}_0 u)|_{\text{free}}=u,\\ &\mathsf{K}_L=\mathsf{C}_0^{\mathsf{T}}(\mathrm{d}_1^{\mathsf{T}}\mathrm{d}_1+\mathcal{T}^{\mathsf{T}}\mathcal{T})\mathsf{C}_0,\quad Y\sim N(0,\mathsf{K}_L^{-1}),\quad Z=\mathsf{C}_0 Y.\end{aligned}\tag{6.cxlviii}$$

The quadratic form here is exactly the first-step form, with no previous finer-level minimization. This is the classical reference with action weight $x=\theta$, so $\tau=x/\theta=1$. The canonical normalization $\theta g^2=1$ then gives coefficient one both to the Wilson curl form and to the prescribed actual soft gauge. In particular $\mathcal{T}$ is not a divergence gauge or a freely chosen projector.

The pivot matrix has finite range with at most C_L nonzero blocks in each row and column and entries bounded by C_L. The column assertion follows by the same double-block support as the row assertion: a free bond belongs to only finitely many double blocks when L is fixed. The flat gap and the exponential inverse estimate of § 3.6 give $\|\mathsf{K}_L^{-1}(b,c)\|\leq C_L e^{-\mu_L d(b,c)}$, uniformly on the admitted tori. Consequently

$$\Gamma=\mathsf{C}_0\mathsf{K}_L^{-1}\mathsf{C}_0^{\mathsf{T}},\quad \max\left(\sup_b\sum_c\|\Gamma_{bc}\|,\sup_c\sum_b\|\Gamma_{bc}\|\right)\leq S_L,\quad \Gamma_{bb}\leq\sigma_L^2 I.\tag{6.cxlix}$$

To check volume uniformity, a four-dimensional shell of distance m has at most $C_L(m+1)^3$ bond indices in block coordinates. Summing $e^{-\mu_L m}$ over these shells is finite; periodic image sums have the same upper bound. Multiplying the finite row and column sums of C_0, its transpose and the inverse proves the two sums in eq. 6.cxlix. The diagonal bound follows, for example, from either sum. Increase σ_L to at least one if convenient.

Thus eq. 6.cxxix is realized with $a_b=\mu_b=1$, $S=S_L$, independent of the number of blocks. This is a statement at a fixed current spacing and fixed L. Pointwise decay in a multilevel physical metric would not alone give its unweighted analogue: the number and normalization of coordinates at different scales must still be charged in the actual weighted norm in eq. 6.cxxix.

Why the actual contour gauge leaves no physical quadratic residue. The following range calculation justifies integrating out this soft gauge; it does not apply to an arbitrary soft gauge. Let $\mathcal{S}_0$ be the real site fields vanishing at every block center. For any target internal contour data $s=(s_{y,x})$, $x\in B(y)\setminus\{y\}$, define the site field Rs by $(Rs)(x)=s_{y,x}$ and $(Rs)(y)=0$. Blocks partition the sites, so this is well defined. The plain-gradient identity and the internal path telescoping identity give exactly

$$\begin{aligned}&P_L\mathrm{d}_0 Rs=0,\qquad \mathrm{d}_1\mathrm{d}_0 Rs=0,\qquad (\mathcal{T}\mathrm{d}_0 Rs)_{y,x}=s_{y,x},\\ &\|Rs\|_2=\|s\|_2,\qquad \|\mathrm{d}_0 Rs\|_2\leq 4\|s\|_2.\end{aligned}\tag{6.cl}$$

Here d_0 is the forward site gradient and d_1 the plaquette circulation. The last norm estimate follows by summing $|f(x+e_\mu)-f(x)|^2\leq 2|f(x+e_\mu)|^2+2|f(x)|^2$ over four directions. Internal contour means average paths, but on a gradient every one of those paths gives the same difference $f(x)-f(y)$; hence no path count or L^{-4} factor occurs in the third identity. The constraint identity is $P_L\mathrm{d}_0 f=\mathrm{d}_L(f|_{\text{centers}})$, not a site-average gradient identity.

In particular the image of $\mathcal{T}$ on $\ker \mathrm{d}_1 \cap \ker P_L$ is the entire internal target space. It equals the image of $\mathcal{T}$ on $\ker P_L$. This is the precise range condition that prevents a leftover physical gauge penalty. If an arbitrary alternative gauge failed this condition, integrating its gauge directions could instead leave a positive quadratic form in curvature.

Put $\mathcal{E}_C = \mathrm{d}_1 \ker P_L$. The linear map

$$\ker P_L \longrightarrow \mathcal{E}_C \oplus \mathcal{S}_0, \qquad a \longmapsto (\mathrm{d}_1 a, \mathcal{T} a) \quad \text{is a bijection.} \tag{6.cli}$$

It is onto because any initial lift of a prescribed curvature in $\mathcal{E}_C$ can be adjusted to any prescribed contour data by adding $\mathrm{d}_0 Rs$ from eq. 6.cl. It is one-to-one because the flat gap on $\ker P_L$ says that both $\mathrm{d}_1 a = 0$ and $\mathcal{T} a = 0$ force $a = 0$. Equivalently use the actual internal-bond and crossing-face zero-mode argument of § 3.4.

Apply the constant linear change of variables $Y \mapsto (F, s) = (\mathrm{d}_1 \mathsf{C}_0 Y, \mathcal{T} \mathsf{C}_0 Y)$. Its Jacobian is a nonzero constant between the indicated Euclidean spaces. The quadratic exponent in eq. 6.cxlviii becomes exactly $\frac{1}{2}\|F\|^2 + \frac{1}{2}\|s\|^2$. The constant Jacobian and the integral in s cancel from normalized curvature expectations. Therefore

$$F = \mathrm{d}_1 Z \text{ is a standard Gaussian on } \mathcal{E}_C, \qquad \mathrm{d}_1 \Gamma \mathrm{d}_1^{\mathsf{T}} = P_{\mathcal{E}_C}. \tag{6.clii}$$

The same calculation with any prescribed positive quadratic form in s changes only the gauge normalization. It works here because eq. 6.cl was proved for the actual gauge. It would be invalid merely to call a quadratic penalty a gauge term and omit the range check.

If the action weight is instead $x = \tau\theta$, $\tau > 0$, multiply the curl term in eq. 6.cxlviii by τ, leaving the reference soft gauge coefficient one. The same bijection gives exponent $\frac{\tau}{2}\|F\|^2 + \frac{1}{2}\|s\|^2$, so the corresponding covariance satisfies $\mathrm{d}_1 \Gamma_\tau \mathrm{d}_1^{\mathsf{T}} = \tau^{-1} P_{\mathcal{E}_C}$. All numerical reference applications below use $\tau = 1$. No uniform covariance bound as $\tau \downarrow 0$ is inferred.

The precise relation with the full free-curvature comparison. Let $\mathcal{E} = \mathrm{ran}\, \mathrm{d}_1$ on the same finite periodic lattice, with each positive plaquette counted once. Generally $\mathcal{E}_C$ is a proper subspace of $\mathcal{E}$. With $\mathcal{E}_\perp = \mathcal{E} \cap \mathcal{E}_C^\perp$, ordinary orthogonal decomposition gives

$$P_{\mathrm{ex}} = P_{\mathcal{E}} = P_{\mathcal{E}_C} + P_{\mathcal{E}_\perp}, \qquad F_{\mathrm{full}} = F_C + F_\perp, \tag{6.cliii}$$

where the two summands on the right can be taken independent standard Gaussians on their respective subspaces. This proves that the law of F_{full} is the full exact-cochain Gaussian used in the free-kernel comparison. Conditional on $F_\perp$, its centered fluctuation has exactly the curvature law in eq. 6.clii. Conversely, integrating this complementary Gaussian supplies the missing curvature covariance.

The decomposition is an exact classical Gaussian identity. It does not identify the law of a coarse mean in an interacting run. In particular it does not permit replacing $P_{\mathcal{E}_C}$ by P_{ex} in a single fixed-fibre Gaussian estimate. Fine fluctuations alone omit the second term of eq. 6.cliii; exterior or coarse averaging is a separate covariance contribution in the complete conditional-law identity.

There is a finite-dimensional expression for this distinction which needs no chosen coarse-coordinate parametrization. Let Q_C be any matrix whose kernel inside $\mathcal{E}$ is $\mathcal{E}_C$. Then

$$P_{\mathcal{E}_C} = P_{\mathrm{ex}} - P_{\mathrm{ex}} Q_C^{\mathsf{T}} (Q_C P_{\mathrm{ex}} Q_C^{\mathsf{T}})^{+} Q_C P_{\mathrm{ex}}. \tag{6.cliv}$$

To prove the formula, set $B = Q_C P_{\mathrm{ex}}$ restricted to $\mathcal{E}$. Singular-value decomposition shows that $B^{\mathsf{T}}(BB^{\mathsf{T}})^{+}B$ is the orthogonal projection onto $(\ker B)^\perp$ within $\mathcal{E}$. Subtract it from the identity on $\mathcal{E}$, then extend by zero on $\mathcal{E}^\perp$. This yields exactly eq. 6.cliv. The identity is not an estimate that the correction is small. Such an estimate on a particular physical window would require its own quantitative proof.

At fine physical spacing η, write the canonical raw curvature as F. The physical curvature of this canonically normalized field is $\eta^{-2}F$. The full exact-cochain covariance is therefore $\eta^{-4} P_{\mathrm{ex}}$, precisely the normalization of Requirement F1 in the dependency catalogue. Its plaquette components are

sampled at their own barycentres. For three independent color copies and $Q_f = \frac{1}{2}\sum_p f(x_p)|F_p|^2$, Gaussian Wick contraction gives

$$\mathrm{Cov}_0(Q_f, Q_h) = \frac{1}{2}\sum_{p,q} f(x_p)h(x_q)\|\mathbb{E}[F_p F_q^{\mathsf{T}}]\|_{\mathrm{HS}}^2. \tag{6.clv}$$

The physical Riemann weight η^4 multiplying the squared physical curvature cancels its η^{-4} scaling in Q_f. Thus the $\mathrm{tr}(F^2)$ readout is the unweighted plaquette sum displayed here; inserting an additional η^4 into that sum would change the observable.

For the full law in eq. 6.cliii, eq. 6.clv has the F1 kernel and its proved separated-smearing comparison. For the first-step fluctuation it has $P_{\mathcal{E}_C}$ instead. The cutoff estimates compare each specified Gaussian reference with its own Wick kernel. They transfer F1 only after the reference used in the application has actually been identified with, or compared to, the full exact-cochain reference. The decomposition records how this works in the free Gaussian theory without asserting it for a conditional interacting measure.

Uniform cutoff errors for the curvature polynomial. Take all physical tangent bond radii equal to $B \geq \sigma_L$ in eq. 6.cxlviii, and retain counting weights and unit amplitudes. From eq. 6.cxxv, including all ranks from one through three and enlarging the fixed constants,

$$\sup_b \beta_b^* \leq \beta_L(B) := C_L B^2 e^{-c_L B^2}, \qquad D \leq S_L \beta_L(B), \qquad R = B, \quad v \leq \sigma_L. \tag{6.clvi}$$

The bounds remain valid if some physical blocks are deterministic. For a sampled test function let $W_f = \sum_p |f(x_p)|$, and define the canonical quadratic curvature polynomial

$$Q_f(Z) = \frac{1}{2}\sum_p f(x_p)|\mathrm{d}_1 Z(p)|^2, \qquad \mathcal{A}(Q_f) \leq 24 W_f. \tag{6.clvii}$$

Indeed a fixed color component of a plaquette curl has four coefficients of absolute value one, hence $U \leq 4$. There are three colors and the coefficient is $f/2$, so $(1/2)\cdot 3 \cdot 4^2 = 24$. Each positive direction pair is already counted once in the sum over p. This calculation requires no estimate on the number of unobserved bonds.

For $p = 2, 3, 4$, equations in eq. 6.cxlv– eq. 6.clvi now imply, with $\Delta_p = \kappa_\nu(Q_{f_1}, \dots, Q_{f_p}) - \kappa_0(Q_{f_1}, \dots, Q_{f_p})$,

$$\begin{aligned} |\nu Q_f - \mathbb{E} Q_f| &\leq C_L \beta_L(B) B W_f, \\ |\Delta_p| &\leq C_{L,p}\beta_L(B)(B^{2p-1} + B^{2p-3} + \cdots + B)\prod_{j=1}^{p} W_{f_j}. \end{aligned} \tag{6.clviii}$$

Here all expectations are normalized, including the sharp product cutoff law. The third and fourth lines implicit in the second formula use sixth and eighth underlying linear moments. The vanishing of odd linear moments alone would not establish them. The Gaussian values on the right are the actual cycle contractions in eq. 6.cxlvii, with the constrained curvature projection of eq. 6.clii in this particular application.

If each test is supported in a ball of current radius $r \geq 1$, then $W_f \leq C(r+1)^4\|f\|_\infty$. Thus the covariance error has the expected two localized volume factors $C(r+1)^8\|f\|_\infty\|h\|_\infty$, rather than a factor proportional to the volume of the torus. At orders three and four the factors are $(r+1)^{12}$ and $(r+1)^{16}$. These are insertion-support counts; all constants in their coefficients are uniform over torus size and support positions.

The nonlinear Wilson readout on the actual joint chart. The Gaussian law need not be restricted to a merely formal observable. At the flat background let $a = \Phi_0(u)$ be the actual nonlinear fibre chart of § 3.3, so u is the free raw logarithm and $D\Phi_0(0) = \mathsf{C}_0$. Its domain contains $\|u\|_\infty < r_L$, with $r_L = cL^{-9}$ after reducing the fixed constant. The finite local support and the uniform holomorphic bounds on that joint domain give, on a smaller real ball,

$$\begin{aligned} \|\Phi_0(u) - \mathsf{C}_0 u\|_\infty &\le C_L \|u\|_\infty^2, \\ A_p(e^{i\Phi_0(u)}) &= \frac{1}{2}|\mathrm{d}_1 \mathsf{C}_0 u(p)|^2 + R_p(u), \\ |R_p(u)| &\le C_L \|u\|_\infty^3. \end{aligned} \tag{6.clix}$$

For the second assertion use the holomorphic extension $1 - \frac{1}{2}\operatorname{tr} U_p$, which equals the real Wilson readout on SU(2). Its constant and linear terms at the identity are zero. Differentiating the four bond products shows its quadratic term is $\frac{1}{2}|\mathrm{d}_1 \mathsf{C}_0 u(p)|^2$, with Pauli pairing $|X|^2 = \frac{1}{2}\operatorname{tr} X^2$. To bound the remainder, apply one-variable Cauchy to the actual local function of tu on a disc of radius proportional to $r_L/\|u\|_\infty$. The joint chart bounds this function uniformly; summing the Taylor terms of order at least three on a smaller disc gives the displayed cubic estimate. The first assertion follows by the same argument at order two. A plaquette and its pivot dependencies occupy a fixed number of double blocks, so neither remainder constant contains the lattice volume.

Set $u = gY$. Under the full physical tangent cutoff $|\mathsf{C}_0 Y(b)| < B$, the identity free restriction implies $\|Y\|_\infty \le B$. Thus $gB < r_L/2$ places every field of this cutoff event in the actual chart, and for $O_f = \sum_p f(x_p) A_p$,

$$O_f(e^{i\Phi_0(gY)}) = g^2 Q_f(Z) + \mathcal{R}_f(Y), \quad |\mathcal{R}_f| \le C_L g^3 B^3 W_f, \quad |Q_f| \le C_L B^2 W_f. \tag{6.clx}$$

This uses the literal sampled $\mathrm{tr}(F^2)$ sum, with no extra fine-cell volume factor. The probability measure in this identity is still the Gaussian cutoff measure, rather than the nonlinear action measure.

The finite partition definition of a cumulant gives $|\kappa(X_1, \dots, X_p)| \le C_p \prod_j \|X_j\|_\infty$. Expand each slot of eq. 6.clx. If $gB \le 1$, the terms with at least one remainder have total absolute value at most $C_{L,p} g^{2p+1} B^{2p+1} \prod_j W_{f_j}$. Indeed a remainder replaces one factor $g^2 B^2$ by $g^3 B^3$; the finite sum over subsets costs at most a constant times $gB(1+gB)^{p-1}$. Together with eq. 6.clviii, this proves

$$\begin{aligned} &|\kappa_\nu(O_{f_1}, \dots, O_{f_p}) - g^{2p} \kappa_0(Q_{f_1}, \dots, Q_{f_p})| \\ &\quad \le C_{L,p} g^{2p} \left[\beta_L(B)(B^{2p-1} + B^{2p-3} + \cdots + B) + gB^{2p+1}\right] \prod_{j=1}^{p} W_{f_j}, \qquad p = 2, 3, 4. \end{aligned} \tag{6.clxi}$$

The same reasoning for one insertion gives mean error $C_L g^2 [\beta_L(B) B + gB^3] W_f$. This is a concrete sharp-cutoff Gaussian clean-law estimate with the actual nonlinear observable numerator. It includes neither the nonlinear change in its probability density nor any missing coarse-mean contribution to the chosen free reference.

Literal radius conversions and comparison of cutoff sets. At physical fine spacing η, raw bond logarithm and physical potential obey $a_b = \eta A_b$. In canonical tangent variables $a_b = gZ_b$. Consequently the conversions are

$$|a_b| < \alpha_b \iff |Z_b| < \alpha_b/g, \qquad |\ell_b A_b| < r_b \iff |Z_b| < \frac{\eta r_b}{g \ell_b}. \tag{6.clxii}$$

The second relation refers to the tangent physical potential; ℓ_b is the actual scale multiplying it in that field bound. For the nonlinear chart use eq. 6.clix: its raw field differs from gZ by at most $C_L g^2 B^2$ on the event in question. Any comparison with a cutoff on the nonlinear field must charge this error and preserve a stated radius margin.

A free-coordinate box and the complete physical tangent product box are not equal events. With $c_L = \|\mathsf{C}_0\|_{\infty\to\infty} \geq 1$, one has only

$$\{\|Y\|_\infty < B/c_L\} \subset \{\|\mathsf{C}_0 Y\|_\infty < B\} \subset \{\|Y\|_\infty < B\}. \tag{6.clxiii}$$

The first inclusion uses the actual row norm of the pivot map; the second uses its identity free restriction. Inclusion alone does not compare the corresponding normalized conditional expectations. The proof in this section works directly with the middle, complete physical event, so requires no false identification of these boxes. If an actual integration rule instead cuts only free coordinates, apply the abstract theorem to those actual independent-coordinate blocks and carry the observable coefficient map separately; it is a different cutoff law with its own explicitly specified covariance and radii.

For growing canonical radius $B = c_*(\log\theta)^s$, $s > 0$, and $g = \theta^{-1/2}$, every fixed power of $\log\theta$ times $\beta_L(B)$ tends to zero, as does every fixed such power times g. The chart condition $gB < r_L/2$ holds eventually. Thus for support radii bounded by any fixed power of $\log\theta$, the bracket and localized volume factors in eq. 6.clxi tend to zero, uniformly in torus volume. This is an absolute error relative to the displayed insertion norms. Converting it into a relative error for a specified two-point coefficient also requires a proved lower bound for that coefficient in the same test class.

What passes to limits and what remains an interaction estimate. The finite-volume cutoff laws have Gaussian-dominated moments for every fixed local linear statistic by eq. 6.cxxxii. In the fixed-step setting their marginal variances are bounded uniformly by eq. 6.cxlix. These bounds give tightness on each finite collection of bond coordinates. A diagonal subsequence on the countable lattice therefore has compatible finite-dimensional limits. Uniform higher local moments give uniform integrability, so the local polynomial estimates above pass to every such limit. This conclusion does not assert uniqueness of the limit, and does not identify it with conditioning an infinite-volume Gaussian on a global event of positive probability. It only uses uniform finite-volume bounds.

The boundary proof also identifies its precise obstruction in a general conditional law. If in actual free coordinates, with $G > 0$, its complete density is $Z_e^{-1}\chi(CY)\exp[-\frac{1}{2}Y^{\mathsf{T}}G^{-1}Y + R_e(Y)]$, integration by parts has, in addition to the boundary defect, the force term

$$\mathbb{E}_{\nu_e}[P(CY)\,(CG\nabla R_e(Y))_i]\,. \tag{6.clxiv}$$

This follows by differentiating the entire density, with its actual normalizer; all integrability and chart-domain conditions must hold. An arbitrary exterior linear force can translate the law toward the boundary, and an arbitrary old activity can destroy the even log-concavity used in eq. 6.cxx. Neither its small Hessian alone nor the Gaussian boundary theorem bounds these two effects.

The same radial argument would remain valid for a further even log-concave factor in the physical variables, because that factor can be included in the joint log-concave integrand defining $w_{b,\delta}$. Its new force term still has to be bounded in the complete integration-by-parts identity. No such convexity, symmetry or force bound is asserted for the resummed interacting conditional density.

Accordingly the result established here is the boundary and connected-error estimate for the specified centered classical Gaussian sector, with a realized fixed-step covariance and actual observable coordinates. Applying it to the interacting extraction requires the complete measure, exterior averaging, old-activity and force identifications of the conditional-law section, as well as the correct full free reference for F1. It supplies a proved reference estimate for that boundary task, rather than assuming the interacting extraction law or an all-depth unweighted covariance bound.

6.7. **A normalized Gaussian comparison on a finite run window.** The conditional interacting law can be compared directly with a Gaussian when the complete residual exponent has small oscillation on the tested window. The oscillation is measured after removing a field-independent constant, so an exterior-dependent vacuum energy causes no loss. This route is useful when the number of retained coordinates and their tested ranges grow only as powers of the logarithm

of the inverse coupling. It estimates the normalizer together with the numerator and avoids an integration-by-parts argument at a sharp boundary.

The criterion below concerns the complete exponent. In particular it includes the coarea density, Haar density, history multiplicity and all old activities that vary with the retained coordinates. Bounds on the nonlinear Wilson action alone are insufficient for its application. We first prove the comparison, then give explicit estimates for several of the factors that occur when the criterion is verified.

6.7.1. *The tested domain and the reference Gaussian.* Let γ be a centered Gaussian on $\mathbb{R}^N$ with positive definite covariance C. If the Gaussian is supported on a proper linear subspace, choose orthonormal coordinates on that support throughout; the statements then have exactly the same meaning. Let $v = \max_j C_{jj}$. For $R > 0$, put

$$B_R = \{y : \max_j |y_j| \le R\}. \tag{6.clxv}$$

Let D be measurable and contain B_R, up to a Gaussian null set. The domain may be nonconvex. Define $t = \gamma(D^c)$. The one-dimensional Gaussian bound and the union bound give

$$t \le 2N \exp[-R^2/(2v)]. \tag{6.clxvi}$$

Here and below a zero marginal variance can simply be omitted. For completeness, for a marginal Y with variance σ^2, $\mathbb{E}e^{sY} = e^{s^2\sigma^2/2}$. Markov's inequality at $s = R/\sigma^2$ bounds $\mathbb{P}(Y \ge R)$ by $e^{-R^2/(2\sigma^2)}$; apply the same estimate to $-Y$. This argument uses no independence between coordinates.

Suppose a real measurable function P on D has oscillation at most 2α in the following specified sense: there is a real constant c such that

$$|P(y) - c| \le \alpha \quad \text{for } \gamma\text{-almost every } y \in D. \tag{6.clxvii}$$

The constant may depend on the exterior configuration. Set

$$d\nu = Z^{-1} 1_D e^{P-c}\, d\gamma, \qquad Z = \gamma(1_D e^{P-c}). \tag{6.clxviii}$$

If $t < 1$, this is a probability and

$$e^{-\alpha}(1-t) \le Z \le e^{\alpha}(1-t). \tag{6.clxix}$$

The sharper upper bound displayed here is useful: the clean domain mass belongs to the same reference in both numerator and denominator. Let $\gamma_D = \gamma(\,\cdot \mid D)$. Then

$$e^{-2\alpha} \le \frac{d\nu}{d\gamma_D} \le e^{2\alpha} \quad \text{almost everywhere.} \tag{6.clxx}$$

This proves non-vanishing of the real normalizer with its correct domain factor. It does not assert a complex source-domain estimate.

Proposition 6.16 (Weighted comparison of the normalized laws)**.** For every $H \in L^2(\gamma)$,

$$|\nu(H) - \gamma(H)| \le \frac{e^{2\alpha} - 1 + t}{1-t}\,\gamma(|H|) + \frac{\gamma(|H|1_{D^c})}{1-t} \tag{6.clxxi}$$

$$\le \frac{e^{2\alpha} - 1 + t + \sqrt{t}}{1-t}\,\|H\|_{L^2(\gamma)}. \tag{6.clxxii}$$

Also $\nu(|H|) \le e^{2\alpha}(1-t)^{-1}\gamma(|H|)$ for every nonnegative integrable $|H|$. ■

Proof. The density estimate eq. 6.clxx gives $|\nu(H) - \gamma_D(H)| \le (e^{2\alpha} - 1)\gamma_D(|H|)$. On the other hand,

$$\gamma_D(H) - \gamma(H) = \frac{t\gamma(H) - \gamma(H1_{D^c})}{1-t}.$$

Taking absolute values proves eq. 6.clxxi. Cauchy–Schwarz bounds its last tail integral by $\sqrt{t}\|H\|_2$, and $\gamma(|H|) \le \|H\|_2$. The last assertion follows by direct integration of eq. 6.clxx. □

The estimate only uses a Gaussian measure of the symmetric difference from its full support through t. Thus one can replace a complicated tested domain by a convenient inner box, provided that box actually lies in the image of the physical tests. An upper bound on the size of every retained coordinate does not prove this inner inclusion. The latter is a separate domain-admission calculation.

6.7.2. *Dimension-explicit moments of quadratic readouts.* Let A be real symmetric and set

$$L(A) = \operatorname{tr}|C^{1/2}AC^{1/2}|, \qquad Q_A(y) = y^{\mathsf{T}}Ay - \operatorname{tr}(AC). \tag{6.clxxiii}$$

The absolute value in $L(A)$ is the operator absolute value of a real symmetric matrix. This definition also covers signed profiles. It often gives a better bound than the matrix dimension times a supremum of its entries.

For an integer $k \geq 1$, diagonalize $C^{1/2}AC^{1/2}$ with eigenvalues λ_j. Under γ, its quadratic form has the law $\sum_j \lambda_j G_j^2$, where the G_j are independent standard Gaussians. The triangle inequality in L^k yields

$$\|Q_A\|_{L^k(\gamma)} \leq u_k L(A), \qquad u_k = ((2k-1)!!)^{1/k} + 1. \tag{6.clxxiv}$$

Indeed $\|G_j^2\|_k = ((2k-1)!!)^{1/k}$ and $|\sum_j \lambda_j| \leq \sum_j |\lambda_j|$. The Gaussian even moment formula used here follows by integration by parts: $\mathbb{E}G^{2k} = (2k-1)\mathbb{E}G^{2k-2}$ with $\mathbb{E}G^0 = 1$. The estimate includes singular matrices A; if $L(A) = 0$, the quadratic readout is identically zero on the Gaussian support.

For readouts $Q_i = Q_{A_i}$ and any nonempty set S of s indices, Hölder gives

$$\left\| \prod_{i\in S} Q_i \right\|_{L^2(\gamma)} \leq u_{2s}^s \prod_{i\in S} L_i, \qquad L_i = L(A_i). \tag{6.clxxv}$$

There is no factor depending on N apart from the actual sizes L_i. This matters when an observable sums over a window: its coefficient mass must be counted once in L_i, rather than once for each moment estimate.

Let $0 < g \leq 1$. Suppose the physical readouts on D are

$$X_i(y) = c_i + g^2[Q_i(y) + I_i(y)], \qquad |I_i(y)| \leq \rho_i L_i. \tag{6.clxxvi}$$

The constants c_i are deterministic at the fixed exterior; their variation with the exterior is retained when applying the law of total cumulance. Assume $L_i > 0$ and $0 \leq \rho_i \leq 1$. An entry with $L_i = 0$ may instead be handled separately using a positive bound for its remainder.

Proposition 6.17 (Mixed moments of the physical readouts)**.** Assume $\alpha \leq 1/4$ and $t \leq 1/2$. For every nonempty S of size $s \leq n$,

$$\left| \nu\left(\prod_{i\in S} (X_i - c_i) \right) - g^{2s}\gamma\left(\prod_{i\in S} Q_i \right) \right| \leq K_n \left(\alpha + \sqrt{t} + \max_i \rho_i \right) g^{2s} \prod_{i\in S} L_i, \tag{6.clxxvii}$$

where K_n depends only on n. The absolute mixed moments of both displayed laws are at most $K_n g^{2s} \prod_{i\in S} L_i$. ∎

Proof. First compare the product of Q_i under ν and γ. Apply Prop. 6.16 and eq. 6.clxxv. Since $\alpha \leq 1/4$ and $t \leq 1/2$, the coefficient there is at most a fixed multiple of $\alpha + \sqrt{t}$.

Next expand $\prod(Q_i + I_i) - \prod Q_i$ by the nonempty subset of positions at which the remainder I_i is used. Its absolute expectation is bounded by

$$\sum_{\varnothing \neq J \subset S} \prod_{i\in J} (\rho_i L_i)\, \nu\left(\prod_{i\in S\setminus J} |Q_i| \right).$$

The final assertion of Prop. 6.16 and Hölder bound the last moment by a constant depending only on n times $\prod_{i\in S\setminus J} L_i$. The sum of the remainder coefficients is at most $\prod_{i\in S}(1+\rho_i) - 1 \leq$

$(2^n-1)\max_i \rho_i$. Multiply by g^{2s} to obtain eq. 6.clxxvii. The same estimates without subtraction bound the absolute mixed moments. □

6.7.3. *The conditional connected coefficient.* The cumulant polynomial in § 6.4 now proves, for $2 \le n \le 4$,

$$\left|\kappa_\nu(X_1,\dots,X_n) - g^{2n}\kappa_\gamma(Q_1,\dots,Q_n)\right| \le K_n'\left(\alpha+\sqrt{t}+\max_i \rho_i\right) g^{2n}\prod_i L_i. \tag{6.clxxviii}$$

Here the constants c_i disappear by translation invariance of a cumulant of order at least two. To see the stated dependence, use eq. 6.clxxvii for the one replaced block in the telescoping product proof of Prop. 6.13. The other blocks have the moment bound of Prop. 6.17. There are only finitely many partitions at fixed n, giving K_n'.

For the one-point function the corresponding estimate is

$$|\nu(X_i) - c_i| \le K_1(\alpha+\sqrt{t}+\rho_i)g^2 L_i, \tag{6.clxxix}$$

because $\gamma(Q_i)=0$. When exteriors vary, the error from $c_i(e)$ relative to a fixed reference must be added to this bound; it is not removed by centering the global observable.

The reference quadratic cumulants have a finite trace formula. Put $B(z)=\sum_i z_i C^{1/2}A_iC^{1/2}$. For $2\|B(z)\|<1$, diagonalizing the real Gaussian integral first for real z near zero, and then continuing analytically, gives

$$\begin{aligned}\log\gamma\left(e^{\sum_i z_iQ_i}\right) &= -\operatorname{tr}B(z) - \tfrac{1}{2}\log\det(I-2B(z)) \\ &= \sum_{m\ge 2}\frac{2^{m-1}}{m}\operatorname{tr}B(z)^m.\end{aligned} \tag{6.clxxx}$$

The determinant branch equals one at zero. The logarithmic series converges absolutely in operator norm on every smaller ball, so coefficient extraction is legitimate. In particular

$$\kappa_\gamma(Q_1,Q_2) = 2\operatorname{tr}(A_1CA_2C). \tag{6.clxxxi}$$

At order four it is the sum over closed four-cycles, with the coefficient and colour multiplicity fixed in the free curvature calculation. Thus eq. 6.clxxviii controls an interacting connected coefficient, rather than merely a change in its quadratic precision.

6.7.4. *A finite-dimensional graph for the constraints.* We next estimate one contribution to P. Let $p\in\mathbb{R}^m$ be pivot variables and $y\in\mathbb{R}^N$ retained variables. Suppose a real C^1 constraint is $q(p,y)=0$. On an open neighborhood of the retained domain assume it has one admitted solution $p=\varphi(y)$ and that $D_pq(\varphi(y),y)$ is invertible. These assumptions concern the actual constraint and its chosen branch; the implicit function theorem supplies only a local solution until uniqueness and domain coverage are checked.

Let Q be a fixed invertible pivot matrix and suppose

$$D_pq(\varphi(y),y) = Q[I+E(y)], \qquad \|E(y)\|\le\delta<1. \tag{6.clxxxii}$$

The operator norm here is Euclidean. Then

$$\left|\log\frac{|\det D_pq(\varphi(y),y)|}{|\det Q|}\right| \le \frac{m\delta}{1-\delta}. \tag{6.clxxxiii}$$

Indeed $I+sE$ is invertible for $0\le s\le 1$. Its real determinant remains positive, since it equals one at $s=0$. The logarithmic derivative is $\operatorname{tr}[(I+sE)^{-1}E]$, whose absolute value is at most $m\delta/(1-s\delta)$. Integrating and using the weaker constant $1/(1-\delta)$ proves the estimate. The same proof works for a complex branch of the determinant logarithm on a norm ball, but the probability comparison itself remains real.

Consequently the coarea factor $|\det D_pq|^{-1}$ has a field-dependent logarithm bounded, after subtraction of $-\log|\det Q|$, by the right hand side of eq. 6.clxxxiii. The dimension m is essential. An

operator perturbation $\delta = o(1)$ alone does not imply a small total determinant logarithm if $m\delta$ is large.

The identity underlying this coarea factor is elementary but fixes which determinant occurs. The map $(p, y) \mapsto (q(p, y), y)$ has block-triangular derivative with determinant $\det D_p q$. Changing variables in an integral with the constraint delta function and then evaluating at $q = 0$ gives

$$\int f(p, y)\delta(q(p, y))\, dp\, dy = \int f(\varphi(y), y)|\det D_p q(\varphi(y), y)|^{-1}\, dy \tag{6.clxxxiv}$$

on the admitted branch. With several branches the right side is summed over them. A gauge quotient or a change of the retained coordinates contributes its own factor and must be included as well.

For a useful quantitative graph estimate, suppose

$$q(p, y) = Qp + Ry + g\mathcal{N}(p, y), \tag{6.clxxxv}$$

where $\|Q^{-1}\| \le K$ and $\mathcal{N}$ is Lipschitz in p with constant L_p on a specified closed pivot ball for each y in the retained domain. Put $p_0(y) = -Q^{-1}Ry$. If

$$gKL_p \le \tfrac{1}{2}, \qquad gK \sup_y |\mathcal{N}(p_0(y), y)| \le b/2, \tag{6.clxxxvi}$$

and the radius-b ball about every $p_0(y)$ lies in the declared pivot domain, the map $p \mapsto p_0(y) - gQ^{-1}\mathcal{N}(p, y)$ is a contraction of that ball. Thus

$$|\varphi(y) - p_0(y)| \le 2gK|\mathcal{N}(p_0(y), y)|. \tag{6.clxxxvii}$$

The proof is the contraction inequality with its inhomogeneous term moved to the left. If $\|D_p\mathcal{N}\| \le L_p$, then eq. 6.clxxxii holds with $\delta = gKL_p$. This is a finite-window criterion with a specified radius. For an actual multiscale constraint, a uniform K and coverage of the entire tested set still have to be proved.

6.7.5. *Haar factors and the action remainder.* The analytic Haar density and the bare Wilson remainder are estimated in eq. 4.dlvii and eq. 4.dlviii. In particular, at a fixed coupling, M link logarithms ga with $|a| \le R_1$ and $gR_1 \le 1/4$ contribute at most $CMg^2R_1^2$ to the Haar logarithm after subtraction of its value at zero. The coordinate graph may change a to a function of y; the tested bound must then hold on that whole graph. The fixed Jacobian powers of g cancel in normalized expectations. Source-dependent powers must be retained.

Let S be a real analytic action on a finite coordinate chart and write $a = gTy$, where T is a specified linear map. Assume the quadratic reference has been extracted exactly, so

$$g^{-2}S(gTy) = c_S + \ell^{\mathsf{T}}y + \tfrac{1}{2}y^{\mathsf{T}}Qy + R_S(y). \tag{6.clxxxviii}$$

If $S'(0) = 0$ and the quadratic form is the actual Hessian, then $\ell = 0$. At a noncritical reference the linear term must be retained or removed by a verified Gaussian shift. Suppose that for every $y \in D$ the full segment $a = tgTy$, $0 \le t \le 1$, lies in the declared analytic chart, and that on that segment the third derivative obeys

$$|D^3S(a)[Ty, Ty, Ty]| \le K_S(y). \tag{6.clxxxix}$$

Taylor's integral remainder gives

$$|R_S(y)| \le \tfrac{1}{6}gK_S(y). \tag{6.cxc}$$

The power g comes from the cubic numerator divided by g^2. In a local action with M terms, each depending on a uniformly bounded list of coordinates of size at most R_1, a uniform third-derivative bound gives $K_S(y) \le CMR_1^3$. This assertion requires those local derivative bounds; when S is the Wilson action composed with a constrained background, the derivatives of that background are part of them.

If the graph of the constraints is nonlinear, it is equally valid to take the third derivative of the composed action on the graph. Replacing that derivative by the bare Wilson third derivative

would omit derivatives of φ. The complete constraint-curvature term in the Hessian is also part of the reference Q in eq. 6.clxxxviii. The present comparison does not justify replacing it by a flat Feynman precision.

6.7.6. *Old activities that meet the window.* Let W be a finite set of retained cells. Suppose an old interaction has a convergent representation

$$H(y) = \sum_X H_X(y), \tag{6.cxci}$$

where a term is independent of y if X does not meet W. Let y_* be one admitted reference. If

$$\sup_{v\in W} \sum_{X\ni v} \sup_{y\in D} |H_X(y) - H_X(y_*)| \le \epsilon, \tag{6.cxcii}$$

then

$$\sup_{y\in D} |H(y) - H(y_*)| \le |W|\epsilon. \tag{6.cxciii}$$

To prove this, bound the sum over terms that meet W by the sum over all incidences (v, X) with $v \in W \cap X$. Each contributing term is counted at least once. The positive bound in eq. 6.cxcii gives absolute and uniform convergence of the varying part, so the subtraction and sum are justified.

The norm in eq. 6.cxcii is a norm of the evaluated terms on one common admitted chart. A formal norm at different centers, or a bound after a different levelled substitution, cannot be inserted without an estimate transferring it to this domain. Terms with old fine-scale origins can meet the retained window in many fine cells. Their incidences must be charged in their actual units; the number $|W|$ cannot be taken to be the coarse window volume unless the formation theorem has already performed that accounting.

This qualification is one reason to state the criterion in terms of the complete oscillation rather than claim that every polylogarithmic coarse window automatically has a small residual exponent. The primitive spatial filing and the admitted substitution are what decide whether eq. 6.cxcii is available.

6.7.7. *Putting the complete exponent together.* Suppose the actual constrained positive density, after a fixed change to its retained coordinates, has the form

$$1_D(y) \exp\{-\tfrac{1}{2} y^{\mathsf{T}} Q y + P(y)\}\, dy, \tag{6.cxciv}$$

with the same Q as the covariance $C = Q^{-1}$. A Gaussian shift may be made first if its determinant, domain image and readout change are retained. Suppose there are field-independent constants subtracting the following parts of P, and that their residual absolute bounds are respectively

$$\alpha_{\mathrm{act}}, \quad \alpha_{\mathrm{Haar}}, \quad \alpha_{\mathrm{coarea}}, \quad \alpha_{\mathrm{old}}, \quad \alpha_{\mathrm{hist}}, \quad \alpha_{\mathrm{bdry}}. \tag{6.cxcv}$$

They denote the nonlinear action, Haar density, coarea and coordinate Jacobians, old activities, resummed history density, and the remaining boundary or stored-field terms. Then eq. 6.clxvii holds with their sum

$$\alpha = \alpha_{\mathrm{act}} + \alpha_{\mathrm{Haar}} + \alpha_{\mathrm{coarea}} + \alpha_{\mathrm{old}} + \alpha_{\mathrm{hist}} + \alpha_{\mathrm{bdry}}. \tag{6.cxcvi}$$

This follows from addition of logarithms on the specified positive branch and the triangle inequality. A factor that can vanish must be kept in the domain or resolved into positive components; it cannot simply be assigned a bounded logarithm.

The preceding estimates give, for example,

$$\alpha \le CMgR_1^3 + CMg^2R_1^2 + \frac{m\delta}{1-\delta} + |W|\epsilon + \alpha_{\mathrm{hist}} + \alpha_{\mathrm{bdry}}. \tag{6.cxcvii}$$

Every quantity on the right is measured in the actual retained coordinate chart. This is a sufficient estimate, not a substitute for the actual determinant or old-core calculation.

6.7.8. *A scale criterion for the second and fourth correlations.* Write $g = x^{-1/2}$, $x \to \infty$. Suppose all of the following bounds hold uniformly on the admitted exteriors:

$$\begin{aligned} N + M + m + |W| &\le C(\log x)^A, & R_1 &\le C(\log x)^B, \\ \delta + \epsilon + \alpha_{\mathrm{hist}} + \alpha_{\mathrm{bdry}} &\le Cx^{-a}(\log x)^E, & a &> 0, \\ L_i &\le C(\log x)^{A_i}\|f_i\|_\infty, & \rho_i &\le Cx^{-a}(\log x)^E. \end{aligned} \tag{6.cxcviii}$$

Suppose also that D contains a box for which $R^2/v \ge c(\log x)^b$, $b > 0$. Then eqs. 6.clxvi and 6.cxcvii give

$$\alpha \le Cx^{-\min(a,1/2)}(\log x)^{E'}, \qquad t \le C(\log x)^A e^{-c'(\log x)^b}. \tag{6.cxcix}$$

Thus eq. 6.clxxviii yields

$$\kappa_\nu(X_1, \dots, X_n) = x^{-n}\kappa_\gamma(Q_1, \dots, Q_n) + o\left(x^{-n}\prod_i \|f_i\|_\infty\right), \qquad n = 2, 4. \tag{6.cc}$$

Indeed every power of $\log x$ in $\prod L_i$ is outweighed both by a positive power of x and by $e^{-c'(\log x)^b/2}$. The same estimates give the lower conditional errors relative to their conditional Gaussian values. If C or A_i varies with the exterior, those Gaussian cumulants must also be compared with one fixed reference before applying the exterior averaging formula. If $c_i(e)$ varies, its error relative to a deterministic reference must likewise be added to eq. 6.clxxix.

The finite-window criterion supplies one explicit route to the interacting law. It has no boundary-flux assumption and does not require convexity of the image of the tests. Its cost is the complete total-oscillation bound and an inner Gaussian box on one actual chart. When fine-scale origins, stored terms or class multiplicities prevent a small total oscillation, the force method of § 6.3 is the appropriate alternative; one cannot infer eq. 6.cc from a small old-activity Hessian in that situation.

6.8. **The four-point curvature kernel: quantitative sign and lattice stability.** The free curvature calculation fixes the normalization of every separated Gaussian cycle. Its collinear four-point value is positive, but a continuity argument at one configuration does not give a uniform margin on the class of test functions used in the short-distance assertion. This subsection supplies that margin. It also computes a negative configuration, proves that its sign persists on an explicit open set, and transfers both signs to the free lattice reference at a uniform mesh floor. These are statements about the leading kernel. They do not compare an interacting measure with its Gaussian reference.

We use the covariance convention of the free curvature chapter. Put $\mathcal{V} = \Lambda^2\mathbb{R}^4$, with orthonormal basis $e_P = e_\mu \wedge e_\nu$, $P = (\mu, \nu)$, $\mu < \nu$. Thus $\dim \mathcal{V} = 6$. The position-space curvature kernel is denoted by K. The lattice comparison used below is precisely eq. A.iii; no stronger lattice error exponent is assumed.

6.8.1. *Reflections and the closed-ring formula.* For a unit vector $u \in \mathbb{R}^4$ define

$$s_u = I - 2u \otimes u, \qquad R_u = \Lambda^2 s_u, \qquad P_u\omega = u \wedge \iota_u\omega. \tag{6.cci}$$

Here ι_u denotes contraction. The map P_u is the orthogonal projection onto $u \wedge u^\perp$, so $R_u = I - 2P_u$. In a basis u, v_1, v_2, v_3, R_u is minus the identity on $u \wedge v_i$ and plus the identity on $v_i \wedge v_j$. Consequently it is a symmetric orthogonal involution, with three eigenvalues of each sign. For $x \ne 0$ the normalization is

$$\mathsf{K}(x) = \frac{R_{\widehat{x}}}{\pi^2|x|^4}. \tag{6.ccii}$$

Indeed, differentiating $G(x) = (4\pi^2|x|^2)^{-1}$ gives

$$\partial_\mu\partial_\rho G(x) = -\frac{\delta_{\mu\rho} - 4\widehat{x}_\mu\widehat{x}_\rho}{2\pi^2|x|^4}. \tag{6.cciii}$$

Substitution into the curvature covariance gives the entries of $\pi^{-2}|x|^{-4}(I-2P_{\widehat{x}})$. This verifies that the reflection in eq. 6.cci acts first on $\mathbb{R}^4$; its second exterior power, rather than a rank-one reflection of $\mathcal{V}$, occurs in the curvature kernel.

Let $\mathcal{R}$ be the three unoriented cycles (1234), (1243), (1324). For pairwise distinct points put

$$k_4(x_1,x_2,x_3,x_4)=\sum_{\varsigma\in\mathcal{R}}\operatorname{tr}_{\mathcal{V}}\prod_{j=1}^{4}\mathsf{K}(x_{\varsigma(j)}-x_{\varsigma(j+1)}),\qquad \varsigma(5)=\varsigma(1). \tag{6.cciv}$$

The products are ordered along the cycle. A cyclic change of its starting point preserves the trace. Transposition reverses the order, and $\mathsf{K}(-x)=\mathsf{K}(x)$, so reversing a cycle also preserves its contribution.

Proposition 6.18 (The trace of a closed ring)**.** Let $w_1,\dots,w_4\neq 0$ and $\sum_j w_j=0$. There is an $\alpha\in[0,\pi]$ such that

$$\operatorname{tr}_{\mathcal{V}}[\mathsf{K}(w_1)\mathsf{K}(w_2)\mathsf{K}(w_3)\mathsf{K}(w_4)]=\frac{2+4\cos\alpha}{\pi^8}\prod_{j=1}^{4}|w_j|^{-4}. \tag{6.ccv}$$

In particular the absolute value of the angular factor is at most six. ∎

Proof. Exterior powers preserve products. Thus the angular matrix in the left side is Λ^2T, where $T=s_{\widehat{w_1}}\cdots s_{\widehat{w_4}}\in\mathrm{SO}(4)$. The space $V=\operatorname{span}\{w_1,\dots,w_4\}$ has dimension at most three. Each factor preserves V and fixes $V^\perp$. If $\dim V=3$, then $T|_V\in\mathrm{SO}(3)$ has an eigenvalue one: the other nonreal eigenvalues come in conjugate pairs, while the product of all eigenvalues is one. If $\dim V\le 2$, the fixed space $V^\perp$ already has dimension at least two. In all cases T fixes a plane and rotates its orthogonal complement. Its eigenvalues are $1,1,e^{i\alpha},e^{-i\alpha}$.

For any four-dimensional matrix T, summing its diagonal two-by-two minors gives

$$\operatorname{tr}(\Lambda^2T)=\tfrac12\{(\operatorname{tr}T)^2-\operatorname{tr}(T^2)\}. \tag{6.ccvi}$$

Equivalently this trace is the sum of the six pairwise products of the eigenvalues. For the eigenvalues just found it is $2+4\cos\alpha$. Multiplication by the four radial factors in eq. 6.ccii proves the formula. □

An orientation-preserving or orientation-reversing orthogonal change of coordinates conjugates every angular matrix by the same Λ^2O. Hence k_4 is invariant under isometries and homogeneous of degree -16. Permuting its arguments permutes the three cycles. For separated integrable functions define

$$\mathcal{B}_4(f_1,f_2,f_3,f_4)=\int_{(\mathbb{R}^4)^4}k_4(x_1,x_2,x_3,x_4)\prod_{i=1}^{4}f_i(x_i)\,dx_1\cdots dx_4. \tag{6.ccvii}$$

If every two supports have distance at least $d>0$, absolute convergence and Prop. 6.18 give

$$|\mathcal{B}_4(\underline{f})|\le 18\pi^{-8}d^{-16}\prod_i\|f_i\|_{L^1}. \tag{6.ccviii}$$

The sixteen powers of length in the measure cancel the homogeneity of k_4. Thus simultaneous dilations of the four arguments leave $\mathcal{B}_4$ unchanged.

6.8.2. *A uniform positive cone of configurations.* For $0<\vartheta\le 1$ consider nonzero nonnegative $f_i\in C_c^1(\mathbb{R}^4)$ with $F_i=\|f_i\|_\infty$, each supported in a ball of radius d, and satisfying, for $i\neq j$,

$$\begin{aligned} d\le\operatorname{dist}(\operatorname{supp}f_i,\operatorname{supp}f_j)\le 6d,\\ \int f_i\ge\vartheta d^4F_i,\qquad \operatorname{Lip}f_i\le F_i/(\vartheta d).\end{aligned} \tag{6.ccix}$$

The positive-cone condition is that one unit vector e works for every pair of points in distinct supports:

$$|w-(w\cdot e)e|\le |w|/8, \qquad w=x_i-x_j, \quad i\neq j. \tag{6.ccx}$$

Proposition 6.19 (Quantitative positive margin)**.** Under eq. 6.ccix and eq. 6.ccx, every ring has angular factor greater than four, and

$$\mathcal{B}_4(\underline{f})\ge c_4\vartheta^4\prod_i F_i>0, \qquad c_4=12\pi^{-8}10^{-16}. \tag{6.ccxi}$$

■

Proof. Write $\omega=\arcsin(1/8)$. The unoriented line of every edge is at angle at most ω from $\mathbb{R}e$. The angle between the lines of any two edges is therefore at most 2ω. Two reflections with normal lines at angle ψ give a rotation by 2ψ on their span and the identity on its orthogonal complement.

For an orthogonal map O put $a(O)=\sup_{|v|=1}\angle(v,Ov)$. The spherical triangle inequality gives $a(O_1O_2)\le a(O_1)+a(O_2)$. Grouping the four reflections into two pairs therefore gives $a(T)\le 8\omega$. For the closed ring in Prop. 6.18, $a(T)=\alpha$: in the rotating plane the maximal displacement angle is exactly α, and a fixed-plane component cannot increase it.

Three applications of the double-angle identity yield

$$\cos(2\omega)=\frac{31}{32}, \qquad \cos(4\omega)=\frac{449}{512}, \qquad \cos(8\omega)=\frac{70529}{131072}>\frac12. \tag{6.ccxii}$$

The first two positive cosines, starting from $0<\omega<\pi/2$, put 8ω in $(0,\pi)$. Consequently $8\omega<\pi/3$ and

$$2+4\cos\alpha\ge\frac{136065}{32768}>4. \tag{6.ccxiii}$$

Any two points in distinct supports have distance at most $10d$: choose points realizing their minimum distance at most $6d$ and add the two support diameters, each at most $2d$. Each of the three rings thus contributes at least $4\pi^{-8}(10d)^{-16}$. Integrating the resulting bound and using the four mass floors proves eq. 6.ccxi. □

There is an independent matrix check on the positive margin. If ψ is the angle between the lines of u and v, then $\|R_u-R_v\|_{\mathrm F}=4\sin\psi$. To see this, choose coordinates in which the two normals lie in a coordinate plane. The product s_us_v rotates that plane through 2ψ; on Λ^2 it has two fixed coordinates and two copies of that rotation. Taking the Frobenius norm gives the stated identity. Under eq. 6.ccx, telescoping four orthogonal factors gives $\|R_{u_1}\cdots R_{u_4}-I\|_{\mathrm F}\le 2$. For a real orthogonal six-dimensional matrix A, $\operatorname{tr}A=6-\|A-I\|_{\mathrm F}^2/2$. This gives the weaker but still uniform floor four without the closed-ring eigenvalue calculation.

The nearly collinear class in the four-point assertion satisfies the cone condition. Indeed, if $\operatorname{supp}f_i\subset B(c_i,d/16)$ and the c_i lie on $\mathbb{R}e$, the transverse part of x_i-x_j has length at most $d/8$; the separation in eq. 6.ccix makes this at most $|x_i-x_j|/8$. This class is nonempty with explicit constants. Take $\psi(x)=(1-|x|^2)_+^2$ and $f_i(x)=\psi(16(x-c_i)/d)$, with consecutive centres separated by $5d/4$ along the line. Then

$$\int\psi=\frac{\pi^2}{12}, \qquad \operatorname{Lip}\psi=\frac{8}{3\sqrt3}, \qquad 0<\vartheta\le\min\left\{\frac{\pi^2}{12\cdot16^4},\frac{3\sqrt3}{128}\right\} \tag{6.ccxiv}$$

suffices for all the shape conditions. The first integral follows by radial integration; the gradient norm is the maximum of $4r(1-r^2)$ on $[0,1]$. The smallest support separation is $9d/8$, and the largest minimum separation is less than $6d$.

6.8.3. *A negative transverse configuration.*

Proposition 6.20 (A negative box with an explicit neighbourhood)**.** Let $h>0$ and let e_1',e_2',e_3' be an orthonormal triple. Put

$$x_1^0=y, \quad x_2^0=y+he_1', \quad x_3^0=y+h(e_1'+e_2'), \quad x_4^0=y+h(e_1'+e_2'+e_3'). \tag{6.ccxv}$$

Then

$$k_4(\underline{x}^0) = -\frac{7}{36\pi^8}h^{-16}. \tag{6.ccxvi}$$

If $|x_i - x_i^0| \le h/200000$ for all i, then

$$k_4(\underline{x}) \le -\frac{7}{72\pi^8}h^{-16}. \tag{6.ccxvii}$$

Thus nonzero nonnegative tests supported in these four balls have a strictly negative integrated box. ∎

Proof. Isometries and homogeneity reduce the calculation to $h = 1$, $y = 0$ and the first three coordinate vectors. Every reflection fixes the fourth coordinate. Direct multiplication on the three-dimensional span gives the following exact values:

cycle	$(\lvert w_1\rvert^2, \lvert w_2\rvert^2, \lvert w_3\rvert^2, \lvert w_4\rvert^2)$	$\operatorname{tr}_{\mathcal{V}} \Lambda^2 T$	$\prod_j \lvert w_j\rvert^{-4}$
1234	$(1,1,1,3)$	-2	$1/9$
1243	$(1,2,1,2)$	0	$1/16$
1324	$(2,1,2,3)$	4	$1/144$

(6.ccxviii)

For the first row, the first three reflections multiply to $-I$ on that span, so the product has eigenvalues $1, -1, -1$ there. For the second row the product is a three-cycle of the coordinate axes. For the third row its trace on $\mathbb{R}^4$ is three, giving angular factor four by eq. 6.ccvi. All entries may also be obtained from the rational formula $s_w = I - 2ww^{\mathsf{T}}/(w^{\mathsf{T}}w)$, so no choice of square root affects the calculation. The sum is $-2/9 + 4/144 = -7/36$, proving eq. 6.ccxvi.

For completeness the neighbourhood can be chosen without a compactness argument. The normal-form calculation above also gives $\|R_u - R_v\| \le 2\sin\psi$. Differentiating eq. 6.ccii in a unit direction gives

$$\|\mathsf{K}(z)\| \le \pi^{-2}|z|^{-4}, \qquad \|\partial_v \mathsf{K}(z)\| \le 6\pi^{-2}|z|^{-5}. \tag{6.ccxix}$$

If $|x_i - x_i^0| \le \rho h$ and $\rho \le 1/20$, every edge on the straight path between the configurations has length at least $9h/10$. On this path the kernel norm is less than $2\pi^{-2}h^{-4}$ and its directional derivative norm less than $11\pi^{-2}h^{-5}$. Each edge moves by at most $2\rho h$. Telescoping a product of four factors, using $|\operatorname{tr} A| \le 6\|A\|$, bounds the change in all three rings by

$$|k_4(\underline{x}) - k_4(\underline{x}^0)| \le 12672\rho\pi^{-8}h^{-16}. \tag{6.ccxx}$$

At $\rho = 1/200000$ this is smaller than $7\pi^{-8}h^{-16}/72$. This proves eq. 6.ccxvii. Integration against $\prod_i f_i \ge 0$ proves the last assertion, more precisely with upper bound $-7h^{-16}\prod_i \int f_i/(72\pi^8)$. □

The restriction to a nearly collinear class therefore has mathematical content. Positivity of the covariance operator does not imply positivity of every separated fourth cumulant of its quadratic density.

6.8.4. *The finite Gaussian coefficient and the* SU(2) *normalization.* Let $\xi^1, \dots, \xi^q$ be independent centred Gaussian vectors with the same real positive semidefinite covariance C on a finite coordinate set. For real diagonal matrices D_i set $Q_i = \frac{1}{2}\sum_{a=1}^{q} (\xi^a)^{\mathsf{T}} D_i \xi^a$. On a neighbourhood of the origin,

$$\log \mathbb{E} \exp\Big(\sum_i z_i Q_i\Big) = \frac{q}{2}\sum_{m\ge 1} \frac{1}{m} \operatorname{tr}\left(C\sum_i z_i D_i\right)^m. \tag{6.ccxxi}$$

The formula follows by diagonalizing $C^{1/2}(\sum_i z_i D_i)C^{1/2}$ at real parameters and then using the convergent matrix logarithm near zero; a singular C is handled on its range. Taking the coefficient of $z_1 z_2 z_3 z_4$, and grouping the 24 words by cyclic rotation and reversal, gives

$$\kappa(Q_1, Q_2, Q_3, Q_4) = q \sum_{\varsigma \in \mathcal{R}} \operatorname{tr}(C D_{\varsigma(1)} C D_{\varsigma(2)} C D_{\varsigma(3)} C D_{\varsigma(4)}). \tag{6.ccxxii}$$

Each unoriented ring has eight words, canceling $2m = 8$. Replacing C by $x^{-1}C$ multiplies this by x^{-4}. Centering the Q_i does not change this mixed cumulant.

For the Wilson observable of SU(2) use Pauli matrices normalized by $\frac{1}{2}\operatorname{tr}(\sigma^a\sigma^b) = \delta_{ab}$. For real $v \in \mathbb{R}^3$,

$$1 - \tfrac{1}{2}\operatorname{tr}\exp(iv\cdot\sigma) = 1 - \cos|v| = \tfrac{1}{2}|v|^2 + O(|v|^4). \tag{6.ccxxiii}$$

Hence the Gaussian quadratic reference has $q = 3$, with exactly the factor $1/2$ used above. If each first source derivative has coefficient ζ, its four-point leading term is

$$3\zeta^4 x^{-4}\mathcal{B}_4(\underline{f}). \tag{6.ccxxiv}$$

There is no additional factor $1/2$ in this four-point formula. The quartic Wilson Taylor term in eq. 6.ccxxiii, the interacting density, and the actual source remainders have not been discarded by a claim that their cumulants are small. Estimating their combined contribution is the separate comparison problem.

For comparison with three points, the Hodge star satisfies $*R_u* = -R_u$. Inserting $** = I$ between the factors and taking a trace shows that every odd ring of the continuum kernel vanishes. This is a kernel identity at separated points, rather than an assertion that the quadratic density is a Gaussian random field.

6.8.5. *Uniform comparison with the free lattice box.* Let $a = \ell/N$, $N \in \mathbb{N}$, and let P_{ex} be the orthogonal projection onto the exact lattice two-cochains. Plaquettes $p = (y, P)$ have barycentres $x(p) = y + ac_P$, with $c_P = (e_\mu + e_\nu)/2$ for $P = (\mu, \nu)$. For any real symmetric covariance $C(p, q)$ define the lattice box

$$\mathcal{B}_{4,a}[C](\underline{f}) = \sum_{\varsigma\in\mathcal{R}}\sum_{p_1,\dots,p_4}\prod_i f_i(x(p_i))\prod_{j=1}^{4} C(p_{\varsigma(j)}, p_{\varsigma(j+1)}). \tag{6.ccxxv}$$

In particular the fourth cumulant of the finite free Wilson quadratic reference is $3\mathcal{B}_{4,a}[P_{\mathrm{ex}}]$. There is no missing Riemann factor in this expression: $P_{\mathrm{ex}}(p, q) = a^4\mathsf{K}_{a,\ell}(p, q)$, so a product of four covariance entries contributes a^{16}.

Proposition 6.21 (Uniform lattice error on the full shape class)**.** Suppose eq. 6.ccix holds on a common short lift of the four supports to $\mathbb{R}^4$, with $a \le d/100$ and $\ell \ge 200d$. There is a numerical C, depending only on the constant in eq. A.iii, such that

$$\left|\mathcal{B}_{4,a}[P_{\mathrm{ex}}](\underline{f}) - \mathcal{B}_4(\underline{f})\right| \le C\left\{(a/d)^{1/2} + (d/\ell)^4 + \frac{a}{\vartheta d}\right\}\prod_i F_i. \tag{6.ccxxvi}$$

The bound is uniform in positions, directions, shapes and the number of lattice sites. The cone condition is unnecessary for this error estimate. ∎

Proof. Write the lattice box using four factors $a^4\mathsf{K}_{a,\ell}$. On distinct supports every relevant distance lies between d and $10d$. The comparison in eq. A.iii, entrywise and hence in six-dimensional operator norm, gives

$$\|\mathsf{K}_{a,\ell}(p, q) - \mathsf{K}(x(p) - x(q))\| \le Cd^{-4}\{(a/d)^{1/2} + (d/\ell)^4\}. \tag{6.ccxxvii}$$

All covariance factors are bounded by Cd^{-4}. Replacing the four factors one at a time therefore costs at most $Cd^{-16}\{(a/d)^{1/2} + (d/\ell)^4\}$ per term, before the a^{16} factor and the four test functions. For each orientation, the number of grid points in a ball of radius d is at most $C(d/a)^4$, by placing disjoint mesh cubes about the points. Summation in four variables and in the finitely many orientations gives the first two error terms in eq. 6.ccxxvi.

The remaining sum still samples the test functions and kernels at orientation-dependent barycentres. Move $y_i + ac_{P_i}$ to y_i, one factor at a time. Along these movements a nonzero test function stays in its support enlarged by Ca, and distinct supports remain at distance at least $d/2$. The

test-function cost is at most $CaF_i/(\vartheta d)$, and eq. 6.ccxix bounds each kernel cost by Cad^{-5}. The same grid count bounds the entire change by $Ca\prod_i F_i/(\vartheta d)$.

At the common grid sites y_i, summing the four orientation indices gives precisely the matrix trace in eq. 6.cciv. The result is $a^{16}\sum_{y_1,\dots,y_4} k_4(\underline{y})\prod_i f_i(y_i)$. This last Riemann sum has the same error bound. In fact the integrand has derivative at most $C\vartheta^{-1}d^{-17}\prod_i F_i$ on the product of the enlarged supports, whose sixteen-dimensional volume is Cd^{16}. Its oscillation in a mesh cell is at most the derivative bound times Ca. Summing cell errors gives $Ca\prod_i F_i/(\vartheta d)$. No diagonal singularity is crossed: the product of the four tests vanishes in a neighbourhood of every coincidence diagonal, so the integrand extends by zero there. These three replacements prove the claim. □

Corollary 6.22 (A uniform lattice sign floor)**.** There is a numerical $c>0$ such that the cone class satisfies

$$\mathcal{B}_{4,a}[P_{\mathrm{ex}}](\underline{f}) \ge \tfrac{1}{2}c_4\vartheta^4\prod_i F_i \tag{6.ccxxviii}$$

whenever $a/d \le c\vartheta^8$ and $d/\ell \le c\vartheta$. ■□

Proof. Choose c so that the right side of eq. 6.ccxxvi is at most $c_4\vartheta^4\prod_i F_i/2$. This is possible because the three displayed errors are then bounded by constants times $c^{1/2}\vartheta^4$, $c^4\vartheta^4$ and $c\vartheta^7$, respectively, and $\vartheta\le 1$. The same choice can enforce $a\le d/100$ and $\ell\ge 200d$. Apply Prop. 6.19. □

For any fixed nonzero nonnegative C^1 tests supported in the negative balls of Prop. 6.20, the same comparison gives a strictly negative free lattice box at a sufficiently fine mesh and sufficiently large torus. To apply the uniform version choose $d=9h/10$ and a fixed positive ϑ smaller than all four mass and inverse Lipschitz ratios. The supports then meet the separation and size conditions in eq. 6.ccix. The continuum negative margin is independent of the mesh, whereas the error in eq. 6.ccxxvi tends to zero.

6.8.6. *Background covariances and perturbed profiles.* The continuum sign also applies to the background covariance once its Gaussian complement has the required decay. The exact decomposition and the decay estimate are different facts. Let E be the space of exact two-cochains and let $A: E\to W$ be the actual linear coarse flux map. For a standard Gaussian F on E put $N=E\cap\ker A$ and $Y=E\ominus N$. The restriction of A to Y is injective, so AF determines the Y component of F. Its N component is an independent standard Gaussian. Thus

$$\mathrm{Cov}(\mathbb{E}[F\mid AF]) = P_Y,\quad \mathrm{Cov}(F-\mathbb{E}[F\mid AF]) = P_N,\quad P_{\mathrm{ex}} = P_Y+P_N. \tag{6.ccxxix}$$

This finite-dimensional identity holds for the specified flux map; it contains no spatial decay assertion. To identify P_Y with the background covariance of a connection integral, one must also verify that the actual constraint induces this flux map, that its gauge integration has the prescribed normalization, and that the closed and zero modes have been treated consistently. The Gaussian projection identity does not replace those identifications.

If, in addition, its fluctuation complement satisfies

$$|P_N(p,q)| \le C(a/b)^4 e^{-\delta|x(p)-x(q)|/b},\quad |x(p)-x(q)|\ge b, \tag{6.ccxxx}$$

then the proof of Prop. 6.21 gives

$$\begin{aligned} |\mathcal{B}_{4,a}[P_Y](\underline{f}) - \mathcal{B}_4(\underline{f})| &\le C\left\{(a/d)^{1/2}+(d/\ell)^4+\mathfrak{e}(d/b)+\frac{a}{\vartheta d}\right\}\prod_i F_i,\\ \mathfrak{e}(t) &= \sup_{u\ge t} u^4 e^{-\delta u},\qquad d\ge b. \end{aligned} \tag{6.ccxxxi}$$

Indeed $a^{-4}|P_N(p,q)|$ is bounded by $C|x(p)-x(q)|^{-4}\mathfrak{e}(d/b)$ at the relevant distances. Only the first covariance-replacement step changes. For the actual flat witness, take the flux map Q^{pl}_{K-s} and $b=a_s$. The flat conditioning of §6.1.1.1 identifies P_N with $C^{\mathrm{fl}}_{K,s}$. The sum of the finer slices gives

the tail at the separated distances used here, including the enlarged profiles at distance at least $\mathsf{d}/2$. The flat gauge comparison identifies the curvature law of each slice with the flat step law. Other flux maps require their own complement estimate.

The form is also stable under the small changes of profiles produced by Gaussian extraction. Retain $a \le d/100$. Suppose a covariance satisfies $|C(p,q)| \le C_0 a^4 d^{-4}$ between the distinct enlarged supports. Let $h_i(p)$ depend on the plaquette orientation if necessary, with $|h_i(p)| \le \varepsilon F_i$, supported within distance $d/8$ of $\operatorname{supp} f_i$, and $0 \le \varepsilon \le 1$. The enlarged supports still have separation at least $3d/4$ and volume $O(d^4)$. The absolute grid-mass bound $a^4 \sum_p |h_i(p)| \le C\varepsilon F_i d^4$ uses only that support bound and the point count. Expanding by four-linearity, the fifteen nonempty choices of perturbed arguments give

$$|\mathcal{B}_{4,a}[C](f_1+h_1,\dots,f_4+h_4) - \mathcal{B}_{4,a}[C](\underline{f})| \le C\{(1+\varepsilon)^4 - 1\} \prod_i F_i \le C'\varepsilon \prod_i F_i. \tag{6.ccxxxii}$$

No differentiability or positivity of the h_i is needed. Orientation-dependent perturbations therefore cause no additional covariance or Riemann-sum assumption.

6.8.6.1. The normalized comparison of four bounded insertions. The four-point witness may require the larger room $C_W^{\square}(s) = c_W C_W(s)$, with a fixed $c_W \ge 1$ chosen for the shape class. In this comparison write s for the depth selected with that room and $k_0 = K - s$, $x = x_{k_0}$, $\rho_{\mathsf{d}} = L^s \mathsf{d}$. At the witness take the four windowed plaquette reads G_i, with profiles ϕ_i supported in the allowed enlargements. Use a segment of r steps and a single nonwrapping box for the four supports at each step. At the first input level k_0, include the full datum box of each native localized witness minimizer, with its four test layers. Their size in witness units is included in $C\rho_{\mathsf{d}}$. At a later input level $j-1$, use one localized minimizer cube around the union of the four supports, with a margin of order D in input units. Use one prescribed rooted axial tree for the common frame. Its root and all its paths belong to the read. A simultaneous change of gauge leaves only the rotation at this common root in the four transformed arguments.

For the input fluctuations, define S_j from these full reads by adjoining all free coordinates within the fixed double-block reach of the one-step pivot and reconstruction maps. The exact dependence on S_j follows from the finite range of those maps. For the comparison integral I_j, add a further D-margin to a cube containing these coordinates. With O_j the free exterior, this gives $S_j \subset I_j$, $\#S_j \le n_j = \#I_j$, and $d(S_j, O_j) \ge D$ in input mesh units. In particular

$$n_j \le C(\rho_{\mathsf{d}} L^{-(j-1-k_0)} + D + C_L)^4.$$

These are the read-set conditions of the normalized product-window estimate.

Use a separate neighborhood for the clean clause. It contains I_j, every native test whose reads can reach it, their full row carriers, and the operation margins. If an operation touches one of these reads, its immediately preceding live component is within the diameter of the operation component. The enlargement by $(200\check{R}_j + 1)M$ in the appropriate level units covers this possibility even when the old live cells do not intersect I_j. These layers enter the clean-history count. The conditional comparison integral retains its own box and its distance D to the exterior. The condition is imposed before that step's healing: no creation or operation meets this enlargement, and no live component meets it on either side of the step. Use the compensated standing representation. The coupling lag has no term supported wholly inside the box, since the profiles of healed regions have been redrawn and the standing large regions miss the padded neighborhood. A lag term reaching the box through an exterior trace uses the fixed-exterior old-origin oscillation estimate.

Fix the coarse field, the older stored slots and the exterior free coordinates after the ordinary gauge draw. Use the product-window calculation on the union of all four reads. An affected pivot is reconstructed on its full double block, including when its bond lies outside I_j. For every query that reads the changed coordinates the interior window implication gives the approximate and old density tests throughout the literal product of balls. No operation or its guards meet these carriers.

For an exterior query the complete read is fixed. Induction along the original order of the queries gives the same exterior outcomes throughout the product, including when the next query depends on an earlier answer. Thus at fixed compatible exterior the selector is constant on this product.

On a clean standing part the numerator with insertion and the uninserted denominator therefore use the same interior window and the same exterior measure. Writing Z_{e} for the uninserted interior integral and $m(d\mathsf{e})$ for the exterior measure with its retained weights, the normalized conditional law on the box is averaged with measure proportional to $Z_{\mathsf{e}}\, m(d\mathsf{e})$. A merge or an operation on the exterior takes a further positive mixture of these quotients. The pointwise clean quotient gives the reference branch with the original weights for these allowed strings. On this branch take the same cutoff and the same flat slices for all four profiles. Use the common-frame estimate for the nested localized readouts on their union, including the separate first witness minimizers. The hybrid through the adjacent-level coupling is defined with the bounded function $\exp(\sum_i \lambda_i G_i)$, with independent source coordinates. Setting the top field to zero yields a single Gaussian determinant independent of the terminal datum and of the history. On the polydisc

$$|\lambda_i| \le \Lambda_i = \frac{cx}{4\rho_{\mathsf{d}}^4 p_0^2 \|\phi_i\|_\infty},$$

the diagonal covariance bound and the count of plaquettes give a uniform trace norm bound on the quadratic Gaussian exponent. Zero profiles can be removed. The same bound on a larger disc gives a uniform positive lower bound for the determinant's modulus and the second moment needed to remove the Gaussian windows.

Apply the one-step comparisons on this disc to the positive law of the original segment. The nonlinear readout error sums with the geometric factor $L^{-2(j-1-k_0)}$. The tilt, covariance and exterior errors sum in the bounds for the normalized box law. Charge a finer history restriction at the steps where its density changes that law. The native top tests give the bound on the top field for all four read sets on the common admitted box. This field is present in the Gaussian model as a shift; the linear cross term is odd under simultaneous reflection of the Gaussian variables. Pairing the reflected points makes its effect quadratic in the shift. This and the top square cost $O(L^{-4r})$ on the polydisc. In the cumulant calculation these errors correspond to open chains with two ends at the top curvature. The normalization by the uninserted box mass is made at each step. In particular decay of the free covariance alone does not give the exterior error, which uses the decay of the response of the tilted product-window law to the exterior force.

For an unconditional comparison, average the generating functions before taking logarithms. A clean sum at terminal datum W can also use the normalized mixture of the clean class laws, with weights $d\mathsf{Q}(h,\cdot)/d\mathsf{Q}_{\mathrm{cl}}(W)$ on the clean classes. Here Q_{cl} is the sum of their terminal measures. This gives a common determinant for the clean mixture when the clean comparison is uniform over its constituents. It uses a refinement for which cleanness is a property of each class. The actual exponent and the density of the refined classes have to be kept in the normalized comparison. On an exceptional part the G_i still have their windowed sup bounds. Hence the probability of that part, times the bounded insertion estimate, suffices here. The physical first derivatives instead use eq. 6.cxii.

For the unconditional comparison use the adjacent positive laws π_j of the two-insertion calculation, now on the union of the four complete read sets. Take Y_j to be the bounded generating function with all slices through j replaced by flat ones. The same law π_j supplies the two marginals in $\mathbb{E}_{\pi_j}(Y_{j-1} - Y_j)$. At a compatible good exterior, where the selector equals one throughout the product window, its conditional bound is

$$C\left[L^{-2(j-1-k_0)}(\rho_{\mathsf{d}}^2 x^{-1/2} p_0 + e^{-c\Delta_j}) + T_j\right].$$

Here T_j is the normalized box error of the two-insertion calculation, evaluated with the four-read coordinate count. The bound for changing the plaquette field in the exponent has the same constant

up to a fixed factor because $\sum_i |\lambda_i| \|\phi_i\|_\infty \le cx/(\rho_{\mathsf{d}}^4 p_0^2)$. The sum over steps compares the two original endpoint expectations. On a bad current part of mass p_j, both integrands have a bounded extension, so it contributes at most Cp_j. The top-field error, the deleted Gaussian windows and the localized-to-flat comparison give, in all,

$$\delta \le C\left[\rho_{\mathsf{d}}^2 x^{-1/2} p_0 + \max_j e^{-c\Delta_j} + \sum_j T_j + L^{-4r} + \sqrt{t} + p_0^{-2} e^{-cd_*} + \sum_j p_j + p_{\mathrm{top}}\right].$$

The notation t, d_*, p_{top} has the same meaning as in the two-insertion calculation. This argument uses the uninserted exterior weights at each step. To use this bound on the adjacent laws, we must estimate the box errors on the actual four-read domains and the masses of the incompatible exteriors.

There is also a comparison using the clean restriction of the original run. On a clean class use the reference branch of weight P_0 from the pointwise clean quotient, with the stored variables and exterior datum kept in the disintegration. The box and its padding are the same in the restriction and the comparison. Thus each reference conditional expectation uses the original positive weights for the allowed strings. Compose the carried densities on the complete retained states, and project to the terminal datum at the end. Replace one slice at a time in these conditional expectations. The remaining outer composition has sup norm at most one, so the conditional errors add. For the fixed conditional laws, prove the disc estimate on a countable dense set and extend by analyticity, which gives a common exceptional null set for the source parameters. Write Z^0 for the resulting deterministic flat determinant and δ_{ref} for the uniform relative error of this reference branch. If $\nu(\mathrm{cl})$ is the full law's mass of clean classes, averaging the reference and remaining branches gives

$$\left|\frac{\mathbb{E}\exp(\sum_i \lambda_i G_i)}{Z^0} - 1\right| \le C\big(\delta_{\mathrm{ref}} + 1 - P_0\nu(\mathrm{cl})\big).$$

Indeed the reference weight is $P_0\nu(\mathrm{cl})$, and on the complementary branch the uniform bounds on G_i and the lower bound on $|Z^0|$ control the ratio. This is a bound on the unconditional generating function before taking its logarithm. The hypotheses of this route are the support-adapted clean restriction, the verified bracket majorants, and the conditional comparisons on the common product windows.

For the clean class sum, the excluded histories are counted by live cells meeting the padded box from the lower waiting band through the end of the segment. A union bound over this band and the r steps costs at most $C(1 + r + \check{R}_{k_0})(\rho_{\mathsf{d}} + M\check{R}_{k_0})^4 L^{4r + C\check{R}_{k_0}}$ times the normalized bound per cell. Here the factor in L converts the count from the terminal scale to the finest scale in the band. The healed histories outside this criterion are included in the standing sum. For an estimate by adjacent-step selectors, the corresponding count uses their actual current readsets. In either case spend the rarity reserve after these counts and after the source loss below.

If δ bounds the resulting relative error of the averaged generating function on the polydisc and $\delta < 1/2$, the two logarithms differ by $C\delta$. Mixed Cauchy gives an error at order four of at most

$$C\delta \prod_i \Lambda_i^{-1} \le C\delta\, x^{-4} \rho_{\mathsf{d}}^{16} p_0^8 \prod_i \|\phi_i\|_\infty.$$

The comparison therefore requires that $\delta\rho_{\mathsf{d}}^{16} p_0^8$ tend to zero. For instance, if the old-origin removal has $\epsilon_j^{\mathrm{old}} \le C n_j (\log x)^{\mathfrak{p}_0 - q}$ on the four-read box and $n_j \le C\rho_{\mathsf{d}}^4$, its contribution after Cauchy is bounded by

$$Cr\, \rho_{\mathsf{d}}^{20} p_0^8 (\log x)^{\mathfrak{p}_0 - q}.$$

For $r = O(\log\log x)$ and $\rho_{\mathsf{d}} \asymp (\log x)^{2\mathfrak{p}_0}$, this tends to zero when $q > 49\mathfrak{p}_0$.

On the admitted clean reference windows take $D = A\log x$ and $r = \lceil B \log_L \log x \rceil$. The native margins give $\Delta_j, d_* \ge c_0 \min\{D, \check{R}_{k_0}\} - C_0$, and $\check{R}_{k_0}/\log x$ grows without bound. Hence the geometric errors, including $n_j b_j^2 e^{-cD}$, beat the Cauchy factor. In T_j, the cubic density term costs

$Cn_j x^{-1/2} p_0^3$, the covariance term is bounded by $Cn_j(\rho_{\mathsf{d}} x^{-1/2} p_0 + e^{-cD})$, and $t_j \le Cn_j e^{-cb_j^2}$ with b_j comparable to p_0 on the segment. These and the square root of the total window error also beat every required logarithmic power. Removing the top field costs CL^{-4r}, so take $4B > 40\mathfrak{p}_0$ for $\rho_{\mathsf{d}}^{16} p_0^8 L^{-4r} \to 0$. The loss of the clean reference branch contains both $1 - \nu(\mathrm{cl})$ and $1 - P_0 \le r\epsilon_{k_1}$. The padded cell count and the rooted bound on the deleted histories bound their sum by

$$C(1 + r + \check{R}_{k_0})^C (\rho_{\mathsf{d}} + M\check{R}_{k_0})^4 L^{4r + C\check{R}_{k_0}} e^{-cp_0}.$$

Since $\check{R}_{k_0} = o(p_0)$, this loss tends to zero after multiplication by the Cauchy factor. The terminal test reads are included in the clean neighborhood. With the fixed-torus age estimate, use the unprolonged run and write $h = g^{-2}$. The last lattice has ℓ^4 sites and $x_K \le h + B_\sharp$. In the survival term of Prop. 5.71 a sufficient depth floor is

$$s_{\mathrm{vol}}(g, \ell) = \max\left\{0, \left\lceil \frac{\mathsf{B}(h + B_\sharp)\ell^4}{\bar{c}_a} \right\rceil - 1\right\}.$$

At $k = k_0 + r$, the condition $s - r \ge s_{\mathrm{vol}}(g, \ell)$ gives $\mathsf{B}(x_K)\ell^4 - \bar{c}_a(K - k + 1) \le 0$. The survival term retains $e^{-\bar{c}_a a - 2p_0(g_k)}$, and the healed term already has age decay without a volume factor. For $\bar{c}_a \ge 17 \log L + \log 2$ the weighted age sum is geometric and gives the required bound for $Q_{17}(k)$. All earlier reads meet the same depth floor. At fixed g, the segment has $r \le s/2$ above a fixed depth, so $s \ge 2s_{\mathrm{vol}}(g, \ell)$ there suffices. The witness rule, whose room is at least one, gives this depth for sufficiently small separation. In particular a cutoff of the form $\mathsf{d} \le e^{-C_g(1+\ell^4)}$ suffices for this age condition, in addition to the formation and clean-box conditions. These choices require the stated nonwrapping room and the native density and marginal estimates on the common comparison boxes.

If the comparison is also made at fixed clean class and datum, the same disc controls the proper conditional cumulants relative to the deterministic reference values. On the clean part the multi-block terms in total cumulance contain products of at least two conditional errors. They are absent when comparing the averaged generating functions directly.

The determinant has covariance $\sum_{j=k_0+1}^{k_0+r} x_{j-1}^{-1} \mathcal{C}_{(j)}$. On separated supports the slice bound gives a summable absolute kernel. Replacing x_{j-1}^{-1} by x^{-1} then costs $C(B_\sharp r + c_5)/x$ relative to the natural smeared scale. Each term in the omitted ring sum has at least one coarse edge, which costs L^{-4r} in witness units. Since $L^r \ge \rho_{\mathsf{d}}$ by the segment choice, any further coarse edge costs at most the separated edge bound $C\rho_{\mathsf{d}}^{-4}$. Counting the four supports gives $C\rho_{\mathsf{d}}^4 L^{-4r}$ at the same relative scale. These two comparisons are made on the ring itself and do not pay the source-polydisc loss. To compare the enlarged witness profiles with the original profiles in the ring, use eq. 6.ccxxxii with relative perturbation $CM/(\vartheta\rho_{\mathsf{d}})$. Indeed the enlargement is at most CMa_s, and the slope bound is in units of $\vartheta\mathsf{d}$, with $\mathsf{d}/a_s = \rho_{\mathsf{d}}$. Choose the room so that $CMa_s \le \mathsf{d}/8$ and the relative perturbation is at most one. The witness comparison and the ring use the same enlarged profiles before this replacement. To pay that loss for the $O(L^{-4r})$ term in the generating function, take L^{4r} larger than ρ_{d}^{16} times the prescribed power of $\log x$. A segment of length $O(\log\log x)$ suffices in the stated room, with its constant chosen for the error budget. Fix the reference coupling first. As the witness depth tends to infinity, $x \asymp \bar{x}_s$ and $\bar{x}_s = O_g(1 + s)$, so $r \le s - 1$ and $s - r \to \infty$. The padded neighborhoods have side at most $C(\rho_{\mathsf{d}} + D + M\check{R}_{k_0})L^{-(s-r)}$ in physical units. Their polylogarithmic prefactor is dominated by the mesh decay. Take the separation threshold small enough that this side is below a fixed fraction of the torus side and that the stated volume floor holds at $s - r$. The resulting drift is $o(x)$. The box-law estimates must apply to the actual normalized laws on these boxes.

The coupling in the four-point assertion uses the original two-point depth, say s_2. To compare, the room functions obey

$$\frac{C_W(u+t)}{C_W(u)} \le \bigl(1+\log(1+B_\sharp t)\bigr)^{2\mathfrak{p}_0} \qquad (u,t\ge 0),$$

since $\bar{x}_u \ge e$ and $\bar{x}_{u+t} = \bar{x}_u + B_\sharp t$. Choose a fixed integer t_0 so that L^{t_0} exceeds c_W times the right side. By minimality of the witness depths, $s_2 \le s \le s_2 + t_0$: the original room condition at s_2 implies the enlarged one at $s_2 + t_0$. Thus a required formation floor $K - s \ge n$ follows from $K - s_2 \ge n + t_0$. The two-sided flow bound gives $|x_{K-s} - x_{K-s_2}| \le B_\sharp t_0 + c_5$. Consequently

$$x_{K-s}^{-4} = g(\mathsf{d})^8\bigl(1 + O(x_{K-s_2}^{-1})\bigr).$$

This transfers the leading size and the error scale of the four-point comparison to the coupling used in the assertion. The shape margin is taken from the ring at the chosen witness.

6.8.7. *The exact remaining interacting estimate.* This closes the sign, nondegeneracy and shape stability of the continuum free box, and its comparison with the full free lattice reference. It supplies the corresponding background conclusion whenever the explicitly named complement tail is proved. With the running law $x^{-1} \asymp (\log(1/d))^{-1}$ and $\zeta \to 1$, these bounds give size $(\log(1/d))^{-4}$ for the leading four-point term. They do not prove that running law.

To obtain the interacting four-point assertion, the unresolved comparison must identify the actual normalized history/block-field law and establish, on its whole prescribed class,

$$S_4^T(\underline{f}) = 3\zeta^4 x^{-4}\mathcal{B}_{4,a}[P_Y](\underline{f}) + \mathcal{R}_4(\underline{f}), \qquad |\mathcal{R}_4(\underline{f})| \le \epsilon_4(d)\, x^{-4}\prod_i F_i, \quad \epsilon_4(d) \longrightarrow 0. \tag{6.ccxxxiii}$$

For a relative error at most one half, the actual error must in particular beat the fixed shape margin proportional to ϑ^4. Every contribution belongs in $\mathcal{R}_4$: nonquadratic Wilson terms, the interacting conditional density, source jets, cutoff boundaries, fluctuations not represented by P_Y, and the histories excluded from the clean comparison. The required constants must have the stated cutoff, support-position, reference-volume and state uniformity; the torus-only four-point claim must retain its torus scope.

The bounded windowed insertions use the probability of an unclean history in the normalized comparison. The physical first source derivatives can carry the age weight L^{16a}. They use the weighted sum in eq. 6.cxii or a direct bound for the four physical insertions. Nor does a bound on the interior Hessian determine the exterior force in the fixed conditional density. Those estimates concern the interacting construction, and none is inferred from the sign of the free box.

6.9. **A uniform one-field insertion bound.** An estimate for each correlation function does not automatically give an estimate in the Hilbert norm of an arbitrary polynomial of fields. The argument below obtains that stronger norm by repeated reflections at a fixed lattice spacing, before taking a continuum limit. Its analytic hypotheses are the ordinary scalar source upper bound and floor; no typed insertion estimate is required.

Assume the all-mirror invariance and reflection positivity of every periodic Wilson DLR state, the ordinary torus source hypothesis in eq. 5.cdxxxv, and the fixed-layer rooted domain geometry in eq. 5.cdxlvi–eq. 5.cdxlviii. The localization size is $M = L^{m_0}$, with L odd. Torus limits use the cofinal compatible family $\ell = 2L^m$, $m \ge m_0$. Every scale cube Ma_s then tiles the torus, since $\ell/(Ma_s) = 2L^{m-m_0+s}$. Every fixed board of power-of-L side, and every fixed coarser such board, tiles all sufficiently large tori in this family. No scale terms are omitted.

A raw-algebra reflection argument. Fix the spacing $a = L^{-K}$ and a periodic state ρ. Take a board cell C of side $l = L^j \ge a$, centered at a lattice site, with lower time face t. Its face planes are link

mirrors: l/a is odd. Its middle time plane is a site mirror. Both are supplied by the all-mirror theorem. For bounded finite-support functions above t put

$$\langle B, A\rangle_t = \rho(\overline{\theta_t B}A), \qquad \|A\|_t^2 = \langle A, A\rangle_t. \tag{6.ccxxxiv}$$

For a bounded complex cell function D, let $q_D = \limsup_k p_{l,\ell_k}(D)$ along a compatible cofinal sequence. Define, on the raw half-space algebra,

$$T_D A = D\,\tau_{le_4}A, \qquad D^* = \overline{\theta_{t+l/2}D}.$$

Reflection and translation invariance give the formal adjoint identity $\langle B, T_D A\rangle_t = \langle T_{D^*}B, A\rangle_t$. No bounded operator on a quotient has been assumed.

Put $K_D = T_{D^*}T_D$ and $m_j = \langle A, K_D^j A\rangle_t$. Formal adjoints and reflection Cauchy–Schwarz imply

$$m_{2r} = \|K_D^r A\|_t^2, \qquad m_{2r+1} = \|T_D K_D^r A\|_t^2, \qquad m_j^2 \le m_{j-1}m_{j+1}. \tag{6.ccxxxv}$$

For odd $j = 2r+1$ the last inequality uses the two vectors $K_D^r A, K_D^{r+1}A$; for even $j = 2r \ge 2$ it uses $T_D K_D^{r-1}A, T_D K_D^r A$. Thus it is a raw semidefinite-form calculation, not an application of a spectral theorem to an operator whose boundedness is still to be proved. If $m_0 = 0$, Cauchy–Schwarz already gives $m_1 = 0$. Otherwise log-convexity gives

$$m_1^N \le m_0^{N-1} m_N. \tag{6.ccxxxvi}$$

The expression for m_N consists of the left endpoint $\overline{\theta_t A}$, a column of $2N$ alternating translated copies of D^* and D, and the right endpoint $\tau_{2Nle_4}A$. Choose a coarse side $l' = L^r l$ large enough to contain A in a coarse half-space cell above t, spatially aligned with C. The oddness of L^r makes all coarse faces fine-board faces. Take N through sufficiently large multiples of L^r.

On this coarse grid retain fixed endpoint zones containing both endpoint supports and, if convenient, a fixed number c_A of the adjacent column factors. Bound the complete endpoint functions by their fixed-cutoff supremum norms. This yields a finite constant $C(a, A, D)$ independent of N. In the middle, every occupied coarse cell is a product of fine cell functions only. Fine-to-coarse chessboard refinement and product domination in eq. 5.cdxxxiii apply there. Grid-preserving translates and reflected conjugates of D have the same fine seminorm. Therefore, for every $\epsilon > 0$,

$$m_N \le C(a, A, D)(q_D + \epsilon)^{2N - c_A}. \tag{6.ccxxxvii}$$

The volume limit is taken first for each fixed N. The estimate uses no assertion $p(AD) \le \|A\|_\infty p(D)$: a mixed endpoint block, if present, is bounded in its entirety by its supremum norm. The endpoint zones contain only a bounded number of coarse cells; their factor count and supremum bound stay fixed as the column grows.

Taking the Nth root in eq. 6.ccxxxvi–eq. 6.ccxxxvii, then sending $N \to \infty$ and finally $\epsilon \downarrow 0$, gives

$$\|T_D A\|_t \le q_D \|A\|_t, \qquad |\rho(\overline{\theta_t B} D \tau_{le_4}A)| \le q_D \|B\|_t \|A\|_t. \tag{6.ccxxxviii}$$

The same order of limits proves this when $q_D = 0$; no negative power of q_D is introduced. It also proves that null vectors are mapped to null vectors. Only now may the map be regarded as a bounded operator on the Hilbert quotient. Endpoint constants may depend on the number of fields inside A, but they disappear before eq. 6.ccxxxviii. The final constant does not depend on that number, on B, or on their polynomial coefficients.

One ordinary source and a common centering. Let h be real and supported in the ball of radius $l/4$ around the cell center. For $a \le l/64$, apply the three-range count in eq. 5.cdxlix with board side $\eta = l$, support radius $\delta = l/4$ and the same face margin. Since $\eta/\delta = 4$, its face cost is bounded uniformly as $l \downarrow 0$. Coarse scales use the global count divided by the number of cells, not a separate root count at every source copy. Upper stability and the floor cost only Cl^4. Thus, for $l \le 1$, there are holomorphic univariate normalizers with

$$E_{h,\ell}(0) = 0, \qquad p_{l,\ell}(e^{z\mathcal{O}_a(h) - E_{h,\ell}(z)}) \le Q_0, \qquad |z|\|h\|_\sharp < r_0, \tag{6.ccxxxix}$$

where $Q_0, r_0 > 0$ are independent of the spacing and cell side. They are also independent of the surrounding fields. At a fixed cutoff these normalizers are locally bounded uniformly in the torus, so a compatible Montel subsequence gives one E_h, independently of every infinite-volume state.

The remaining coarse mesh ratios can also be included. If $3 \le l/a < 64$, the ball and its contributing plaquettes lie wholly inside the cell, and $\|\mathcal{O}_a(h)\|_\infty \le C64^4\|h\|_\infty$. Set $E_{h,\ell} = 0$ and enlarge Q_0 in eq. 6.ccxxxix. The only smaller allowed ratio is $l/a = 1$; then a radius-$a/4$ ball about a lattice site contains no plaquette barycentre, so $\mathcal{O}_a(h) = 0$. Consequently eq. 6.ccxxxix covers every allowed ratio, with the same constants.

For fixed z put $D_z = e^{z\mathcal{O}_a(h) - E_h(z)}$. Homogeneity of the seminorm and the locally uniform convergence of the normalizers give $q_{D_z} \le Q_0$. Apply eq. 6.ccxxxviii and then Cauchy's formula on the one source disc. The expectation is holomorphic, because at fixed cutoff all observables are bounded. We obtain

$$\left|\rho\left(\overline{\theta_t B}[\mathcal{O}_a(h) - E_h'(0)]\tau_{le_4}A\right)\right| \le (Q_0/r_0)\|h\|_\sharp\|B\|_t\|A\|_t.$$

Taking $A = B = 1$ in a second arbitrary periodic state ν bounds $|\nu(\mathcal{O}_a(h)) - E_h'(0)|$ by the same expression without the outside norms. The case $D = 1$ of eq. 6.ccxxxviii handles the scalar error. Hence

$$\left|\rho\left(\overline{\theta_t B}[\mathcal{O}_a(h) - \nu(\mathcal{O}_a(h))]\tau_{le_4}A\right)\right| \le C\|h\|_\sharp\|B\|_t\|A\|_t. \tag{6.ccxl}$$

Both states are arbitrary. Large cutoff-dependent normalizer derivatives cancel; uniform moments of perturbed Gibbs states have not been assumed. In using eq. 6.ccxxxviii for D_z, endpoint supremum bounds may depend on z and the cutoff. They disappear pointwise before the uniform bound $q_{D_z} \le Q_0$ is used in Cauchy's formula.

Continuum passage with fixed support gaps. Suppose $a_j \downarrow 0$ and two periodic states ρ_j, ν_j at each datum give convergent centered separated moments

$$\sigma_j(f_1, \dots, f_n) = \rho_j \prod_i [\mathcal{O}_{a_j}(f_i) - \nu_j(\mathcal{O}_{a_j}(f_i))] \longrightarrow \sigma(f_1, \dots, f_n).$$

Use the uniform all-state local moment bounds already proved to obtain equicontinuity under small C^1 test changes. In particular, on each fixed separated tuple, $\sigma_j(\tau_{v_j}X) \to \sigma(X)$ whenever $v_j \to 0$. This follows directly by multilinear telescoping and $\|\tau_v f - f\|_\sharp \to 0$ for compact C^1 functions. The constants in this passage may depend on the fixed tuple and its length; they do not enter the constant in eq. 6.ccxl. Approximating a fixed real translation by lattice translations also proves translation invariance of σ, since both states in each datum are lattice-translation invariant.

Let F, G be arbitrary finite complex linear combinations of field products whose entries have compact supports strictly in positive time and are separated within each product. Define $\|[F]\|_\sigma^2 = \sigma(\theta\overline{F} \cdot F)$. This is nonnegative as a limit of the lattice reflection forms. For a fixed power $l \le 1$ and a real h supported in $\bar{B}((\vec{y}, 0), l/4)$, choose the nearest spatial lattice point $\vec{y}_j$ and put

$$v_j = (\vec{y}_j - \vec{y}, a_j/2), \quad t_j = a_j/2, \quad x_{*,j} = (\vec{y}_j, l/2 + a_j/2).$$

For all sufficiently fine cutoffs l/a_j is odd. Therefore $x_{*,j}$ is a lattice site and the cell faces are link mirrors. The shifted inserted test is explicitly $h_j = \tau_{v_j + (l/2)e_4}h$, supported around that cell center. The identity $\theta_{t_j}\tau_{v_j} = \tau_{v_j}\theta_0$ identifies the lattice reflected norm tuples with the corresponding small translations of the continuum norm tuples. No half-mesh translation invariance of ν_j is being assumed.

Apply eq. 6.ccxl to the centered lattice polynomials associated to $\tau_{v_j}F$ and $\tau_{v_j}G$. All insertion and norm tuples have fixed positive support gaps for large j. Their values converge by the preceding equicontinuity, including when a limiting Hilbert norm is zero. Thus

$$|\sigma(\theta\overline{G} \cdot (\tau_{(l/2)e_4}h) \cdot \tau_{le_4}F)| \le C\|h\|_\sharp\|[G]\|_\sigma\|[F]\|_\sigma. \tag{6.ccxli}$$

The constant is independent of the numbers of entries and the finite polynomial coefficients of F, G. Arbitrary centering states ν_j are retained throughout.

For completeness time translations are contractions in these norms. At fixed spacing, reflection Cauchy–Schwarz gives $\|\tau_u A\|_t^2 \le \|A\|_t \|\tau_{2u} A\|_t$ for every positive lattice time u. Iteration against $\|\tau_{2^N u} A\|_t \le \|A\|_\infty$ proves contraction. The same fixed-gap limit passage proves it for every positive real time in the continuum. It uses no bounded insertion operator in advance.

A C^1 insertion estimate near the time mirror. We record the form needed independently of any plate or angular argument. Let $0 < \eta \le 1$, and let $f \in C_c^1$ be supported in $\{\eta \le x_4 \le 3\eta\}$, with support diameter at most R. Take the largest power l of L below η and partition f at mesh cl into pieces in radius-$l/4$ balls. There are at most $C_L(1+R)^3\eta^{-3}$ pieces: only the three spatial directions have unbounded length in units of η. Since f vanishes on both time faces, $\|f\|_\infty \le \eta \|\partial_4 f\|_\infty$. This cancels the $1/l$ from the partition derivative, because $\eta/l \le L$. Each piece has sharp norm at most $C\|f\|_{C^1}$.

Translate a piece to the middle of its side-l time slab and use eq. 6.ccxli. Its center time lies between $\eta - l/4$ and $3\eta + l/4$; both outside factors therefore retain a positive margin of at least $\eta - 3l/4$. Time contraction absorbs those margins. Summing gives

$$|\sigma(\theta\overline{G} \cdot (f) \cdot \tau_{4\eta e_4} F)| \le C(1+R)^3 \eta^{-3} \|f\|_{C^1} \|[G]\|_\sigma \|[F]\|_\sigma.$$

Taking $G = (f) \cdot \tau_{4\eta e_4} F$ and dividing its norm proves the field-operator estimate; splitting real and imaginary parts handles complex f. We may weaken η^{-3} to η^{-4} and write

$$\|[(f) \cdot \tau_{4\eta e_4} F]\|_\sigma \le C(R)\eta^{-4} \|f\|_{C^1} \|[F]\|_\sigma. \tag{6.ccxlii}$$

Proposition 6.23 (Uniform one-field insertion)**.** Under the stated ordinary source, rooted-domain and lattice-symmetry hypotheses, every limit just described satisfies eq. 6.ccxli–eq. 6.ccxlii. Choose a fixed $0 < c < 1/64$. If a real $k \in C_c^1$ is supported in a ball of radius $c\eta$ centered at y, $|y_4| \le \eta/8$, and all entries of F, G lie strictly above $\eta/4$, then

$$|\sigma(\theta\overline{F} \cdot (k) \cdot G)| \le C\eta^{-4} \|k\|_\sharp \|F\|_{(\eta/4)} \|G\|_{(\eta/4)}, \quad \|F\|_{(\eta/4)} = \|[\tau_{-(\eta/4)e_4} F]\|_\sigma. \tag{6.ccxliii}$$

The constant depends only on the ordinary source and localization constants and the fixed geometric choices. It is independent of the defining sequence, the states, support positions, and the numbers of fields in the surrounding finite complex polynomials. ∎

Indeed put $\xi = c\eta$ and translate the insertion in time by $2\xi - y_4$, placing it in $[\xi, 3\xi]$. After this translation the left and right polynomials are, respectively, $\tau_{y_4 - 2\xi} F$ and $\tau_{-y_4 - 2\xi} G$, the latter followed by $\tau_{4\xi e_4}$. Each is a positive time translate of its $\eta/4$-downshift by at least $\eta/8 - 2\xi > 0$. Apply eq. 6.ccxlii, reflection Cauchy–Schwarz and contraction, absorbing the fixed factor c^{-4}. This proves eq. 6.ccxliii. The theorem asserts the C^1 insertion bound only. It does not assert a plate density theorem, an L^1 insertion bound, or full rotational covariance.

6.10. **Analytic insertion densities and the plate bound.** This section derives an L^1 insertion bound from the proved C^1 Hilbert insertion bound. All operators are regularized by positive Euclidean time. No unsandwiched point field is presumed to exist. The exact spectral cube cone is used, but rotational covariance is not.

Let σ be a symmetric, real, time-reflection-invariant, translation-invariant functional on admissible separated tests, with its reflection-positive Hilbert reconstruction. Write $\mathcal{D}$ for the dense classes of finite complex positive-time polynomials and $\Omega = [1]$. Use the probability normalization $\sigma(1) = 1$, so Ω is a unit vector fixed by all translations. Positive time translation is e^{-tH}, spatial translation is $U(\mathbf{x}) = e^{i\mathbf{x}\cdot\mathbf{P}}$, and these operators strongly commute. Assume their joint spectral measure is carried by

$$E \ge 0, \qquad |q_j| \le E \quad (j = 1, 2, 3). \tag{6.ccxliv}$$

Also assume local C^1 continuity of the separated moments, as proved from the ordinary source bounds. This continuity is used for fixed finite polynomials only; none of its field-number constants enter the uniform bounds below.

The insertion input has fixed constants $C_I, c_I > 0$, $p \geq 0$, with $c_I < 1/64$. For $0 < \eta \leq 1$, let

$$I(F; h; G) = \sigma(\theta\overline{F} \cdot (h) \cdot G), \qquad \|F\|_{(\eta/4)} = \|[\tau_{-(\eta/4)e_4} F]\|.$$

Whenever the entries of F, G lie strictly above $\eta/4$ and h is real with support in a radius-$c_I\eta$ ball centered at y, $|y_4| \leq \eta/8$, the input is

$$|I(F; h; G)| \leq C_I \eta^{-p} \|h\|_\sharp \|F\|_{(\eta/4)} \|G\|_{(\eta/4)}. \tag{6.ccxlv}$$

The norm is $\|h\|_\sharp = \max(\|h\|_\infty, c_M \|\nabla h\|_\infty)$. Splitting real and imaginary parts permits complex h, at a fixed factor two. The preceding insertion theorem supplies $p = 4$; keeping p general makes the additional five powers transparent.

Bounded forms, real translations and holomorphy. For h supported in $\bar{B}(0, c_I\eta)$, define the form on raw positive-time polynomials by

$$b_{h,\eta}(A, B) = I(\tau_{(\eta/4)e_4} A; h; \tau_{(\eta/4)e_4} B).$$

By eq. 6.ccxlv it descends through null vectors and extends to a bounded sesquilinear form on the Hilbert space. Riesz representation gives a unique bounded operator $B_{h,\eta}$, with

$$\|B_{h,\eta}\| \leq C\eta^{-p} \|h\|_\sharp, \quad B_{h,\eta}[A] = [(\tau_{(\eta/4)e_4} h) \cdot \tau_{(\eta/2)e_4} A]. \tag{6.ccxlvi}$$

The vector identity follows by testing against the dense polynomial classes and translating the insertion form. Its displayed product is admissible: the insertion is strictly positive in time and is separated from the shifted entries of A. Thus this identity proves the action of the bounded operator; it does not postulate a point field on the quotient.

For complex $z = (z_4, \mathbf{z})$ put

$$T(z) = \int e^{-z_4 E + i\mathbf{z}\cdot\mathbf{q}} \, d\Pi(E, \mathbf{q}).$$

The spectral cone gives $\|T(z)\| \leq 1$ if $\operatorname{Re} z_4 \geq \sum_j |\operatorname{Im} z_j|$. It is operator-norm holomorphic in the strict interior. Indeed, on a neighbourhood with margin $\epsilon > 0$, derivatives of total order m of the integrand are bounded by $E^m e^{-\epsilon E}$. Its supremum is at most $m!\epsilon^{-m}$. The exponential Taylor series consequently converges uniformly in spectral variables on smaller complex neighbourhoods, so its spectral integrals converge in operator norm and may be differentiated there.

Now take h supported in $\bar{B}(0, c_I\eta/2)$, and set $\Phi = [\tau_{-(\eta/4)e_4} F]$, $\Psi = [\tau_{-(\eta/4)e_4} G]$. For real x, $|x_4| < \eta/8$, direct use of eq. 6.ccxlvi gives

$$I(F; \tau_x h; G) = \langle \Phi, M_{h,\eta}(x) \Psi \rangle, \quad M_{h,\eta}(z) = T(\tfrac{\eta}{8} e_4 + z) B_{h,\eta/2} T(\tfrac{\eta}{8} e_4 - z). \tag{6.ccxlvii}$$

For clarity, the real time factors in this formula are $e^{-(\eta/8 + x_4)H}$ and $e^{-(\eta/8 - x_4)H}$; the spatial factors are $U(\mathbf{x})$ and $U(-\mathbf{x})$. Substitution in eq. 6.ccxlvi, followed by one common time translation, recovers exactly $\theta\overline{F} \cdot (\tau_x h) \cdot G$. Both factors in eq. 6.ccxlvii are contractions on

$$\mathcal{O}_\eta = \{z : |\operatorname{Re} z_4| + \textstyle\sum_{j=1}^3 |\operatorname{Im} z_j| < \eta/8\}. \tag{6.ccxlviii}$$

Hence $M_{h,\eta}$ is operator-norm holomorphic there and $\|M_{h,\eta}(z)\| \leq C\eta^{-p} \|h\|_\sharp$. There is no restriction on real spatial translations.

A scaled compact parametrix, with its distribution proof. In four dimensions let $G(x) = -(64\pi^2)^{-1}|x|^2\log|x|$, with value zero at the origin. It is C^1. For $x \neq 0$,

$$\Delta(|x|^2\log|x|) = 8\log|x| + 6, \quad \Delta\log|x| = 2|x|^{-2}, \quad \Delta|x|^{-2} = 0.$$

The first two identities also hold as distributions: Green's formula on $\{|x| > \epsilon\}$ has boundary errors tending to zero, respectively of orders $O(\epsilon^4|\log\epsilon|)$ and $O(\epsilon^2)$, up to smaller terms. In the third identity the boundary term is nonzero. Against a compact smooth test f, the inner normal is $-\partial_r$, so the term containing $f\partial_n|x|^{-2}$ tends to $-2|S^3|f(0) = -4\pi^2 f(0)$; the other boundary term is $O(\epsilon)$. Thus

$$\Delta|x|^{-2} = -4\pi^2\delta_0, \qquad \Delta^3 G = \delta_0. \tag{6.ccxlix}$$

Choose real $\chi \in C_c^\infty(B(0,1))$ equal to one near zero. Put $n = \chi G$ and $s = \delta_0 - \Delta^3 n$. Since $\chi = 1$ near the singularity, eq. 6.ccxlix cancels its delta term. Every remaining Leibniz term contains a derivative of χ supported away from zero, where G is smooth. Therefore $s \in C_c^\infty(B(0,1))$. For $0 < r \leq 1$ define

$$n_r(x) = r^2 n(x/r) = -\frac{\chi(x/r)|x|^2\log(|x|/r)}{64\pi^2}, \qquad s_r(x) = r^{-4}s(x/r). \tag{6.ccl}$$

Distributional scaling in four dimensions gives $\Delta^3 n_r = \delta_0 - s_r$: six derivatives contribute r^{-6}, the prefactor contributes r^2, and the scaled delta contributes r^4. Ordinary differentiation gives

$$\|n_r\|_\sharp \leq Cr, \qquad \|s_r\|_\sharp \leq Cr^{-5}. \tag{6.ccli}$$

Both supports lie in $\bar{B}(0,r)$. The logarithm is $\log(|x|/r)$, not $\log|x|$ after simply cutting off G. The subtracted quadratic polynomial removes a spurious $|\log r|$ in eq. 6.ccli.

For smooth compact k, convolution with eq. 6.ccxlix–eq. 6.ccl gives

$$k = (\Delta^3 k) * n_r + k * s_r. \tag{6.cclii}$$

This can be verified directly against compact smooth tests by Fubini and distributional integration by parts. Alternatively, the compact C^1 kernel n_r is integrable, so all derivatives of its convolution with k may be placed on k under the integral; the distribution identity then yields eq. 6.cclii. Both sides are C^1, so their distributional equality is also pointwise equality.

A bounded analytic density and the L^1 bound. Fix $\epsilon = \min(c_I/8, 1/1024)$ and put $r = \epsilon\eta$. Both n_r and s_r fit the source ball used in eq. 6.ccxlvii. Define the operator-valued holomorphic function

$$V_\eta(z) = \Delta_z^3 M_{n_r,\eta}(z) + M_{s_r,\eta}(z). \tag{6.ccliii}$$

On the smaller domain $|\operatorname{Re} z_4| + \sum_j |\operatorname{Im} z_j| < \eta/32$, a polydisc of radius $\eta/128$ lies in $\mathcal{O}_\eta$. Cauchy's inequalities bound the six derivatives by $6!(128/\eta)^6$ times the bound in eq. 6.ccxlvii. The sum of coefficients of Δ^3 is 4^3. eq. 6.ccli therefore give

$$\|V_\eta(z)\| \leq C\eta^{-p}(\eta^{-6}r + r^{-5}) \leq C\eta^{-(p+5)}. \tag{6.ccliv}$$

Every constant is independent of the surrounding polynomials and their numbers of entries.

Let $k \in C_c^\infty$ have support in $|x_4| < \eta/64$. For a continuous compact ϕ and a compact C^1 kernel q, Riemann sums for $\phi * q = \int \phi(x)\tau_x q\,dx$ converge in C^1, with common compact support. Local C^1 continuity of the insertion form consequently implies $I(F;\phi * q;G) = \int \phi(x) I(F;\tau_x q;G)\,dx$. All convolution supports here stay strictly between the two outside time supports. Applying this observation to eq. 6.cclii, then integrating six derivatives off k onto the analytic matrix element in eq. 6.ccxlvii, proves

$$I(F;k;G) = \int k(x)\langle\Phi, V_\eta(x)\Psi\rangle\,dx. \tag{6.cclv}$$

The integrations by parts have no boundary terms, since k is compactly supported in the open strip. This proves the density identity, not just an inequality.

Mollification carries eq. 6.cclv to compact C^1 tests in the strip: the left side converges by local C^1 continuity and the right side by L^1 convergence and eq. 6.ccliv. Thus it has the unique continuous extension to every L^1 function on that strip, with

$$|I(F;k;G)| \le C\eta^{-(p+5)}\|k\|_{L^1}\|F\|_{(\eta/4)}\|G\|_{(\eta/4)}. \tag{6.cclvi}$$

For an L^1 test this formula defines the extended insertion; no pointwise field interpretation is required. The operator weak integral $\int k(x)V_\eta(x)\,dx$ is well-defined by its bounded sesquilinear forms and has the same norm bound. For compact C^1 tests it agrees with the regularized field product in eq. 6.ccxlvi. If two choices of η admit the same outside polynomials and test strip, their forms agree first on compact smooth tests and then on the common L^1 domain by density. Thus the extension is compatible on intersecting pulled-down domains.

Different compact parametrices give the same density on the real strip: eq. 6.cclv makes their continuous matrix-element differences zero against every compact smooth test. They therefore agree pointwise. Their holomorphic continuations agree on connected overlapping domains, by uniqueness from an open set of real points, first in scalar matrix elements and then as bounded operators.

Plates and compatible point-plate operators. Split $x = (t, u, x_\perp)$, with $x_\perp \in \mathbb{R}^2$. For $\varphi \in L^1(\mathbb{R}^2)$ set

$$V_{\varphi,\eta}(t,u) = \int \varphi(x_\perp)V_\eta(t,u,x_\perp)\,dx_\perp. \tag{6.cclvii}$$

The weak integral is a bounded operator, of norm at most $C\eta^{-(p+5)}\|\varphi\|_1$. It is operator-norm holomorphic for $|\operatorname{Re} t| + |\operatorname{Im} u| < \eta/32$. Indeed the integrands are uniformly bounded and holomorphic on smaller neighbourhoods, so their locally uniformly convergent Taylor series may be integrated. For an L^1 plane profile α supported in $|t| < \eta/64$, Tonelli and eq. 6.cclv–eq. 6.cclvi give

$$|I(F;\alpha\otimes\varphi;G)| \le C\|\varphi\|_1\eta^{-\wp}\|\alpha\|_1\|F\|_{(\eta/4)}\|G\|_{(\eta/4)}, \qquad \wp = p+5. \tag{6.cclviii}$$

Profiles may extend arbitrarily far in the spatial coordinate u. For smooth compact profiles and labels this is the original insertion; all other stated L^1 cases are its continuous extension.

For $0 < a \le 1/4$ define the regularized point-plate operator

$$B_{\varphi;a} = V_{\varphi,4a}(0,0), \qquad \|B_{\varphi;a}\| \le Ca^{-\wp}\|\varphi\|_1. \tag{6.cclix}$$

It is the operator-norm limit of the regularized insertions of $\alpha_\epsilon \otimes \varphi$, where α_ϵ is a unit-integral smooth plane approximate identity at zero. This follows from the operator-norm continuity in eq. 6.cclvii. For $0 < a < b \le 1/4$,

$$B_{\varphi;b} = e^{-(b-a)H}B_{\varphi;a}e^{-(b-a)H}. \tag{6.cclx}$$

To prove it, first use a compact smooth plate supported in the central strips of both scales. The vector formula in eq. 6.ccxlvi, or its dense matrix-element identity, proves the relation for its two regularized operators. Approximate the plane point by α_ϵ and pass in operator norm. Finally approximate an L^1 label by smooth compact labels using eq. 6.cclviii. This proves compatibility on the stated domains without assuming an unbounded field common to the scales.

The same calculation gives real translation compatibility. For $0 < a' < a \le 1/4$ and $|t| < a/16$,

$$V_{\varphi,4a}(t,u) = e^{-(a-a'+t)H}U(ue_1)B_{\varphi;a'}U(-ue_1)e^{-(a-a'-t)H} \tag{6.cclxi}$$

whenever $a - a' > |t|$. One proves this first for a sufficiently narrow smooth approximate identity, using the real translation calculation of eq. 6.ccxlvii, and then passes in operator norm. The right side also supplies the corresponding holomorphic continuation. These identities are suitable for composing independently regularized plate insertions.

Proposition 6.24 (Analytic density and plate bound)**.** Under eq. 6.ccxliv–eq. 6.ccxlv and the stated local continuity, the insertion has the analytic operator density in eq. 6.ccliii–eq. 6.cclv, the uniform L^1 bound in eq. 6.cclvi, and the plate bound in eq. 6.cclviii with exponent $\wp = p + 5$. The point-plate operators in eq. 6.cclix obey the compatibility and translation identities in eq. 6.cclx–eq. 6.cclxi. All constants are independent of the numbers of outside fields. No additional typed source estimate is used. ∎

As a useful spectral consequence, suppose φ is real. Reflection of real, time-even approximate identities proves $B^*_{\varphi;a} = B_{\varphi;a}$. Let $v_{\varphi,a} = B_{\varphi;a}\Omega$ and let $\mu_{\varphi,a}$ be its finite positive joint spectral measure for (H, P_1). Since $H\Omega = 0$, eq. 6.cclx gives $\mu_{\varphi,b} = e^{-2(b-a)E}\mu_{\varphi,a}$. The positive measure $\mu_\varphi = e^{2aE}\mu_{\varphi,a}$ is thus independent of a, is finite on bounded-energy sets, and may have infinite total mass. For $t > 0$ choose $0 < a < \min(t/2, 1/4)$ and put

$$K_\varphi(t,u) = \langle v_{\varphi,a}, e^{-(t-2a)H+iuP_1} v_{\varphi,a}\rangle = \int e^{-tE+iuq}\, d\mu_\varphi(E,q). \tag{6.cclxii}$$

It is independent of a, finite, and its spectral measure is supported on $E \geq |q|$. The integral is holomorphic on $\mathrm{Re}\, t > |\mathrm{Im}\, u|$: on smaller neighbourhoods all differentiated integrands are bounded by a polynomial in E times a strictly decaying exponential, integrable by eq. 6.cclxii at a smaller positive real time.

To identify this as the original two-plate kernel, take real plane approximate identities even in time, first with a smooth compact real label φ. The vectors $[(\tau_{ae_4}\alpha_\epsilon) \otimes \varphi]$ converge to $v_{\varphi,a}$ by eq. 6.cclix. Their matrix elements in eq. 6.cclxii are precisely the two-plate moments at time separation t, with the narrow profiles, by reflection and common translation. For compact profiles with a fixed positive time gap, choose a smaller than half that gap. Convolution approximates those profiles in C^1, while the approximating matrix elements are uniformly bounded by the two vector norm bounds. Fubini and dominated convergence therefore recover the integral of K_φ against the original profiles. Smooth compact approximation of an L^1 label uses the uniform bounds above. The kernel here is the full two-point moment kernel; for connected moments one applies the construction to the centered functional. This is a statement in the chosen coordinate frame. No diagonal-frame cone, contact value at $t = 0$, or rotational covariance is asserted here.

6.11. **Analytic planar kernels and the finite angular band.** A plate estimate uniform in the numbers of outside fields yields the analytic planar kernels used in the angular argument. Rotation invariance also requires the short-distance two-point estimate. Both estimates are hypotheses in this section.

The assumptions and the meaning of a product. Write a point of Euclidean space as (y, z), where $y = (y^0, y^1) = (x_4, x_1)$ and $z = (x_2, x_3)$. Put $\theta(y^0, y^1) = (-y^0, y^1)$. A tuple is a finite ordered list of compactly supported C^1 test functions with pairwise disjoint supports. Products of tuples mean concatenation, whenever the concatenation still has disjoint supports. We use finite complex linear combinations of such tuples, including the empty tuple 1. The notation (h) denotes the tuple with its single entry h.

Assume the following properties of a centered functional σ. It is multilinear in the entries, symmetric, real on real entries, and invariant under simultaneous real translations and the hypercubic group. Its values satisfy $\sigma(1) = 1$ and $\sigma((h)) = 0$. On every fixed collection of separated compact support sets it is continuous for the C^1 norms, with a bound independent of the positions of those sets when their diameters and mutual distances are fixed. No bound on the growth of these constants with the number of entries is assumed in this section.

Let $\mathscr{A}_+$ denote the combinations of tuples supported strictly in $\{x_4 > 0\}$. Reflection positivity and the reconstruction give a Hilbert space $\mathcal{H}$, a dense class map $F \mapsto [F]$, and $\Omega = [1]$, such that

$$\langle [F], [G]\rangle = \sigma(\theta\overline{F} \cdot G), \qquad \|\Omega\| = 1. \tag{6.cclxiii}$$

The inner product is antilinear in the first entry. The reconstructed time and planar spatial translations have the actions

$$e^{-tH}[F] = [\tau_{te_4}F], \qquad e^{ixP}[F] = [\tau_{xe_1}F], \qquad t \geq 0, \tag{6.cclxiv}$$

where H, P are strongly commuting self-adjoint operators, $H \geq 0$, and

$$H \geq |P|, \qquad H\Omega = P\Omega = 0. \tag{6.cclxv}$$

Only this one planar consequence of the exact cube cone is used.

For F supported above a height a define the pulled-down norm by

$$\|F\|_{(a)} = \|[\tau_{-ae_4}F]\|.$$

A label is a real $\varphi \in C_c^1(\mathbb{R}^2)$ in the transverse variables. A profile is a complex $\alpha \in C_c^1(\mathbb{R}^2)$. The corresponding plate is $\alpha \otimes \varphi$. Fix constants $0 < c < 1/4$ and $\wp > 0$. The plate input is that, for each label, a constant $C_\varphi < \infty$ satisfies

$$\begin{aligned} &|\sigma(\theta\overline{F} \cdot (\alpha \otimes \varphi) \cdot G)| \\ &\qquad \leq C_\varphi \eta^{-\wp} \|\alpha\|_1 \|F\|_{(\eta/4)} \|G\|_{(\eta/4)} \end{aligned} \tag{6.cclxvi}$$

for $0 < \eta \leq 1$, profiles supported in $|y^0| < c\eta$, and F, G supported strictly above $\eta/4$. This includes arbitrary finite combinations and arbitrary numbers of entries in F, G. The constant C_φ is the same for all these choices and all η. Every concatenation in this inequality has separated supports. The plate theorem obtained from the ordinary-source insertion estimate supplies precisely this input, with a fixed small c and $\wp = p + 5$.

Bounded plates and their padding. For a profile in the strip of eq. 6.cclxvi put $u = \eta/4$. On the dense classes define

$$B_\varphi[\alpha; \eta][G] = \big[(\tau_{ue_4}(\alpha \otimes \varphi)) \cdot \tau_{2ue_4}G\big]. \tag{6.cclxvii}$$

The plate on the right lies at times strictly between 0 and $2u$; the other entries lie strictly above $2u$. Thus the right side is an actual class in $\mathcal{H}$.

To prove that it depends only on $[G]$, test it against $[F]$ and translate the full tuple down by u. The resulting expression is

$$\langle [F], B_\varphi[\alpha; \eta][G] \rangle = \sigma\big(\theta\overline{\tau_{ue_4}F} \cdot (\alpha \otimes \varphi) \cdot \tau_{ue_4}G\big).$$

The two pulled-down norms on the right are $\|[F]\|$ and $\|[G]\|$. By eq. 6.cclxvi, density and Hilbert duality,

$$\|B_\varphi[\alpha; \eta][G]\| \leq C_\varphi \eta^{-\wp} \|\alpha\|_1 \|[G]\|. \tag{6.cclxviii}$$

In particular null classes map to null classes. There is a unique bounded extension to the whole Hilbert space, with the same norm bound. No domain containing an unspecified number of fields remains in this statement.

The definitions also fix all padding conventions. If $\eta' \leq \eta$ and the profile is supported in $|y^0| < c\eta'$, then, with $d = (\eta - \eta')/4$,

$$B_\varphi[\alpha; \eta] = e^{-dH} B_\varphi[\alpha; \eta'] e^{-dH}. \tag{6.cclxix}$$

Indeed both sides applied to $[G]$ give the right side of eq. 6.cclxvii; density proves equality of the bounded operators. Realness, symmetry, reflection invariance and a translation by $2u$ similarly give

$$B_\varphi[\alpha; \eta]^* = B_\varphi[\overline{\alpha} \circ \theta; \eta]. \tag{6.cclxx}$$

For example, conjugate the expression defining $\langle [G], B_\varphi[\alpha; \eta][F] \rangle$, reflect all its entries, translate by $2u$, and permute the entries. The resulting expression is $\langle [F], B_\varphi[\overline{\alpha} \circ \theta; \eta][G] \rangle$. The label remains unchanged because it is real and the reflection acts only on the plane.

The tube and its bounded translations. For $v = (v^0, v^1) \in \mathbb{C}^2$ use the linear coordinates $v_\pm = v^0 \pm i v^1$, and set

$$\mathbb{V} = \{\operatorname{Re} v_+ > 0, \operatorname{Re} v_- > 0\} = \{\operatorname{Re} v^0 > |\operatorname{Im} v^1|\}, \qquad v^* = (\overline{v^0}, -\overline{v^1}). \tag{6.cclxxi}$$

This is an open convex cone. Its real points are the half-plane $\mathbb{H} = \{v^0 > 0\}$. Both entrywise conjugation and the star preserve it, and $\operatorname{Re} v \in \mathbb{V}$ whenever $v \in \mathbb{V}$. These assertions follow directly from the two strict real linear inequalities in eq. 6.cclxxi. Notice the distinct identities

$$(v^*)_\pm = \overline{v_\pm}, \qquad v^* = -\theta v \quad \text{for real } v.$$

The joint spectral measure of (H, P) is carried by $\{(E, q) : E \geq |q|\}$. Define on the closed tube

$$T(v) = \int e^{-v^0 E + i v^1 q} \, d\mathsf{P}(E, q). \tag{6.cclxxii}$$

Writing $E_\pm = (E \pm q)/2 \geq 0$ gives $-v^0 E + i v^1 q = -v_+ E_- - v_- E_+$. Consequently

$$\|T(v)\| \leq 1, \quad T(v)T(w) = T(v+w), \quad T(v)^* = T(v^*), \quad T(v)\Omega = \Omega. \tag{6.cclxxiii}$$

The last assertion uses $H\Omega = P\Omega = 0$. Dominated convergence in the spectral measure of each vector proves strong continuity on the closed tube.

The map T is holomorphic in operator norm on $\mathbb{V}$. Here is a direct proof, which also records why the exact cone is appropriate. At a point with $\operatorname{Re} v_\pm \geq r > 0$, expand in increments $\Delta_\pm$. The coefficient of $\Delta_+^j \Delta_-^k$ is the bounded functional-calculus operator with multiplier

$$\frac{(-E_-)^j (-E_+)^k}{j!k!} e^{-v_+ E_- - v_- E_+}.$$

Its norm is at most r^{-j-k}, since $x^j e^{-x}/j! \leq 1$ for $x \geq 0$. The resulting two power series converge in operator norm when $|\Delta_\pm| < r$. For real v with $v^0 \geq 0$, the reconstruction gives

$$T(v)[F] = [\tau_{v^0 e_4 + v^1 e_1} F]. \tag{6.cclxxiv}$$

Let R_z be the complex rotation with the usual matrix

$$R_z = \begin{pmatrix} \cos z & -\sin z \\ \sin z & \cos z \end{pmatrix}.$$

In light coordinates $(R_z v)_\pm = e^{\pm i z} v_\pm$. In particular

$$R_{is}\mathbb{V} = \mathbb{V}, \qquad (R_{is} v)^* = R_{is}(v^*) \quad (s \in \mathbb{R}). \tag{6.cclxxv}$$

These are algebraic identities: the multipliers $e^{\mp s}$ are positive real numbers. For a tuple $v = (v_i)$ in the tube define

$$d_{\mathbb{V}}(v) = \min\{1, \min_{i,\pm} \operatorname{Re}(v_i)_\pm\}.$$

Then its exact transformation and a useful lower bound are

$$d_{\mathbb{V}}(R_{is} v) = \min\{1, \min_i e^{-s} \operatorname{Re}(v_i)_+, \min_i e^{s} \operatorname{Re}(v_i)_-\} \geq e^{-|s|} d_{\mathbb{V}}(v). \tag{6.cclxxvi}$$

The same assertions hold in every quarter-turn frame $\mathbb{V}_\nu = R_\nu \mathbb{V}$, $\nu \in (\pi/2)\mathbb{Z}$. The rotations commute; R_ν is real; and the real points of $\mathbb{V}_\nu$ are $\{e_\nu \cdot v > 0\}$, where $e_\nu = R_\nu(1, 0)$.

We will use the following elementary uniqueness principle. A holomorphic function on a connected open subset of $\mathbb{C}^N$ which vanishes on a nonempty relatively open subset of $\mathbb{R}^N$ vanishes identically. At an interior real point all real derivatives are zero, so its complex Taylor series is zero; overlapping balls then propagate the equality along a path. The same proof applies to Hilbert-valued holomorphic functions after testing against each vector. An antiholomorphic variable is treated by conjugating that variable first. This last use will always take place on domains stable under conjugation.

Products with smooth plane profiles. For $n \geq 1$ define the open convex domain

$$\mathbb{D}^{+}_{n,\eta} = \{\mathbf{x} : x_1 - \eta e_0/4 \in \mathbb{V},\ x_{i+1} - x_i - \eta e_0/2 \in \mathbb{V}\ (i < n)\}. \tag{6.cclxxvii}$$

For profiles α_i in the strip $|y^0| < c\eta$ and labels φ_i, abbreviate $B_i = B_{\varphi_i}[\alpha_i; \eta]$ and put

$$\begin{aligned}\Psi_\eta[\vec{\alpha}](\mathbf{x}) = T(x_1 - \eta e_0/4)B_1 T(x_2 - x_1 - \eta e_0/2)B_2 \cdots \\ T(x_n - x_{n-1} - \eta e_0/2)B_n \Omega.\end{aligned} \tag{6.cclxxviii}$$

It is Hilbert-valued holomorphic, and

$$\|\Psi_\eta[\vec{\alpha}](\mathbf{x})\| \leq \prod_{i=1}^{n} C_{\varphi_i} \eta^{-\wp} \|\alpha_i\|_1. \tag{6.cclxxix}$$

The definitions remain valid on the closed domain using strong continuity of T. When all x_i are real and the displayed non-strict time inequalities hold, direct substitution gives

$$\Psi_\eta[\vec{\alpha}](\mathbf{x}) = \Big[\prod_{i=1}^{n} \tau_{x_i}(\alpha_i \otimes \varphi_i) \Big]. \tag{6.cclxxx}$$

For clarity this is an induction from the right. The rightmost operator first puts its plate at time $\eta/4$. The preceding translation moves it by $x_n - x_{n-1} - \eta e_0/2$; the next plate operator translates that entry forward by $\eta e_0/2$ and inserts its own plate at $\eta e_0/4$. The two centers are therefore $\eta e_0/4$ and $\eta e_0/4 + x_n - x_{n-1}$. Iteration and the leftmost translation put all centers at the x_i. Spatial shifts follow the same addition rule. Time gaps and $c < 1/4$ ensure that every tuple in this induction is separated.

Define the smoothed scalar kernel on $U_\eta = (\eta e_0/2 + \mathbb{V})^{n-1}$ by

$$K_{n,\eta}[\vec{\alpha}](v) = \langle \Omega, B_1 T(v_1 - \eta e_0/2)B_2 \cdots T(v_{n-1} - \eta e_0/2)B_n \Omega \rangle. \tag{6.cclxxxi}$$

It is holomorphic and bounded by the right side of eq. 6.cclxxix. If the y_i are real and $y^0_{i+1} - y^0_i \geq \eta/2$, then

$$\sigma\Big((\tau_{y_i}(\alpha_i \otimes \varphi_i))_{i=1}^{n} \Big) = K_{n,\eta}[\vec{\alpha}](v(\mathbf{y})), \qquad v(\mathbf{y})_i = y_{i+1} - y_i. \tag{6.cclxxxii}$$

Translate the first center to $(\eta/4, 0)$ and use eq. 6.cclxxx; taking its scalar product with Ω proves the formula. Translation invariance then restores the original centers. Set $K_0 = 1$ and $K_1 = 0$, consistently with the empty and centered one-point moments.

Removing the plane smoothing. Fix η and choose real radial nonnegative smooth bumps $\beta_{i,j}$, each of mass one, whose support radii tend to zero. For all large j the bumps fit in $D(0, c\eta)$. The kernels $K_{n,\eta}[\vec{\beta}_j]$ have a common bound

$$C_\eta = \prod_i C_{\varphi_i} \eta^{-\wp n} \quad \text{on } U_\eta. \tag{6.cclxxxiii}$$

The bumps need not have the same radii or shapes in different entries. This freedom is needed later for mixed inner products.

Here are the details identifying every limit. Let b_i be C^1 profiles whose successive support time gaps exceed η. For all large j, their convolutions with $\beta_{i,j}$ have separated supports in fixed compact sets. The identity

$$b_i * \beta_{i,j} = \int b_i(y) \tau_y \beta_{i,j}\, dy$$

holds also as a C^1 Riemann integral. Indeed, for fixed j, the integrand and its first derivatives in the test variable are uniformly continuous on a common compact set. Riemann sums converge there in C^1, with their supports in the same compact neighborhood. Multilinearity, the assumed separated C^1 continuity, and successive Riemann summation in all entries give

$$\sigma\big(((b_i * \beta_{i,j}) \otimes \varphi_i)_i\big) = \int \prod_i b_i(y_i)\, K_{n,\eta}[\vec{\beta}_j](v(\mathbf{y}))\, d\mathbf{y}. \tag{6.cclxxxiv}$$

The integrands are continuous and compactly supported; thus Fubini and the successive integrals are legitimate.

A locally bounded family of holomorphic functions has locally uniformly convergent subsequences here. One can see this directly: Cauchy estimates on smaller polydiscs bound first derivatives, Arzelà–Ascoli gives convergence there, and a diagonal choice on a countable exhaustion gives convergence on all compact subsets. The Cauchy integral formula shows that the limit is holomorphic. Apply this observation to eq. 6.cclxxxiii. Along a subsequence let the limit be K'. Since $b_i * \beta_{i,j} \to b_i$ in C^1, passage in eq. 6.cclxxxiv gives

$$\sigma\big((b_i \otimes \varphi_i)_i\big) = \int \prod_i b_i(y_i) K'(v(\mathbf{y}))\, d\mathbf{y}. \tag{6.cclxxxv}$$

All differences in this integral lie in a compact subset of U_η, so locally uniform convergence suffices.

There is at most one holomorphic K' with this property. If two continuous densities give the displayed integrals, choose the b_i to be unit-mass bumps in successively smaller discs around any fixed real configuration with gaps $> \eta$. Their integrals converge to the values of the two densities there. These values coincide. Such differences contain the nonempty relatively open set $\{v \text{ real} : v_i^0 > \eta\}$ in the connected set U_η; the uniqueness principle proves equality on U_η. Consequently the entire smoothing family converges, not merely a subsequence. Otherwise a sequence staying away on a compact set would have a further subsequence with the same uniquely determined limit. Denote it by $K_{n,\eta}$.

The argument proves a useful strengthened conclusion: for any choice of unit-mass bumps in the different entries with maximal support radius tending to zero, the corresponding kernels converge to the same $K_{n,\eta}$, locally uniformly on U_η. No relation between their rates of shrinkage is required.

If $\eta' < \eta$, the two limiting kernels agree on U_η. Both satisfy eq. 6.cclxxxv for gaps $> \eta$, and the same uniqueness proof applies. Since $\bigcup_{\eta>0} U_\eta$ equals $\mathbb{V}^{n-1}$, this constructs a unique holomorphic function

$$K_n(v; \vec{\varphi}) \quad \text{on } \mathbb{V}^{n-1}.$$

It represents σ on every time-ordered family of profiles:

$$\sigma\big((\alpha_i \otimes \varphi_i)_i\big) = \int \prod_i \alpha_i(y_i) K_n(v(\mathbf{y}); \vec{\varphi})\, d\mathbf{y}. \tag{6.cclxxxvi}$$

Choose η below all the support gaps to obtain this formula. It also proves reality at every real point of the tube, by testing against real profiles concentrated near the chosen points.

The bound retains exactly one factor per field:

$$|K_n(v; \vec{\varphi})| \le \Big(\prod_i C_{\varphi_i}\Big) d_{\mathbb{V}}(v)^{-\wp n}. \tag{6.cclxxxvii}$$

Indeed $v \in U_\eta$ whenever $\eta < \min\{1, 2 \min_{i,\pm} \operatorname{Re}(v_i)_\pm\}$. Take the limit up to this upper endpoint in eq. 6.cclxxxiii; that endpoint is at least $d_{\mathbb{V}}(v)$. Neither a derivative of a shrinking bump nor an estimate whose constant depends on outside field counts has entered this step.

Real overlap identities and the four frames. For a quarter turn ν define $K_n^{(\nu)}(v; \vec{\varphi}) = K_n(R_{-\nu} v; \vec{\varphi})$ on $\mathbb{V}_\nu^{n-1}$. Hypercubic invariance and the change of variables $y_i = R_\nu y_i'$ show that eq. 6.cclxxxvi holds with $K_n^{(\nu)}$ whenever the profiles are ordered in the direction e_ν. The rotations act only on profiles and leave the labels unchanged.

It is useful to account for permutations as well. For a permutation π of $\{1, \dots, n\}$ let

$$\mathcal{U}_{\nu,\pi} = \{\mathbf{z} \in (\mathbb{C}^2)^n : R_{-\nu}(z_{\pi(i+1)} - z_{\pi(i)}) \in \mathbb{V} \ (i < n)\}. \tag{6.cclxxxviii}$$

On it use K_n with these ordered differences and the correspondingly permuted labels. Each domain is open, convex, nonempty, invariant under simultaneous complex translations, and satisfies $\operatorname{Re} \mathbf{z} \in \mathcal{U}_{\nu,\pi}$ whenever $\mathbf{z} \in \mathcal{U}_{\nu,\pi}$.

Two of these kernels agree on every nonempty intersection. The intersection is convex and hence connected. It contains the real part of each of its points, so contains a relatively open real ball. At any real configuration in the intersection take small discs about its points which preserve both strict orders. The moment of profiles supported in these discs has both continuous kernel densities, by eq. 6.cclxxxvi, the frame identity and symmetry of σ. Testing with unit-mass profiles shrinking to the points shows equality of the two densities at that configuration. The holomorphic uniqueness principle now gives equality on the whole complex intersection. This proves the overlap identity without assuming arbitrary-angle rotation symmetry.

Thus the ordered kernels glue to a single holomorphic function $\mathbf{K}_n(\mathbf{z};\vec{\varphi})$ on

$$\mathcal{U}_n^{\mathrm{ord}} = \bigcup_{\nu,\pi} \mathcal{U}_{\nu,\pi}. \tag{6.cclxxxix}$$

This union is connected. To check this explicitly, a real configuration can be assigned any prescribed strict time ordering and, independently, any prescribed strict abscissa ordering. Hence each 0-frame permutation domain intersects every $\pi/2$-frame permutation domain. These convex domains form a connected union. The other two frames give the same domains with their orderings reversed, so add no disconnected components. Its real points form

$$\mathrm{Ord}_n = \{\mathbf{y} : \text{all times are distinct or all abscissae are distinct}\}.$$

The function is translation invariant, symmetric in the labelled points, real on real configurations, and invariant under the quarter turns. These properties follow first from the corresponding moment densities on real open sets and then from uniqueness. Imaginary rotations preserve each domain $\mathcal{U}_{\nu,\pi}$ and hence preserve their union.

Point product vectors and their Gram kernel. Put

$$\mathbb{D}_n^+ = \{\mathbf{x} : x_1 \in \mathbb{V},\ x_{i+1} - x_i \in \mathbb{V}\ (i < n)\}. \tag{6.ccxc}$$

This is the union of the nested $\mathbb{D}_{n,\eta}^+$ as η decreases to zero. For $n = 0$ there is one empty configuration and its vector will be Ω.

We prove strong convergence of the smooth product vectors, rather than analytically continuing an inequality. Fix η, choose a real radial unit-mass bump β_ϵ supported in $D(0,\epsilon)$, and take $\epsilon < c\eta$. Use it in every entry of eq. 6.cclxxviii, writing the result as $\Psi_{\eta,\epsilon}(\mathbf{x};\vec{\varphi})$.

If $\mathbf{x} \in \mathbb{D}_{n,\eta}^+$ and $\mathbf{y} \in \mathbb{D}_{m,\eta}^+$, define the list of differences

$$J(\mathbf{x},\mathbf{y}) = \big((x_n - x_{n-1})^*, \dots, (x_2 - x_1)^*, x_1^* + y_1, y_2 - y_1, \dots, y_m - y_{m-1}\big). \tag{6.ccxci}$$

If $n = 0$, omit the left list and the central entry. If $m = 0$, omit the central entry and the right list. The labels of this list are $(\varphi_n, \dots, \varphi_1, \psi_1, \dots, \psi_m)$. Every entry belongs to $\eta e_0/2 + \mathbb{V}$: for the central one subtracting $\eta e_0/2$ gives the sum $(x_1 - \eta e_0/4)^* + (y_1 - \eta e_0/4)$ in the open cone. The other entries follow from star invariance.

For different radii ϵ, ϵ' the exact identity is

$$\begin{aligned}&\langle \Psi_{\eta,\epsilon}(\mathbf{x};\vec{\varphi}), \Psi_{\eta,\epsilon'}(\mathbf{y};\vec{\psi})\rangle \\ &\quad = K_{n+m,\eta}[\underbrace{\beta_\epsilon, \dots, \beta_\epsilon}_{n}, \underbrace{\beta_{\epsilon'}, \dots, \beta_{\epsilon'}}_{m}](J(\mathbf{x},\mathbf{y})),\end{aligned} \tag{6.ccxcii}$$

with the reversed left labels specified above. For real positions this is just eq. 6.cclxxx, the Hilbert inner product, symmetry, and eq. 6.cclxxxii. Radiality and realness are important: $\theta\overline{\tau_x\beta_\epsilon} = \tau_{\theta x}\beta_\epsilon$ for real x. The left side is antiholomorphic in $\mathbf{x}$ and holomorphic in $\mathbf{y}$; the right side has exactly the same properties because the star is conjugate linear. The product domains are convex, conjugation stable and have real interior points. Mixed holomorphic uniqueness therefore proves eq. 6.ccxcii for complex positions too. For total length one both sides are zero; for length zero both equal one.

The strengthened smoothing conclusion after eq. 6.cclxxxv shows that the right side converges to $K_{n+m}(J(\mathbf{x},\mathbf{y}))$ when both radii tend to zero, with no restriction on their relative rate. Convergence

is uniform on compact sets of the position domains. In particular, for a compact subset of $\mathbb{D}^+_{n,\eta}$, expand

$$\|\Psi_{\eta,\epsilon}(\mathbf{x}) - \Psi_{\eta,\epsilon'}(\mathbf{x})\|^2$$

as its four mixed inner products. All four tend uniformly to the same diagonal kernel value; their signed sum tends to zero. This proves a locally uniform strong Cauchy property. The limit $\Psi_\eta(\mathbf{x};\vec{\varphi})$ is Hilbert-valued holomorphic: uniform convergence on smaller polydiscs passes the vector Cauchy formula and its power series to the limit.

These vectors are independent of η on overlaps. For any fixed sufficiently small physical bump and real positions in an overlap, both definitions give the same class in eq. 6.cclxxx. Vector holomorphic uniqueness on the connected overlap proves equality for complex positions, and then the strong limits agree. We have therefore constructed

$$\Psi(\mathbf{x};\vec{\varphi}) \in \mathcal{H}, \qquad \mathbf{x} \in \mathbb{D}^+_n, \tag{6.ccxciii}$$

holomorphically, with the bound $\|\Psi(\mathbf{x};\vec{\varphi})\| \le \prod_i C_{\varphi_i}\eta^{-\wp}$ for every admissible η. On the domain where $v \in \overline{\mathbb{V}}$, the semigroup rule also gives

$$\Psi(\mathbf{x}+v;\vec{\varphi}) = T(v)\Psi(\mathbf{x};\vec{\varphi}). \tag{6.ccxciv}$$

It holds before removing the bumps and hence afterward.

For labelled positive configurations define

$$\mathrm{Gr}(\mathsf{x},\mathsf{y}) = K_{n+m}(J(\mathbf{x},\mathbf{y});\varphi_n,\dots,\varphi_1,\vec{\psi}).$$

Use the empty and one-point conventions already specified. The construction proves the exact equality

$$\mathrm{Gr}(\mathsf{x},\mathsf{y}) = \langle\Psi(\mathsf{x}),\Psi(\mathsf{y})\rangle. \tag{6.ccxcv}$$

Thus this is a positive semidefinite kernel at complex positions, for arbitrary finite families and different lengths, including the empty configuration.

Finally $R_{is}\mathbb{D}^+_n = \mathbb{D}^+_n$, and eq. 6.cclxxv gives $J(R_{is}\mathbf{x},R_{is}\mathbf{y}) = R_{is}J(\mathbf{x},\mathbf{y})$. Consequently

$$\begin{aligned}\mathrm{Gr}_s(\mathsf{x},\mathsf{y}) &:= K_{n+m}(R_{is}J(\mathbf{x},\mathbf{y});\text{the same labels})\\ &= \langle\Psi(R_{is}\mathsf{x}),\Psi(R_{is}\mathsf{y})\rangle\end{aligned} \tag{6.ccxcvi}$$

is positive semidefinite for every real s. This is an actual Gram representation; positivity has not been inferred from analytic continuation of a positive scalar function.

Narrow pencils and the entire angle function. Fix $0 < \phi_0 < \pi/4$ and let

$$\mathrm{Sec} = \{v \in \mathbb{R}^2 \setminus \{0\} : |\arg(v^0 + iv^1)| < \phi_0\}.$$

For $n \ge 2$, a pencil is a configuration with every consecutive difference in this sector. The cases $n = 0,1$ have their separate constant kernels fixed above. Write $r_{\mathbf{y}} = \min_i |y_{i+1} - y_i| > 0$. For a pencil with differences v_i and labels $\vec{\varphi}$ put, on the vertical strip

$$S_\nu = \{z = t + is : |t - \nu| < \pi/2 - \phi_0\}, \qquad \nu \in (\pi/2)\mathbb{Z},$$

the function

$$a^{(\nu)}_{\mathbf{y}}(z) = K_n(R_{z-\nu}v;\vec{\varphi}). \tag{6.ccxcvii}$$

It is well defined and holomorphic. In fact, writing $(v_i)_\pm = |v_i|e^{\pm i\phi_i}$ with $|\phi_i| < \phi_0$ gives

$$\mathrm{Re}(R_{t+is-\nu}v_i)_\pm = |v_i|e^{\mp s}\cos(\phi_i + t - \nu) > 0. \tag{6.ccxcviii}$$

Only neighboring strips intersect. Their intersection is exactly

$$S_\nu \cap S_{\nu+\pi/2} = \{t + is : \nu + \phi_0 < t < \nu + \pi/2 - \phi_0\},$$

which is nonempty and connected. At a real angle there, all the rotated differences lie strictly in the quadrant between the two frame normals. Small discs about the rotated points are ordered in both frames. The proved real overlap identity therefore identifies the two values in eq. 6.ccxcvii on this

real interval. The one-variable identity theorem identifies the holomorphic functions throughout the intersection.

The strip width $\pi - 2\phi_0$ exceeds their spacing $\pi/2$. They cover the complex plane and glue to a unique entire function $a_{\mathbf{y}}(z;\vec{\varphi})$. The construction immediately gives

$$a_{\mathbf{y}}(z + \pi/2) = a_{\mathbf{y}}(z). \tag{6.ccxcix}$$

Indeed use the patch with center $\nu + \pi/2$ for the shifted argument and the patch with center ν for the original argument; the arguments of K_n are identical. For real t it equals $\mathbf{K}_n(R_t\mathbf{y};\vec{\varphi})$, since a suitable frame orders this rotated pencil. In particular it is real on the real axis, and $a_{\mathbf{y}}(is) = K_n(R_{is}v;\vec{\varphi})$.

For every real t choose a nearest quarter turn ν, so $|t - \nu| \le \pi/4$. Set $c_0 = \cos(\phi_0 + \pi/4) > 0$. By eq. 6.ccxcviii, every light-coordinate margin is at least $c_0 r_{\mathbf{y}} e^{-|s|}$. Hence

$$|a_{\mathbf{y}}(t + is)| \le \Big(\prod_i C_{\varphi_i}\Big) \min\{1, c_0 r_{\mathbf{y}} e^{-|s|}\}^{-\wp n} \le A_{\mathbf{y},\vec{\varphi}} e^{\wp n|s|}, \tag{6.ccc}$$

where $A_{\mathbf{y},\vec{\varphi}} = \prod_i C_{\varphi_i} \max\{1, (c_0 r_{\mathbf{y}})^{-\wp n}\}$. This proves the claimed exponential type with its linear dependence on n; an uncontrolled prefactor depending on n would not change that conclusion.

The finite band and analytic harmonic coefficients. Define

$$c_m(\mathbf{y};\vec{\varphi}) = \frac{2}{\pi} \int_0^{\pi/2} a_{\mathbf{y}}(t;\vec{\varphi}) e^{-4imt}\, dt. \tag{6.ccci}$$

Cauchy's theorem on a rectangle of height s and periodicity give

$$c_m = \frac{2}{\pi} \int_0^{\pi/2} a_{\mathbf{y}}(t + is) e^{-4im(t+is)}\, dt, \qquad |c_m| \le A_{\mathbf{y},\vec{\varphi}} e^{4ms + \wp n|s|}.$$

The vertical sides cancel exactly. Sending s to $-\infty$ for $4m > \wp n$, and to $+\infty$ for $4m < -\wp n$, proves

$$c_m = 0 \quad \text{if } 4|m| > \wp n, \qquad a_{\mathbf{y}}(z) = \sum_{4|m| \le \wp n} c_m e^{4imz}. \tag{6.cccii}$$

For the equality, periodicity makes $a(z)$ a single-valued holomorphic function of $w = e^{4iz}$ on $\mathbb{C}\setminus\{0\}$. Its Laurent coefficients are the displayed c_m, so its Laurent series is the finite sum after the vanishing just proved. Equivalently one may use the uniformly convergent Fourier series of the smooth periodic function on the real axis and then the identity theorem. Reality implies $c_{-m} = \overline{c_m}$.

We next construct coefficients beyond pencils, without assuming continuity across different ordering charts. Put $N = \lfloor \wp n/4 \rfloor$ and on planar configurations introduce the angular vector field

$$\mathcal{L} = \sum_{i=1}^{n} (-y_i^1 \partial_{y_i^0} + y_i^0 \partial_{y_i^1}).$$

On translation-invariant functions it is the same angular vector field in the consecutive-difference coordinates. Let

$$P(X) = \prod_{m=-N}^{N} (X - 4im), \qquad p_m(X) = \prod_{\substack{-N \le j \le N \\ j \ne m}} \frac{X - 4ij}{4im - 4ij}.$$

The finite-band identity gives $P(\mathcal{L})\mathbf{K}_n = 0$ on the relatively open real set of pencils. The left side is holomorphic on the connected domain $\mathcal{U}_n^{\mathrm{ord}}$. Uniqueness therefore proves this equation everywhere on that domain. Define there

$$c_m = p_m(\mathcal{L})\mathbf{K}_n \quad (|m| \le N). \tag{6.ccciii}$$

On pencils these are the Fourier coefficients in eq. 6.ccci: each polynomial p_m selects its corresponding distinct exponential. The polynomial identities $\sum_m p_m = 1$ and $(X - 4im)p_m(X) =$ constant $P(X)$ give

$$\sum_m c_m = \mathbf{K}_n, \qquad \mathcal{L}c_m = 4imc_m. \tag{6.ccciv}$$

The coefficients are holomorphic on the ordered domain, symmetric in labelled points and invariant under simultaneous translations. On its real points $c_{-m} = \overline{c_m}$: the angular vector field has real coefficients, the density is real there, and $\overline{p_m(X)} = p_{-m}(X)$ for real X. For translation invariance, note that applying $\mathcal{L}$ to a translation-invariant function again gives one: the extra term under a common shift is a linear combination of the total derivatives $\sum_i \partial_{y_i^\mu}$, which vanish.

Since imaginary rotations preserve the domain, the last equation in eq. 6.ccciv can be integrated along them:

$$c_m(R_{is}\mathbf{z}) = e^{-4ms}c_m(\mathbf{z}), \qquad \mathbf{K}_n(R_{is}\mathbf{z}) = \sum_m e^{-4ms}c_m(\mathbf{z}). \tag{6.cccv}$$

The same equation gives $c_m(R_t\mathbf{y}) = e^{4imt}c_m(\mathbf{y})$ on any real interval whose rotated configurations remain in Ord_n.

These coefficients extend uniquely and real-analytically to every configuration of distinct real planar points. Here is the full gluing argument. Let $\mathcal{G}_n$ consist of configurations with distinct points and with no two nonzero difference vectors perpendicular. This is open and dense: its complement, in addition to the collisions, is a finite union of zero sets of nonzero real polynomials. Each polynomial is nonzero, as can also be checked by taking distinct points on one line. Every real rotation of a configuration in $\mathcal{G}_n$ is ordinary. Failure of ordinariness would produce a time tie and an abscissa tie, whose nonzero difference vectors are perpendicular. Thus the preceding angular ordinary differential equation proves covariance for every real angle on $\mathcal{G}_n$.

For an arbitrary distinct configuration $\mathbf{y}$, choose an angle t at which all its rotated times are distinct. Only finitely many angles are forbidden. In a neighborhood of $\mathbf{y}$ define the extension by

$$\widetilde{c}_m(\mathbf{u}) = e^{-4imt}c_m(R_t\mathbf{u}). \tag{6.cccvi}$$

This is real-analytic. Two choices agree on the dense set $\mathcal{G}_n$ in every overlap, by the covariance already proved there; continuity makes them agree everywhere in the overlap. They consequently glue, agree with the original coefficients on ordinary configurations, and obey exact covariance

$$\widetilde{c}_m(R_t\mathbf{y}) = e^{4imt}\widetilde{c}_m(\mathbf{y}) \quad (t \in \mathbb{R}). \tag{6.cccvii}$$

This last equality, permutation symmetry, translation invariance and $\widetilde{c}_{-m} = \overline{\widetilde{c}_m}$ follow by continuity from $\mathcal{G}_n$. Uniqueness follows because Ord_n is dense in the collision-free set. The collision-free set itself is connected: one may move its points successively along polygonal paths avoiding the finitely many positions occupied by the other points, with small preliminary moves if necessary. Removing finitely many points does not disconnect the plane.

Set $\overline{m}(0) = \overline{m}(1) = 0$; for $n \geq 2$ let $\overline{m}(n)$ be the largest $|m|$ occurring for any pencil and any real labels, or zero if none occurs. It is a finite integer and

$$\overline{m}(n) \leq \wp n/4. \tag{6.cccviii}$$

Coefficients with $|m| > \overline{m}(n)$ vanish identically on the ordered domain by uniqueness, and then on every collision-free configuration by eq. 6.cccvi. If $\overline{m}(n) > 0$, some pencil and labels have $c_{-\overline{m}(n)} \neq 0$, by reality.

Boost positivity without time ordering and the top kernel. For arbitrary labelled configurations of k and l distinct points in the real open half-plane, define

$$\widetilde{\mathrm{Gr}}_s(\mathsf{x},\mathsf{y}) = \sum_m e^{-4ms}\widetilde{c}_m^{(k+l)}(\theta\mathbf{x},\mathbf{y};\vec{\varphi},\vec{\psi}). \tag{6.cccix}$$

All points in this combined configuration are distinct: the two groups lie on opposite sides of the mirror. Empty tuples have the conventions $\widetilde{c}_m^{(0)} = \delta_{m0}$ and $\widetilde{c}_m^{(1)} = 0$.

This kernel is positive semidefinite for every real s. First suppose each individual configuration has distinct times. Sort those times. The combined reflected configuration is then ordinary, and eq. 6.cccv, symmetry and eq. 6.ccxcvi identify eq. 6.cccix with the proved Gram kernel. For a finite family with time ties, perturb the positions slightly inside the positive half-plane to remove all such ties. The reflected combined configurations remain collision free. Every coefficient is continuous there, so their finite matrices converge entrywise to the desired matrix. Positive semidefiniteness is closed under this limit. This proves the assertion with time ties, arbitrary lengths and the empty configuration included.

In particular, fix $k \geq 1$, put $m_* = \overline{m}(2k)$, and set $c_* = \widetilde{c}_{-m_*}^{(2k)}$. On k-point configurations the kernel

$$(\mathsf{x}, \mathsf{y}) \longmapsto c_*(\theta\mathbf{x}, \mathbf{y}; \vec{\varphi}, \vec{\psi}) \tag{6.cccx}$$

is positive semidefinite: multiply the matrix in eq. 6.cccix by $e^{-4m_* s}$ and send $s \to +\infty$. All the other finitely many terms tend to zero.

There is also an exact formulation across an arbitrary line $\mathfrak{l}$. Let $b \in \mathfrak{l}$ and let $R_\nu e_0$ be its normal pointing into a chosen side $\mathfrak{l}_+$. The map $r(y) = R_{-\nu}(y - b)$ sends that side to $\mathbb{H}$ and intertwines its reflection $\theta_\mathfrak{l}$ with θ. Using translation invariance and eq. 6.cccvii, eq. 6.cccx becomes positivity of

$$(\mathsf{x}, \mathsf{y}) \longmapsto e^{4im_*\nu} c_*(\theta_\mathfrak{l}\mathbf{x}, \mathbf{y}; \vec{\varphi}, \vec{\psi}) \tag{6.cccxi}$$

on k-point configurations in $\mathfrak{l}_+$. The compensating unit phase is essential. This is a statement about the top coefficient, and does not assume reflection positivity of the original functional at every line.

The cut inequality, including the empty tuple. The preceding constructions imply

$$2\overline{m}(k + l) \leq \overline{m}(2k) + \overline{m}(2l) \qquad (k, l \geq 0). \tag{6.cccxii}$$

If the left top frequency is zero there is nothing to prove. Otherwise choose a pencil and labels whose negative top coefficient is nonzero. When $k, l \geq 1$, translate the midpoint between y_k, y_{k+1} to the origin, and put

$$x_i = \theta y_{k+1-i} \ (1 \leq i \leq k), \qquad z_j = y_{k+j} \ (1 \leq j \leq l),$$

with the correspondingly reversed left labels. Both are positive configurations. Their first points and all consecutive differences are in Sec: reflection followed by a minus sign changes the sign of a real spatial coordinate and preserves this sector. The first points are the two reflected halves of the cut difference.

The combined reflected configuration for x, z is exactly the original pencil. The doubled configurations for x, x and z, z are also pencils. Their central differences are respectively $2x_1^0 e_0$ and $2z_1^0 e_0$, and all other differences are sector vectors or their stars. The Gram Cauchy–Schwarz inequality gives

$$|a_{\mathbf{y}}(is)|^2 \leq a_{(\theta x_k, \ldots, \theta x_1, x_1, \ldots, x_k)}(is) a_{(\theta z_l, \ldots, \theta z_1, z_1, \ldots, z_l)}(is).$$

The left side has leading rate $e^{8\overline{m}(k+l)s}$ as $s \to +\infty$, with nonzero coefficient. Each right factor has rate at most $e^{4\overline{m}(2k)s}$ or $e^{4\overline{m}(2l)s}$ by its finite band. Comparison proves eq. 6.cccxii.

If $k = 0$, translate a nonzero pencil so that its first point is in Sec. Apply Gram Cauchy–Schwarz to the empty vector Ω and its product vector. The empty diagonal entry is one, so the same comparison gives $2\overline{m}(l) \leq \overline{m}(2l)$. This is exactly the required inequality with $\overline{m}(0) = 0$. The case $l = 0$ follows by symmetry, and the centered one-point and fully empty cases are immediate. Thus the initial convexity information has not been lost by omitting the vacuum vector.

The two-point interface and its positive plane measure. For two points, Ord_2 is the entire real collision-free set: two distinct points cannot have both coordinates equal. Translation invariance therefore gives a real-analytic function $G_{\varphi,\psi}(r)$ for every real $r \neq 0$, equal to $K_2(r;\varphi,\psi)$ when $r^0 > 0$. Its global coefficients obey

$$\begin{aligned} G_{\varphi,\psi}(r) &= \sum_m \widetilde{c}_m(r;\varphi,\psi), \\ \widetilde{c}_m(R_t r) &= e^{4imt}\widetilde{c}_m(r), \\ K_2(R_{is} r) &= \sum_m e^{-4ms}\widetilde{c}_m(r) \qquad (r^0 > 0). \end{aligned} \tag{6.cccxiii}$$

The last identity holds for every real s, not merely near zero; it is eq. 6.cccv. Every sum is finite, with $|m| \le \overline{m}(2) \le \wp/2$. The kernel in eq. 6.cccix for one-point configurations is positive semidefinite for every s. A quarter-turn frame with projection at least $|r|/\sqrt{2}$ also gives the useful bound

$$|G_{\varphi,\psi}(r)| \le C_\varphi C_\psi \min\{1, |r|/\sqrt{2}\}^{-2\wp}. \tag{6.cccxiv}$$

The density formula for two points also holds for arbitrary disjoint compact plane-profile supports, even if those whole supports have no strict coordinate ordering. Let their distance be $d > 0$ and partition each profile into finitely many pieces supported in sets of diameter less than $d/(10\sqrt{2})$. For each pair of pieces, two chosen points in their supports differ in at least one coordinate by $d/\sqrt{2}$ or more. The small diameters then make the two entire piece supports strictly ordered in that coordinate, in one of the four frames. Apply eq. 6.cclxxxvi and the frame identity to this pair. Summing the finitely many identities by bilinearity proves

$$\sigma(\alpha\otimes\varphi, \beta\otimes\psi) = \iint \alpha(y)\beta(y')G_{\varphi,\psi}(y'-y)\,dy\,dy'$$

for every such pair of profiles. All partitions can be smooth; their products with the original C^1 profiles remain C^1 and have supports in the original separated sets.

There is a positive spectral plane measure for equal real labels. Let $\zeta_s = \Psi((s,0);\varphi)$, $s > 0$. By eq. 6.ccxciv, $\zeta_{s'} = e^{-(s'-s)H}\zeta_s$ if $s' > s$. Let $\mu_s(B) = \langle \zeta_s, \mathsf{P}(B)\zeta_s\rangle$, using the joint spectral measure of (H,P). The locally finite positive measure

$$d\mu_\varphi(E,q) = e^{2sE}\,d\mu_s(E,q) \tag{6.cccxv}$$

is independent of s, because the preceding vector identity multiplies μ_s by $e^{-2(s'-s)E}$. It is carried by $E \ge |q|$ and satisfies

$$K_2(v;\varphi,\varphi) = \int e^{-v^0E + iv^1q}\,d\mu_\varphi(E,q) \qquad (v \in \mathbb{V}). \tag{6.cccxvi}$$

For real $v = (t,x)$ choose $0 < s < t/2$ and use eq. 6.ccxcv and eq. 6.ccxciv: the left side is $\langle \zeta_s, T(t-2s,x)\zeta_s\rangle$, which is the displayed integral. In particular $\int e^{-tE}\,d\mu_\varphi < \infty$ for every $t > 0$. On a compact sub-tube the multiplier is bounded by e^{-dE} for some $d > 0$. Its derivatives are controlled by a smaller exponential weight because $|q| \le E$. The integral is therefore holomorphic there, and uniqueness extends its equality from real points to all of $\mathbb{V}$.

No uniqueness of the vacuum or absence of a zero-energy mass is asserted here. A positive plane measure in a diagonal-reflection picture requires the reflection-positivity input for that picture; it is not inferred from the coordinate cone. Likewise, eliminating the nonzero two-point harmonics requires a separate ultraviolet estimate and the diagonal-frame argument. The polygon and integer arguments can use eq. 6.cccxi and eq. 6.cccxii, but are not contained in this section. Finally, the analytic extension of coefficients to distinct planar points does not identify the original moment functional on every exceptional support arrangement. That distributional passage, in particular arrangements with coincident planar projections and separated transverse supports, requires a separate proof.

6.12. **Eliminating two-point angular harmonics.** This section proves an implication for the two-point function. Its inputs are a continuous planar kernel with its axis-frame spectral realization, the exact cone in that frame, one diagonal reflection, and a uniform short-distance bound on a specified class of positive shapes. It constructs the diagonal spectral measure and proves its cone support; a diagonal cone and continuous rotation covariance are not assumed. The angular continuation needed at order two is proved directly. In particular this argument does not require an all-orders highest-harmonic theorem.

The kernel and Hilbert realization are analytic inputs to this section. They are supplied by the planar-kernel construction when its insertion, continuity and reconstruction hypotheses hold. This section does not prove the interacting source estimates or the short-distance input used below.

6.12.1. *The precise two-point interface.* Write a point of $\mathbb{R}^4$ as (y,z), with $y=(y^0,y^1)=(x_4,x_1)$ and $z=(x_2,x_3)$. On the plane let $e_0=(1,0)$, let R_t be the rotation

$$R_t(u,v)=(u\cos t-v\sin t,u\sin t+v\cos t),\qquad \theta(u,v)=(-u,v).$$

The same notation denotes these maps on $\mathbb{R}^4$, leaving z fixed. Put $n=R_{\pi/4}e_0$. The reflection at $n^\perp$ is $\theta_n=R_{\pi/4}\theta R_{-\pi/4}$.

Let S_2 be a real symmetric bilinear form on pairs of real $C_c^1(\mathbb{R}^4)$ tests with disjoint supports, complexified bilinearly. It is translation- and W_4-invariant and satisfies coordinate reflection positivity. It also satisfies

$$S_2(\theta_n\overline{f},f)\geq 0\quad (f\in C_c^1(\{n\cdot y>0\};\mathbb{C})). \tag{6.cccxvii}$$

Positivity at any one diagonal normal in four dimensions implies this choice by hypercubic conjugation. All scalar products below are conjugate linear in the first variable.

The kernel interface is the following explicit assumption. For real $\varphi,\psi\in C_c^1(\mathbb{R}^2)$ there are continuous functions $G_{\varphi,\psi}$ on $\mathbb{R}^2\setminus\{0\}$ such that

$$S_2(\alpha\otimes\varphi,\beta\otimes\psi)=\iint\alpha(y)\beta(y')G_{\varphi,\psi}(y'-y)\,dy\,dy' \tag{6.cccxviii}$$

whenever the compact supports of $\alpha,\beta\in C_c^1(\mathbb{R}^2;\mathbb{C})$ are disjoint. There is a Hilbert space with strongly commuting self-adjoint operators H,P, with $H\geq|P|$, and vectors $\zeta_{\varphi,a}$, $a>0$, such that

$$\begin{aligned}\zeta_{\varphi,b}&=e^{-(b-a)H}\zeta_{\varphi,a}\quad (b>a),\\ G_{\varphi,\psi}(t,x)&=\langle\zeta_{\varphi,a},e^{-(t-2a)H+ixP}\zeta_{\psi,a}\rangle\quad (t>2a).\end{aligned} \tag{6.cccxix}$$

This is a point-kernel interface, not a bound on unsmeared field operators. At order two every distinct planar pair is in an ordinary coordinate frame. Consequently the two-point specialization of the planar kernel theorem supplies eq. 6.cccxviii–eq. 6.cccxix without an exceptional planar set.

When S_2 is the connected function of a functional with unit vacuum vector Ω, apply the interface to $\zeta_{\varphi,a}-\langle\Omega,\zeta_{\varphi,a}\rangle\Omega$. The vacuum is translation invariant, so its orthogonal projection commutes with H,P; this subtraction preserves eq. 6.cccxix, positivity and the cone. Thus the interface here concerns the connected kernel when the ultraviolet hypothesis concerns the connected function. No uniqueness of the vacuum is required.

Kernel uniqueness follows by testing eq. 6.cccxviii with small nonnegative approximate identities at two distinct points. The same test shows that the kernels inherit reality, bilinearity in the labels, and all symmetries of S_2 that preserve the plane. In particular, for $G_\varphi=G_{\varphi,\varphi}$,

$$G_\varphi(R_{\pi/2}y)=G_\varphi(y),\qquad G_\varphi(y^0,-y^1)=G_\varphi(y),\qquad G_\varphi(y)\in\mathbb{R}. \tag{6.cccxx}$$

6.12.2. *The axis measure and the plate norm.* Fix a real label φ. Let P be the joint spectral measure of (H, P) and set

$$\mu_{\varphi,a}(B) = \langle \zeta_{\varphi,a}, \mathsf{P}(B)\zeta_{\varphi,a}\rangle, \qquad d\mu_{\varphi}(E,q) = e^{2aE}\, d\mu_{\varphi,a}(E,q). \tag{6.cccxxi}$$

The first measure is finite and positive. eq. 6.cccxix gives $d\mu_{\varphi,b} = e^{-2(b-a)E} d\mu_{\varphi,a}$, so the second measure is independent of a. It is positive and carried by

$$\mathcal{C} = \{(E,q) \in \mathbb{R}^2 : E \geq |q|\}.$$

For every $t > 0$ choose $a < t/2$ in eq. 6.cccxix. Then

$$G_\varphi(t,x) = \int e^{-tE+ixq}\, d\mu_\varphi(E,q), \qquad \Gamma_\varphi(t) = \int e^{-tE}\, d\mu_\varphi = G_\varphi(t,0) < \infty. \tag{6.cccxxii}$$

The measure is locally finite and σ-finite: on $\{E \leq N\}$ its mass is at most $e^{tN}\Gamma_\varphi(t)$. The function Γ_φ is nonnegative and nonincreasing. By a quarter turn, any $y \neq 0$ has a positive first coordinate at least $|y|/\sqrt{2}$. Therefore

$$|G_\varphi(y)| \leq \Gamma_\varphi(|y|/\sqrt{2}). \tag{6.cccxxiii}$$

This bound will give the diagonal reconstruction its bounded time orbits. It uses no decay at large distance. Define also

$$\mathbb{V} = \{v \in \mathbb{C}^2 : \operatorname{Re} v^0 > |\operatorname{Im} v^1|\}, \qquad K_\varphi(v) = \int e^{-v^0 E + iv^1 q}\, d\mu_\varphi. \tag{6.cccxxiv}$$

On a compact subset of this tube the absolute multiplier is at most e^{-cE} for some $c > 0$. Its derivatives are dominated by a smaller exponential because $|q| \leq E$. Thus K_φ is holomorphic and agrees with G_φ on the real positive-time half-plane.

On positive-time tests put $\|[f]\|^2 = S_2(\theta\overline{f}, f)$; reflection positivity and polarization give the associated Hilbert seminorm and its triangle inequality. For α supported in $\{y^0 > 0\}$, eq. 6.cccxviii and eq. 6.cccxxii give

$$\|[\alpha \otimes \varphi]\|^2 = \int \left| \iint \alpha(t,x) e^{-tE+ixq}\, dt\, dx \right|^2 d\mu_\varphi(E,q). \tag{6.cccxxv}$$

Indeed, if $t \geq \delta > 0$ on the support, the absolute integral before interchanging the variables is bounded by $\|\alpha\|_{L^1}^2 \Gamma_\varphi(2\delta)$. This proves Fubini's applicability, including when the unweighted measure has infinite mass.

6.12.3. *The ultraviolet class and fixed shapes.* For $d > 0$ and $\vartheta > 0$, let $\mathfrak{T}(d;\vartheta)$ consist of pairs of nonzero, nonnegative $C_c^1(\mathbb{R}^4)$ tests f, h, each supported in a ball of radius d, satisfying

$$\begin{aligned} &d \leq \operatorname{dist}(\operatorname{supp} f, \operatorname{supp} h) \leq 6d, \\ &\int f \geq \vartheta \|f\|_\infty d^4, \qquad \operatorname{Lip} f \leq \|f\|_\infty/(\vartheta d), \end{aligned} \tag{6.cccxxvi}$$

and the analogous conditions for h. The balls may be placed anywhere. The ultraviolet input is a finite nonnegative function u, with $u(d) \to 0$ as $d \downarrow 0$, such that for $0 < d \leq d_0$,

$$0 \leq S_2(f,h) \leq u(d)\|f\|_\infty \|h\|_\infty \quad ((f,h) \in \mathfrak{T}(d;\vartheta_*)). \tag{6.cccxxvii}$$

Here the universal $\vartheta_* > 0$ is chosen below, before S_2. A hypothesis at a smaller shape parameter also suffices. A hypothesis only on a narrower positive-shape class must be checked against this choice; that inclusion is part of the ultraviolet premise.

The following explicit shapes fix all regularity constants. Choose $a \in C_c^1((2,3))$, between zero and one, equal to one on $[9/4, 11/4]$, zero outside $[17/8, 23/8]$, with cubic smoothstep ramps on the two intervening intervals. Then $\int a = 5/8$ and $\|a'\|_\infty \leq 12$. Let $I = [-1/4, 1/4]$, $\tau = \mathbf{1}_I * \mathbf{1}_I$, and

$$b = 12(\tau * \tau), \qquad c_b = \int b = 3/4. \tag{6.cccxxviii}$$

This is a nonnegative C_c^2 spline, supported in $[-1,1]$, with maximum one and $\|b'\|_\infty = 2$. Explicitly it is $1-6s^2+6|s|^3$ for $|s| \le 1/2$, and $2(1-|s|)^3$ for $1/2 \le |s| \le 1$. With the Fourier convention $\widehat{b}(q) = \int b(s)e^{isq}\,ds$, convolution gives

$$\widehat{b}(q) = c_b \left(\frac{\sin(q/4)}{q/4} \right)^4, \tag{6.cccxxix}$$

where the quotient has value one at zero.

For completeness a transverse partition can use $q(s) = b(4s/3)$, $D(s) = \sum_{j\in\mathbb{Z}} q(s-j)$ and $\chi(s) = q(s)/D(s)$. There are at most two nonzero summands, $D \ge 2/27$ by choosing a nearest integer, and $\sum_j \chi(s-j) = 1$. The bounds $\|q'\|_\infty \le 8/3$ and $\|D'\|_\infty \le 16/3$ give $\|\chi'\|_\infty \le 1008$. Put $\psi(z) = \chi(z_1)\chi(z_2)$. It takes values in $[0,1]$, has support in $[-3/4, 3/4]^2$, and its integer translates sum to one. Let $\widetilde{\psi}(z) = \rho(z_1)\rho(z_2)$, where $\rho = 1$ on $[-1,1]$, $\rho = 0$ outside $[-3/2, 3/2]$, and on each intervening interval use the cubic smoothstep. Thus

$$\int \widetilde{\psi} = 25/4, \quad \|\nabla\widetilde{\psi}\|_\infty \le 6, \quad \|\nabla\psi\|_\infty \le 2016, \quad \psi \le \widetilde{\psi}.$$

All these functions are globally C^1. The numerical choice

$$\vartheta_* = 1/12000 \tag{6.cccxxx}$$

will suffice for all tests constructed next.

6.12.4. *Dilation removes the spline zeros.* For $h > 0$ and $1 \le \lambda \le 2$ put

$$\alpha_h^\lambda(t,x) = a(t/h)b(4x/(\lambda h)), \qquad f_h^\lambda = \alpha_h^\lambda \otimes \varphi.$$

The time transform and spatial transform are

$$A_h(E) = \int a(t/h)e^{-tE}\,dt, \qquad B_{h,\lambda}(q) = \frac{c_b \lambda h}{4} \left(\frac{\sin(\lambda h q/16)}{\lambda h q/16} \right)^4.$$

For $E \ge 0$, $A_h(E) \ge (h/2)e^{-3hE}$. There is an absolute $c > 0$ such that

$$\int_1^2 |B_{h,\lambda}(q)|^2\,d\lambda \ge ch^2(1+h^2q^2)^{-4}. \tag{6.cccxxxi}$$

Here is a proof that includes every zero of the transform. Set $x = h|q|/16$. For $0 \le x \le 1$, the sinc in the display is bounded below on $0 \le \lambda x \le 2$, giving a fixed positive lower bound after division by h^2. For $x \ge 1$, that divided integral is at least

$$cx^{-8} \int_1^2 \sin^8(\lambda x)\,d\lambda = cx^{-9} \int_x^{2x} \sin^8 v\,dv.$$

The number $c_1 = \min_{r\in[0,\pi]} \int_r^{r+1} \sin^8 v\,dv$ is positive: the integral is continuous, periodic and never zero. An interval of length $x \ge 1$ contains $\lfloor x \rfloor \ge x/2$ successive intervals of length one. The last display is therefore at least cx^{-8}. Both regimes imply eq. 6.cccxxxi, with constants independent of h, q.

The finite number $C_* = \sup_{r\ge 0} e^{-r}(1+r^2)^4$ and $|q| \le E$ imply

$$e^{-6hE}(1+h^2q^2)^{-4} \ge C_*^{-1}e^{-7hE}.$$

Using eq. 6.cccxxv, eq. 6.cccxxxi and nonnegative Fubini yields

$$\int_1^2 \|[f_h^\lambda]\|^2\,d\lambda \ge ch^4\Gamma_\varphi(7h). \tag{6.cccxxxii}$$

The cone is essential here. Without it, arbitrarily large $|q|$ at small E could make the spline factor too small.

6.12.5. *Positive pedestals put the plate in the ultraviolet class.* Assume $\varphi \neq 0$, choose $r_1 > 0$ with $\operatorname{supp}\varphi \subset B(0, r_1)$, and take $0 < h \leq \min(1, r_1, 2d_0/5)$. Put $A = \|\varphi\|_\infty + h\|\nabla\varphi\|_\infty > 0$ and

$$\psi_i(z) = \psi(z/h - i), \quad \widetilde{\psi}_i(z) = \widetilde{\psi}(z/h - i), \quad \varphi_i^- = 2A\widetilde{\psi}_i, \quad \varphi_i^+ = 2A\widetilde{\psi}_i + \psi_i\varphi.$$

Only indices in $\mathcal{I} = \{i : \psi_i\varphi \not\equiv 0\}$ are needed. Its size is at most $(2r_1/h + 3)^2 \leq 25r_1^2h^{-2}$. For a fixed λ let $h_i^\pm = \alpha_h^\lambda \otimes \varphi_i^\pm$. Then

$$f_h^\lambda = \sum_{i\in\mathcal{I}} (h_i^+ - h_i^-), \qquad A\widetilde{\psi}_i \leq \varphi_i^\pm \leq 3A\widetilde{\psi}_i. \tag{6.cccxxxiii}$$

In particular these tests are nonnegative, nonzero, and have sup norm between A and $3A$.

To check the support geometry in eq. 6.cccxxvi, consider each shape. Each support lies in the ball of radius $d = 5h/2$ about $(5h/2, 0, hi)$: its four coordinate half-widths are at most $h/2, h/2, 3h/2, 3h/2$, whose squared sum is $5h^2 < d^2$. The reflected ball also has radius d. The distance between the support and its time reflection is at least $4h$ and at most $6h$, hence between d and $6d$.

Moreover, direct product integration gives

$$\int h_i^\pm \geq Ah^4 \frac{\int a \int b \int \widetilde{\psi}}{4} = \frac{375}{512} Ah^4.$$

Since $\|h_i^\pm\|_\infty \leq 3A$, the integral condition holds for every $\vartheta \leq 1/160$. The product derivative rule gives

$$\operatorname{Lip} h_i^\pm \leq \frac{A}{h}\,[3(12 + 4\cdot 2) + 2\cdot 6 + 2016 + 1] = 2089A/h.$$

As $\|h_i^\pm\|_\infty \geq A$, eq. 6.cccxxx gives the Lipschitz condition: $2089A/h \leq \|h_i^\pm\|_\infty/(\vartheta_* d)$. The reflected tests have the same integrals and norms. Thus $(\theta h_i^\pm, h_i^\pm) \in \mathfrak{T}(5h/2; \vartheta_*)$.

By eq. 6.cccxxvii, reflection positivity and the Hilbert triangle inequality,

$$\|[f_h^\lambda]\| \leq \sum_i (\|[h_i^+]\| + \|[h_i^-]\|) \leq 6\,\#\mathcal{I}\,A\sqrt{u(5h/2)}.$$

Combining its square with eq. 6.cccxxxii proves

$$\Gamma_\varphi(7h) \leq Cr_1^4(\|\varphi\|_\infty + \|\nabla\varphi\|_\infty)^2 h^{-8} u(5h/2). \tag{6.cccxxxiv}$$

Consequently

$$t^8\Gamma_\varphi(t) \longrightarrow 0 \quad (t \downarrow 0). \tag{6.cccxxxv}$$

The zero label is immediate. The two factors of h^{-4} in eq. 6.cccxxxiv have different origins: normalization in eq. 6.cccxxxii, and the square of the number of transverse cells. No uniform bound on a compact profile's Fourier transform from below was used.

6.12.6. *A short-distance estimate from the ordinary sources.* There is a second way to obtain eq. 6.cccxxxv. It uses reflection positivity at coordinate mirrors, hypercubic and translation invariance, and the joint spectrum $E \geq |p_i|$, $1 \leq i \leq 3$, of the Euclidean Hilbert evolution. For the connected function use the one-field vectors projected off the unit vector Ω. The projection commutes with the evolution and spatial translations. The short-distance input in this argument is an upper bound on a single family of positive mirror pairs.

6.12.6.1. The four-dimensional spectral measure. For a compact C^1 test f in the positive half-space, put

$$\widetilde{f}(E,p)=\int f(x)e^{-x_4E+i\vec{x}\cdot p}\,dx,\qquad m_f(B)=\langle[f],\mathsf{P}(B)[f]\rangle,$$

where P is the joint spectral measure and the brackets refer to the connected form. Integration of positive-time translations against another such test gives $[h*f]=\widetilde{h}(H,P)[f]=\widetilde{f}(H,P)[h]$. The integrals exist in the Hilbert space by strong continuity and compact support. Consequently $|\widetilde{h}|^2m_f=|\widetilde{f}|^2m_h$. Choose a nonnegative $a\in C_c^1((2,3))$ with positive integral and let $v(s)=e^{-s}\mathbf{1}_{[0,1]}(s)$, $v^\vee(s)=v(-s)$, and $b=(v*v^\vee)^{*2}$. This is an even nonnegative C_c^1 function supported in $[-2,2]$. Its Fourier transform satisfies

$$\widehat{b}(q)=\frac{|1-e^{-1+iq}|^4}{(1+q^2)^2}\geq\frac{c}{(1+q^2)^2}.$$

Set $B_1(x)=a(x_4)\prod_{i=1}^3 b(4x_i)$. Its transform is nonzero on the entire spectral carrier, since the time factor is a positive Laplace transform. Thus $d\rho^{(4)}=|\widetilde{B}_1|^{-2}\,dm_{B_1}$ is a positive measure on that carrier, with $dm_f=|\widetilde{f}|^2d\rho^{(4)}$ for each f. Polarization gives the analogous mixed formula. This construction uses only one-field vectors, before taking any pointwise values of a kernel.

For $h>0$ let $B_h(x)=B_1(x/h)$. The time transform is bounded below by che^{-3hE}, and the spatial Fourier bound just proved gives, on the carrier,

$$|\widetilde{B}_h(E,p)|^2\geq ch^8e^{-6hE}(1+h^2E^2)^{-12}\geq c'h^8e^{-ChE}.$$

In particular $s_{\mathrm{a}}(t):=\int e^{-tE}\,d\rho^{(4)}$ is finite for every $t>0$, by taking $Ch\leq t$ and bounding the integral by $(c'h^8)^{-1}\|[B_h]\|^2$. It is nonnegative and nonincreasing. Each support $\operatorname{supp}B_h$ lies in a ball of radius $d=5h/2$ centered at $(5h/2)e_4$, since its four coordinate half-widths are at most $h/2$. Its distance to its reflected support lies between $4h$ and $6h$. Its integral is a positive constant times h^4, its supremum is fixed, and its Lipschitz constant is $O(h^{-1})$. Thus $(\theta B_h,B_h)$ belongs to $\mathfrak{T}(5h/2;\vartheta_1)$ for some fixed $\vartheta_1>0$. If this family of pairs satisfies

$$S_2(\theta B_h,B_h)\leq u(5h/2)\|B_h\|_\infty^2,\qquad d^2u(d)\longrightarrow 0\quad(d\downarrow 0),\tag{6.cccxxxvi}$$

then $s_{\mathrm{a}}(t)\leq Ct^{-8}u(ct)$ for small t, by setting $h=t/C$ in the spectral estimate.

For $t>0$ the continuous kernel on the half-space of displacement vectors is

$$S(te_4+\vec{x})=\int e^{-tE+i\vec{x}\cdot p}\,d\rho^{(4)}(E,p).$$

Indeed the mixed spectral formula gives this kernel when the two test supports lie on opposite sides of the coordinate mirror. By translation it gives the same formula whenever their time projections are strictly ordered. For each nonzero displacement there is a coordinate whose positive or negative projection is nonzero. Use the hypercubic symmetries and small boxes about the two points to obtain the kernel on that neighborhood. Two such formulas agree on overlaps because both represent the same bilinear form there, as can also be seen by testing with approximate identities in the two boxes. Compact separated test pairs are handled by partitions into finitely many such boxes. Choosing a coordinate of largest modulus proves

$$|S(x)|\leq s_{\mathrm{a}}(|x|_\infty)\qquad(x\neq 0).\tag{6.cccxxxvii}$$

6.12.6.2. The transverse integral. For a real transverse label φ, the definition of the plane kernel and uniqueness on separated planar tests give

$$\Gamma_\varphi(t)=\int_{\mathbb{R}^2}S(te_4+\zeta)(\varphi*\varphi^\vee)(\zeta)\,d\zeta,\qquad\varphi^\vee(\zeta)=\varphi(-\zeta).$$

The weight is bounded in modulus by $\|\varphi\|_2^2$, by Cauchy–Schwarz. If φ is supported in a ball of radius R, the weight vanishes for $|\zeta|>2R$. Use eq. 6.cccxxxvii on the square $|\zeta|_\infty\leq t$ and on

the annuli with inner radii $2^i t$ and outer radii $2^{i+1}t$, $i \geq 0$. The area of an annulus is bounded by $C(2^i t)^2$. For $0 < t \leq \delta$ with δ sufficiently small this gives

$$\Gamma_\varphi(t) \leq C\|\varphi\|_2^2 \left[t^{-6} \sum_{2^i t \leq \delta} 2^{-6i} u(c2^i t) + R^2 s_{\mathrm{a}}(\delta) \right]. \tag{6.cccxxxviii}$$

In this sum the central square is included in the $i = 0$ term. Annuli with inner radius greater than δ are bounded using monotonicity of s_{a}. After multiplication by t^8, the sum is bounded by $C \sup_{0<d\leq c\delta} d^2 u(d)$, since its terms are $c^{-2}2^{-8i}(c2^i t)^2 u(c2^i t)$. For fixed δ the remaining term vanishes as $t \downarrow 0$. Then let $\delta \downarrow 0$. This proves eq. 6.cccxxxv.

6.12.6.3. The stopped source bound on the mirror pair. For a periodic-state limit of first-passage data at g, assume the ordinary source systems of Prop. 5.63 at their first-passage stops, including the bounds in eq. 5.cdxxxv–eq. 5.cdxxxvi. The radius, localized energy bound, entropy gap and geometric constants must be uniform over the stops used here. The sum of the upper stability and floor constants at a stop with inverse coupling x must be bounded by $C(1 + \log x)$, as in the stopped estimate of Prop. 5.63. Uniformity at a single reference coupling would give no bound on this sum along the varying stops. The argument also uses the flow inequalities and independence of the self-calibrated prefix from its last level and the reference coupling, together with the exact dilation eq. 5.lxxiv for the periodic Gibbs states.

Call j a record if $x_j < x_i$ for every $i < j$. The indices 0 and K are records at first passage. For $j_0 = 1 + \lceil c_5/\lambda_\sharp \rceil$, the lower bound $x_i - x_{i+j_0} \geq \lambda_\sharp j_0 - c_5 > 0$ gives a new record within j_0 steps of any record $i \leq K - j_0$. When fewer steps remain, K itself supplies the next record. For each fixed small $d > 0$ and all sufficiently large K, choose $b \geq 0$ so that $K - b$ is a record and

$$cL^{-j_0-1} \leq L^b d \leq c, \qquad b \leq \log_L(c/d),$$

where $c \leq 1$ is fixed. In fact, if $n = \lfloor \log_L(c/d) \rfloor$, the depths of successive records have gaps at most j_0, so we may take the greatest record depth $b \leq n$. For $b > 0$, set $g_b^{-2} = x_{K-b} - B_\sharp$. Then $g_b < g$ and $K - b$ is the first-passage cutoff at g_b: every earlier inverse coupling exceeds $g_b^{-2} + B_\sharp = x_{K-b}$. The upper flow bound and the original first-passage window give

$$x_{K-b} \leq g^{-2} + B_\sharp(b + 1).$$

For $b = 0$ use the original reference coupling. At each stop the ordinary source systems are needed on arbitrarily large compatible tori. Their minimum side may depend on g_b, since the all-state transfer takes the side to infinity at fixed cutoff and coupling.

Dilation by L^b takes a periodic state at cutoff K to one at cutoff $K - b$. It preserves the two-source cumulant exactly, with test functions replaced by $f_i^{[b]}(x) = f_i(L^{-b}x)$. For $(f_1, f_2) \in \mathfrak{T}(d; \vartheta_1)$, the rescaled tests have support radii at most one, a fixed positive separation floor, and $\|f_i^{[b]}\|_\sharp \leq C\|f_i\|_\infty$. The latter uses $\mathrm{Lip}\, f_i^{[b]} \leq \|f_i\|_\infty/(\vartheta_1 L^b d)$. In eq. 5.cdxxxix–eq. 5.cdxlii take $n = 2$ and use a cell side bounded by a fixed constant. There are at most two occupied cells. Therefore the normalized generating function has bound $Q \leq \exp[C(1 + \log x_{K-b})]$. The mixed derivative of the holomorphic normalizer is bounded by eq. 5.cdxl at the fixed separation floor. For the remaining factor h_ρ, use $\partial_{12} \log h_\rho(0) = \partial_{12} h_\rho(0) - \partial_1 h_\rho(0)\partial_2 h_\rho(0)$. Cauchy's formula bounds this expression by $C(Q + Q^2) \prod_i \|f_i^{[b]}\|_\sharp$. Returning to the original unit yields the all-state estimate

$$|S_2^T[\rho](f_1, f_2)| \leq C\big[1 + g^{-2} + \log(1/d)\big]^C \|f_1\|_\infty \|f_2\|_\infty. \tag{6.cccxxxix}$$

The constants do not depend on the cutoff, the periodic state, or the support positions. The estimate passes to the continuum limit at each fixed $d > 0$. For the mirror pair this is eq. 6.cccxxxvi, since d^2 times any fixed power of $1 + g^{-2} + \log(1/d)$ tends to zero. Thus the ordinary source estimates at the running stops give eq. 6.cccxxxv for periodic-state limits. The angular argument below

uses this limit and the two mirror representations. The coefficient law has a separate role in the short-distance assertions.

6.12.7. *Entire angular continuation and the critical Fourier modes.* For $r > 0$, define on $|\operatorname{Re} z| < \pi/2$

$$g_r^{[0]}(z) = \int \exp[-rE\cos z + irq\sin z]\, d\mu_\varphi(E,q). \tag{6.cccxl}$$

Writing $z = u + is$, the absolute integrand is $\exp[-r\cos u(E\cosh s + q\sinh s)]$. On the cone this is at most $\exp[-r\cos u\, e^{-|s|}E]$. On a compact substrip its derivatives are dominated by a polynomial in E times a smaller exponential. Thus the integral is holomorphic. Its real restriction is $G_\varphi(r\cos u, r\sin u)$.

On $|\operatorname{Re} z - k\pi/2| < \pi/2$ define $g_r^{[k]}(z) = g_r^{[0]}(z - k\pi/2)$. On real overlaps these functions agree by eq. 6.cccxx. The complex overlaps are connected vertical strips with real intervals, so the identity theorem glues them. Their union is the complex plane. The resulting g_r is entire and $\pi/2$-periodic. For every real u, s choose k with $|u - k\pi/2| \le \pi/4$ to obtain

$$|g_r(u+is)| \le \Gamma_\varphi(re^{-|s|}/\sqrt{2}) = o(e^{8|s|}). \tag{6.cccxli}$$

The last little-o, uniform in u, is exactly eq. 6.cccxxxv.

Define $a_m(r) = \frac{2}{\pi}\int_0^{\pi/2} g_r(u)e^{-4imu}\,du$. Cauchy's theorem on a rectangle of height s, with cancellation of its vertical sides by periodicity, gives

$$|a_m(r)| \le e^{4ms} \sup_{u\in[0,\pi/2]} |g_r(u+is)|.$$

For $m \ge 2$ take $s \to -\infty$; for $m \le -2$ take $s \to +\infty$. eq. 6.cccxli gives $a_m(r) = 0$ in both cases, including $|m| = 2$. A mere $O(t^{-8})$ bound on Γ would not eliminate that boundary mode. Fourier uniqueness for a continuous periodic function now gives, first on the real line and then everywhere by the identity theorem,

$$g_r(z) = a_0(r) + a_1(r)e^{4iz} + a_{-1}(r)e^{-4iz}. \tag{6.cccxlii}$$

One elementary uniqueness proof uses the positive Fejer kernels: their integrals are one, their mass outside every fixed neighbourhood of zero tends to zero, and their convolution converges uniformly on continuous periodic functions. A function with all Fourier coefficients zero has all these convolutions zero. Thus no convergence assumption on a formal Fourier series is implicit in eq. 6.cccxlii.

6.12.8. *The positive measure in the diagonal frame.* Put $D(t,x) = G_\varphi(R_{\pi/4}(t,x))$ for $t > 0$. We construct its positive measure without assuming a diagonal cone. For $y = (t,x)$, $t > 0$, introduce a formal vector e_y with

$$\langle e_y, e_{y'}\rangle_D = D(t+t', x'-x). \tag{6.cccxliii}$$

This kernel is positive semidefinite. To see it, approximate each planar point $R_{\pi/4}y$ by a nonnegative radial smooth mollifier supported strictly on the positive side of the diagonal mirror, tensor it with φ, and apply eq. 6.cccxvii to an arbitrary complex linear combination. The formula in eq. 6.cccxviii and continuity away from zero give eq. 6.cccxliii in the limit. Thus its quotient and completion define a Hilbert space.

On finite sums define $T_s e_{(t,x)} = e_{(t+s,x)}$, $s \ge 0$, and $U_b e_{(t,x)} = e_{(t,x+b)}$, $b \in \mathbb{R}$. The U_b preserve the form and have inverse U_{-b}. The T_s are symmetric and commute with the U_b. If $v = \sum c_i e_{(t_i,x_i)}$ and $\delta = 2\min_i t_i > 0$, eq. 6.cccxxiii gives a finite bound on $\|T_s v\|$ for every $s \ge 0$, namely its square is at most $\Gamma_\varphi(\delta/\sqrt{2})(\sum|c_i|)^2$. On the unquotiented vector space Cauchy–Schwarz gives

$$\|T_s v\|^2 = \langle v, T_{2s}v\rangle_D \le \|v\|\,\|T_{2s}v\|.$$

If $\|v\| = 0$ this preserves the null space. Otherwise iterate and use the bounded orbit to get $\|T_s v\| \le \|v\|$. Therefore T_s descend to self-adjoint contractions. They are positive because $T_s =$

$T_{s/2}^2$. Continuity of D implies strong continuity of both families on point vectors, hence on their completion.

There are strongly commuting generators $H_D \geq 0$ and P_D with $T_s = e^{-sH_D}$ and $U_b = e^{ibP_D}$. For specificity, T_1 is injective: $T_1 v = 0$ implies $T_{1/2} v = 0$, then all its dyadic roots annihilate v, and strong continuity gives $v = 0$. Define $H_D = -\log T_1$ by spectral calculus. Uniqueness of positive roots proves the semigroup identity first at rational times and then at all times. The spectral theorem for the commuting unitary group supplies P_D and the joint spectral measure. This is the elementary Hilbert reconstruction for eq. 6.cccxliii, not an OS analytic-continuation theorem.

Let $v_a = e_{(a,0)}$. If P_D is that joint spectral measure, define

$$\nu_a(B) = \langle v_a, \mathsf{P}_D(B) v_a \rangle_D, \qquad d\nu(E,q) = e^{2aE}\, d\nu_a(E,q). \tag{6.cccxliv}$$

As $v_b = T_{b-a} v_a$ for $b > a$, ν is independent of a. It is a positive, locally finite, σ-finite measure on $[0,\infty) \times \mathbb{R}$, and for $t > 0$

$$D(t,x) = \int e^{-tE+ixq}\, d\nu, \qquad \int e^{-tE}\, d\nu = D(t,0) < \infty. \tag{6.cccxlv}$$

Indeed choose $a < t/2$ and evaluate $\langle v_a, T_{t-2a} U_x v_a \rangle_D$. Nothing so far asserts $|q| \leq E$ for ν.

6.12.9. *Fourier–Laplace uniqueness and the boost identity.* We shall use the following uniqueness fact. Positive Borel measures ρ_1, ρ_2 on $[0,\infty) \times \mathbb{R}$ with finite $\int e^{-tE} d\rho_i$ for every $t > 0$ are equal if their transforms $\int e^{-tE+ixq} d\rho_i$ agree for all $t > 0, x \in \mathbb{R}$. For each real x these transforms are holomorphic in t on $\mathrm{Re}\, t > 0$, by exponential domination, so the identity theorem gives equality at $t = a + i\tau$. These are precisely the joint Fourier transforms of the finite measures $e^{-aE}\rho_i$. Finite Fourier transforms determine their measures: convolve their difference with a Gaussian, apply the Gaussian Fourier integral and Fubini to get zero, and let the Gaussian width tend to zero against compactly supported continuous functions. Hence the weighted measures, and then the original measures, agree. The same proof applies to finite positive linear combinations on either side of an identity.

For $s \in \mathbb{R}$ define the Lorentz map of spectral variables

$$L_s(E,q) = (E\cosh s + q \sinh s,\, E \sinh s + q \cosh s), \qquad \mu_s = (L_s)_* \mu_\varphi. \tag{6.cccxlvi}$$

This preserves $\mathcal{C}$ and $L_s L_t = L_{s+t}$. Its energy satisfies $E_s \geq e^{-|s|} E$, so $\int e^{-tE} d\mu_s \leq \Gamma_\varphi(t e^{-|s|})$. Define $F_s(t,x) = \int e^{-tE+ixq} d\mu_s$ for $t > 0$. Direct multiplication of the rotation matrix by is gives

$$F_s(v) = K_\varphi(R_{is} v) = g_r(\theta + is) \quad (v = R_\theta(re_0),\ v^0 > 0), \tag{6.cccxlvii}$$

where the middle expression uses eq. 6.cccxxiv. In fact $R_{is}(t,x) = (t\cosh s - ix \sinh s, x \cosh s + it \sinh s)$, and its exponential multiplier is exactly $e^{-tE_s + ixq_s}$. Thus eq. 6.cccxlvii holds on the whole real half-plane.

Write $C = \cosh 4 > 1$. The three terms in eq. 6.cccxlii obey the algebraic identity

$$(C-1) g_r(\theta + \pi/4) + g_r(\theta + i) + g_r(\theta - i) = (C+1) g_r(\theta).$$

Using eq. 6.cccxxii, eq. 6.cccxlv and eq. 6.cccxlvii and then transform uniqueness gives the identity of positive measures

$$(C-1)\nu + \mu_1 + \mu_{-1} = (C+1)\mu_\varphi. \tag{6.cccxlviii}$$

Every measure has the required finite Laplace weights. In particular

$$0 \leq \nu \leq \frac{C+1}{C-1} \mu_\varphi. \tag{6.cccxlix}$$

The diagonal measure is therefore carried by the exact cone. This conclusion was deduced from eq. 6.cccxlviii, not inserted as an additional reflection-positivity consequence.

For $r > 0$ and real s the function $w_s(E,q) = \exp[-r(E\cosh s + q\sinh s)]$ is positive on the cone and at most $e^{-re^{-|s|}E}$. It is integrable against all four measures in eq. 6.cccxlviii; for $\mu_{\pm1}$ use $L_sL_{\pm1} = L_{s\pm1}$. Integrating eq. 6.cccxlviii against w_s yields

$$(C-1)\int w_s\,d\nu + F_{s+1}(r,0) + F_{s-1}(r,0) = (C+1)F_s(r,0).$$

Substitute eq. 6.cccxlii into this identity to obtain

$$\begin{aligned} F_s(r,0) &= a_0(r) + a_1(r)e^{-4s} + a_{-1}(r)e^{4s} \geq 0,\\ \int w_s\,d\nu &= a_0(r) - a_1(r)e^{-4s} - a_{-1}(r)e^{4s} \geq 0. \end{aligned} \tag{6.cccl}$$

The first positivity comes from the axis measure, the second from the diagonal measure. Divide by e^{4s} and let $s \to +\infty$: the two limits give $a_{-1}(r) \geq 0$ and $a_{-1}(r) \leq 0$. Then let $s \to -\infty$ to get both signs for $a_1(r)$. The limits also show these coefficients are real, if that was not already deduced from eq. 6.cccxx. Thus $a_1(r) = a_{-1}(r) = 0$ for every $r > 0$.

Proposition 6.25 (Two-point angular elimination)**.** Under eq. 6.cccxvii–eq. 6.cccxix and the short-distance hypothesis in eq. 6.cccxxvi–eq. 6.cccxxx, every equal-real-label plane kernel is radial:

$$G_\varphi(R_t y) = G_\varphi(y) \quad (y \neq 0,\ t \in \mathbb{R}).$$

Every nonzero angular coefficient of the two-point kernel vanishes, including coefficients with mixed transverse labels. ■

Proof. The preceding argument proves the first assertion. It uses the short-distance hypothesis only through eq. 6.cccxxxv, so the same conclusion holds under the other stated hypotheses when that limit is obtained from § 6.12.6. Symmetry of S_2 gives $G_{\varphi,\psi}(y) = G_{\psi,\varphi}(-y)$; invariance under the planar half turn gives $G_{\psi,\varphi}(-y) = G_{\psi,\varphi}(y)$. Therefore the mixed kernel is symmetric in its real labels and

$$G_{\varphi,\psi} = \tfrac{1}{4}(G_{\varphi+\psi} - G_{\varphi-\psi}).$$

Both terms on the right are radial. Complex labels follow by bilinear extension. Uniqueness of Fourier coefficients identifies this conclusion with vanishing of every $m \neq 0$ coefficient in any finite-angular-band construction of the same two-point kernel. In its notation, $\overline{m}(2) = 0$. □

This is the order-two conclusion used by a later all-orders argument. It does not prove that argument, nor does it replace the required extension from planar plate kernels to arbitrary separated four-dimensional tuples. The ultraviolet vanishing and the kernel/spectral interface remain the stated premises. No rotational Ward identity, infrared decay, diagonal cone assumption, or full O(4) covariance was used.

6.13. **Euclidean covariance from the two-point angular law.** The analytic kernels and boost Gram identities of § 6.11, together with the two-point elimination of § 6.12, give Euclidean covariance at every order and on distributions. The argument requires the two-point ultraviolet estimate and uses no rotational Ward identity.

Work first with the centered scalar hierarchy. Compact separated moments are symmetric, translation invariant and hypercubic invariant, have position-uniform local C^1 bounds, and are reflection positive in every coordinate picture. In each such picture the Hilbert generators have the exact cube cone $H_j \geq |P_{j,r}|$ for every tangential coordinate $r \neq j$. Their off-diagonal distributions are those constructed in § 5.25.

6.13.1. *The harmonic data used below.* The chosen plane has coordinates (x_4, x_1), and R_u denotes its rotation through u. A plate label is a real smooth compact function of the two transverse coordinates. The analytic kernel construction supplies, for each n, real-analytic functions

$$c_m(y_1, \dots, y_n; \varphi_1, \dots, \varphi_n), \qquad y_i \in \mathbb{R}^2, \quad y_i \neq y_j, \tag{6.ccli}$$

multilinear in the labels, with only $|m| \leq Cn$ possibly nonzero. Their sum is the moment density on the ordinary ordering charts. They are symmetric under simultaneous permutations of positions and labels, translation invariant in the plane, and satisfy

$$c_m(R_u \mathbf{y}; \vec{\varphi}) = e^{4imu} c_m(\mathbf{y}; \vec{\varphi}), \qquad c_{-m} = \overline{c_m} \quad \text{for real labels.} \tag{6.cclii}$$

An ordinary chart means that all time coordinates are distinct, or that all abscissae are distinct; a fixed ordering is imposed on its connected component. The functions in eq. 6.ccli already extend over the nongeneric planar configurations with distinct points. This is the analytic-projector conclusion of the kernel construction, not a density assertion about distributions on the exceptional set.

Let b_n be the greatest absolute index of a harmonic that is not identically zero for some choice of real labels. Set $b_n = 0$ if there is no nonzero nonconstant harmonic, and put $b_0 = 0$ for the vacuum kernel. Thus b_n are nonnegative integers and $b_n \leq Cn$. The boost Gram identity gives

$$2b_{k+l} \leq b_{2k} + b_{2l}, \qquad k, l \geq 0. \tag{6.ccliii}$$

For clarity, this inequality compares global degrees. A nonzero coefficient can be tested on an open configuration set split into k negative and l positive times: real analyticity and connectedness prevent a nonzero coefficient from vanishing on that whole open set. Cauchy–Schwarz for the boosted product vectors bounds its largest exponential by the two diagonal ones. The empty product is the vacuum vector, so the cases $k = 0$ or $l = 0$ are included.

For $m_* = b_{2k}$ the coefficient c_{-m_*} is a positive kernel on reflected pairs of k-point configurations in a half-plane. This follows by multiplying the positive boost Gram matrix by $e^{-4m_* s}$ and taking $s \to +\infty$. The covariance in eq. 6.ccclii transports it to every oriented line: after multiplication by the fixed unit phase for that line it is again positive. We use the zero-row consequence of this positivity, which is unchanged by that phase. All these statements have explicit product-vector proofs in the preceding kernel section; analytic continuation of a nonnegative real-valued function alone would not prove them.

6.13.2. *The polygon divisibility argument, with label release.* Fix $k \geq 1$, put $m_* = b_{2k}$, and abbreviate $H = c_{-m_*}$. We prove

$$k \mid 2m_*. \tag{6.ccccliv}$$

Suppose otherwise. For any real plate label φ, place that same label at every vertex of a regular $2k$-gon. Rotation through π/k permutes the labelled vertices. Symmetry and eq. 6.ccclii imply

$$H(\mathbf{y}; \varphi, \dots, \varphi) = e^{-4\pi i m_*/k} H(\mathbf{y}; \varphi, \dots, \varphi) = 0. \tag{6.ccclv}$$

The polygon may be translated; rotation about its center has the same effect by translation invariance. The assumption that eq. 6.cccliv fails is exactly what makes the phase in eq. 6.ccclv different from one.

Call a labelled set S a zero set if H vanishes on every $2k$-point extension of it, with all remaining real labels arbitrary. A full polygon with the labels above is a zero set, since no completion is then needed. Here is the reduction of such a set. Suppose it is contained, with its labels, in $\theta Q \cup Q$, where Q has $j \leq k$ points strictly on one side of a line, and the reflected labels agree. Fill Q by any $k - j$ additional points A on that side, with arbitrary real labels. The positive kernel has zero diagonal at $Q \cup A$, because its diagonal configuration contains S. Its entire row is therefore zero. Indeed, positivity of the 2×2 Gram matrix gives $|K(X, Y)|^2 \leq K(X, X)K(Y, Y)$; a zero diagonal makes the right side zero. Consequently

$$H\big(\theta(Q \cup A) \cup B\big) = 0 \tag{6.ccclvi}$$

for every k-point B on the other side of the reflected set, with arbitrary real labels.

For each fixed choice of these free labels, eq. 6.ccclvi holds on a nonempty open set of all the free positions: the reflected points of A and the points of B can be varied independently in their respective half-planes. The configuration space of these $2k - j$ free points, avoiding each other and the fixed reflected Q, is connected. It is the complement of a finite union of affine sets of codimension two. One elementary proof is to join two configurations through a generic intermediate point; the intermediate points whose segment meets one of these affine sets form a finite union of measure-zero cones. Real analyticity and the identity principle extend eq. 6.ccclvi to this whole configuration space. It follows that θQ itself is a zero set, with no restriction on the remaining labels or half-planes. This is the label-release step; it is stronger than just showing that a special diagonal configuration has zero value.

Apply this reduction to the polygon. Reflection in the perpendicular bisector of an edge pairs its vertices and has no vertex on its line. It first reduces the full polygon to a consecutive arc of k vertices. A consecutive arc of $j \leq k$ vertices fits into the reflected union of an arc of $\lceil j/2 \rceil$ vertices. To check the odd case, index the vertices by integers modulo $2k$. For the arc $0, \dots, j - 1$, reflect indices by $i \mapsto j - i$ when j is odd; the union has $j + 1$ vertices, paired without a fixed vertex. For even j, use $i \mapsto j - 1 - i$ and the arc itself is paired. These are edge-bisector reflections, and

the selected half has the stated size. All its labels are still φ. Repeated reduction reaches a single labelled point.

Translation covariance makes every point with label φ a zero set. Since φ was arbitrary, every labelled $2k$-point configuration has zero value: choose any one of its labels as that single fixed label and use the unrestricted completion. Thus H is identically zero, contradicting the definition of m_*. This proves eq. 6.cccliv. When $m_* = 0$ the divisibility is automatic; no contradiction argument is needed.

6.13.3. *Discrete convexity reduces every order to two points.* Set $a_k = b_{2k}$, $a_0 = 0$. eq. 6.ccliii with $k-1, k+1$ gives

$$2a_k \le a_{k-1} + a_{k+1}, \qquad 0 \le a_k \le C'k. \tag{6.ccclvii}$$

The integer increments $d_k = a_k - a_{k-1}$ are nondecreasing, initially nonnegative, and bounded. If one increment exceeded the linear-growth constant, all later increments would do so, contradicting eq. 6.ccclvii. Hence they are eventually a fixed integer d. For large k write

$$a_k = dk - D, \qquad D = \sum_{j\ge 1}(d - d_j) \ge 0, \tag{6.ccclviii}$$

where only finitely many summands are nonzero. By eq. 6.cccliv, $k \mid 2a_k$ for every k, so every sufficiently large k divides $2D$. Thus $D = 0$. Each summand in eq. 6.ccclviii is nonnegative, and every increment equals $d = a_1$. Therefore

$$b_{2k} = kb_2, \qquad 2b_n \le b_{2n} = nb_2. \tag{6.ccclix}$$

The second inequality is the empty-tuple case of eq. 6.ccliii. Convexity and linear growth without eq. 6.cccliv would not suffice: $a_k = \max(0, k-1)$ is a counterexample. The polygon argument is what removes that defect.

The two-point elimination theorem gives $b_2 = 0$ under its ultraviolet shape estimate. eq. 6.ccclix then give $b_n = 0$ for every n. Consequently the ordinary-chart kernel is invariant under rotations in the chosen plane. The following argument upgrades this fact to the actual off-diagonal distributions, including their exceptional supports.

6.13.4. *A local analytic translation lemma.* Fix a coordinate j and divide the entries of a compact separated tuple into two groups whose supports lie on opposite sides of a coordinate hyperplane, with a positive gap. Their scalar moment is a matrix element in the coordinate-j Hilbert picture. After removing some unused gap, it has the form

$$\sigma(F_- \cdot \tau_z F_+) = \langle \Phi, e^{-(d+z_j)H_j} U_{z_\parallel} \Psi \rangle, \qquad d > 0, \tag{6.ccclx}$$

for real z sufficiently small. Here the left group has been reflected to define Φ, both groups have been shifted away from their mirror, and d is the remaining normal separation. This is exactly the compact-tuple translation dictionary, applied to products in each group. Its vectors need not be point fields, and no coincident product is used.

Let v be any real four-vector. The right side with $z = sv$ is holomorphic for small complex s. The precise sufficient domain is

$$d + v_j \operatorname{Re} s > \sum_{r \ne j} |v_r|\,|\operatorname{Im} s|. \tag{6.ccclxi}$$

Indeed the joint spectral cone $|P_{j,r}| \le H_j$ bounds the spectral exponential by one there. On every smaller domain a positive damping margin controls all powers of H_j and $P_{j,r}$, so difference quotients converge in operator norm. This proves holomorphy and local uniform bounds, rather than formally translating test functions to complex arguments. Translating the negative group instead gives the same conclusion with the corresponding signs. In particular, any specified half of a strict coordinate cut may be moved in any real direction, with a holomorphic parameter near zero.

6.13.5. *Removing the exceptional distributional support.* For $n \geq 2$ put

$$\mathcal{C}_n = \{(x_1, \dots, x_n) \in (\mathbb{R}^4)^n : x_i \neq x_l \ (i \neq l)\}.$$

Let T_n be the off-diagonal moment distribution. For a fixed rotation R_u define its difference by

$$D_u(f_1 \otimes \cdots \otimes f_n) = \sigma(f_1, \dots, f_n) - \sigma(R_u f_1, \dots, R_u f_n), \qquad (R_u f)(x) = f(R_u^{-1} x). \tag{6.ccclxii}$$

Both terms are well-defined distributions on $\mathcal{C}_n$.

First suppose all original and all rotated time coordinates at a configuration are distinct. Choose small product support boxes keeping both time orderings strict. In those boxes approximate each smooth test in C^1 by finite sums $\alpha(x_4, x_1)\varphi(x_2, x_3)$, with supports staying inside the boxes. For example, a product Fourier expansion with fixed compact cutoffs gives these approximants with all first derivatives. The rotation-invariant ordinary-chart kernel gives equality for the plate approximants. The local moment bounds pass it to the original tests. Local product-tensor density then says that D_u vanishes on this ordinary open set. This step alone would not rule out a distribution concentrated at the remaining time ties.

Fix any $y \in \mathcal{C}_n$. For each coordinate take all threshold hyperplanes halfway between successive distinct coordinate levels of the finite set $\{y_1, \dots, y_n\}$. Each threshold divides the indices into two nonempty sets, and these finitely many cuts together separate every pair of indices. No point lies on one of their hyperplanes. There exist $u_0 > 0$ and a product neighborhood W of y such that, for every $|u| < u_0$, each cut has the same index partition for x and for $R_u x$, for all $x \in W$, with a uniform positive gap in both configurations. To see this, take the minimum distance of the finitely many original points from these finitely many hyperplanes. Rotation is continuous and the points are bounded, so their displacement and then the size of W can be made smaller than a quarter of that minimum. Also take $u_0 < \pi/3$. The cuts and their partitions are kept fixed throughout the following local argument.

Fix $|u| < u_0$. At $x \in W$ let

$$q(x) = \#\{i < l : x_{i,4} = x_{l,4}\} + \#\{i < l : (R_u x_i)_4 = (R_u x_l)_4\}. \tag{6.ccclxiii}$$

The set $\{q \leq q_0\}$ is open: every inequality between distinct time coordinates remains an inequality in a sufficiently small neighborhood. We prove by induction that D_u vanishes on this open set for each integer q_0. The case $q_0 = 0$ is the ordinary-chart argument above.

Take a point with $q = q_0 > 0$. Choose a tied pair in either frame and one of the fixed common cuts that separates it. Let A be the positive side of that cut. Translate every entry in A by se_4. Original cross-group time differences have slope 1 or -1 in s; rotated cross-group differences have slope $\cos u$ or $-\cos u$. All slopes are nonzero. Internal differences in either group are unchanged. For all sufficiently small nonzero real s, no previously nonzero difference becomes zero, while every previously zero cross difference becomes nonzero. At least the chosen tied pair is of this kind, so the number in eq. 6.ccclxiii decreases.

Choose one such s_* and a small real interval I about it. Shrink the product neighborhood V of the original point so that its translates stay in W, all previously nonzero differences stay nonzero, and all cross-group differences in both frames are nonzero for every $s \in I$. Every configuration in the translated product boxes then has $q \leq q_0 - 1$. By induction, D_u vanishes there as a distribution.

Now take arbitrary smooth slot tests supported in V. Their difference in eq. 6.ccclxii, after the group translation, is a holomorphic function of s near the real segment joining zero to I. For the first moment term this is eq. 6.ccclx–eq. 6.ccclxi with $v = e_4$. For the rotated term the same common cut separates the same two groups, and the direction is $v = R_u e_4$. Strict gaps persist on the chosen segment; shrinking the segment and its complex neighborhood supplies eq. 6.ccclxi in both cases. This is why both configurations were required to share the cut. The holomorphic function is zero on I, hence is zero at zero. Thus D_u vanishes on every such product tensor in V. The explicit local Fourier tensor density for distributions makes it vanish on all tests in V.

This proves the induction step. Since $q \le n(n-1)$, the induction terminates and D_u vanishes on W. It excludes a singular part on any of the exceptional time-tie sets, including configurations with coincident plane projections but separated transverse positions. At no point was the kernel integral assumed analytic across those sets.

6.13.6. *All angles, all planes, and the Schwartz domain.* We have proved local invariance for every sufficiently small u on a neighborhood of each point of $\mathcal{C}_n$. Let a compactly supported off-diagonal test be given, and fix a finite angle v. The union of the supports of its rotations between zero and v is a compact subset of $\mathcal{C}_n$. Cover it by finitely many neighborhoods just constructed, and take the minimum of their positive angle bounds. Partition v into finitely many smaller steps. On each step the difference distribution is zero on the current support, so composition gives invariance through v.

Thus all separated smooth moments are invariant in the chosen plane. Compact C^1 tests follow by smooth approximation on fixed separated neighborhoods. The hypercubic group conjugates this circle of rotations to rotations in every coordinate plane. Givens elimination of the columns of an orthogonal matrix expresses every member of SO(4) as a finite product of such plane rotations: successively zero the entries below each diagonal position, using a rotation in the corresponding two-coordinate plane, and finish with diagonal signs. A coordinate reflection supplies the other component of O(4).

For $n = 1$, the translation-invariant one-point functional is $c \int f$ and is already invariant. Restoring such a mean to a centered field uses a finite subset expansion on each compact tuple; this commutes with every rotation because $\int Rf = \int f$. Finally rotations act continuously on Schwartz space, preserve every pairwise coincidence diagonal, and preserve flatness there. The diagonal-flat extension and its constrained tensor density therefore transfer the same invariance to that full test domain.

Proposition 6.26 (All-orders angular closure)**.** Under the moment, cone, analytic-kernel and two-point hypotheses stated above, the full scalar hierarchy is O(4) invariant, both on separated compact C^1 tuples and on its unique diagonal-flat Schwartz extension. The polygon, discrete-convexity and exceptional-support steps require no further analytic rotation assumption. ■

This closes a conditional Euclidean-covariance implication. It neither proves the ordinary interacting source estimates nor the ultraviolet two-point law, and it does not identify the scalar cyclic theory with a complete family of Yang–Mills observables.

6.14. **Displacement calculus and the exact lattice Ward identity.** This section derives the finite-lattice rotation identity, including its contact terms and its shell flux. The identity is exact before any renormalization or continuum limit. Its separate terms identify which estimates a Ward proof of Euclidean covariance needs. In particular the divergence of the displacement field contributes to the flux and must be retained.

6.14.1. *Plaquette holonomies based at a bond.* Work on the periodic lattice $a\mathbb{Z}^4/\ell\mathbb{Z}^4$ with ℓ/a an integer at least three. Write $\mathcal{B}_+$ for the positive bonds. A configuration is a point of $\mathrm{SU}(2)^{\mathcal{B}_+}$; for a reverse bond $\bar{b}$ set $U_{\bar{b}} = U_b^{-1}$. Let x_b be the midpoint of a bond and x_p the barycentre of a plaquette. A plaquette is counted once in a sum over p, and a sum over its sides uses its four positive bonds, irrespective of the orientation of its boundary.

If b is either orientation of a side of p, let $W_{b,p}$ be the holonomy of the plaquette boundary that starts at b_- and traverses b first. Its first matrix factor is U_b. Reversing the orientation of this boundary inverts the holonomy and leaves its trace unchanged. Set

$$W = w^0(W)I + i\mathbf{w}(W), \qquad w^0(W) = \tfrac{1}{2}\operatorname{tr} W, \qquad \mathbf{w}(W) = \frac{W - W^*}{2i}. \tag{6.ccclxiv}$$

With the Pauli basis t_α and inner product $\langle X, Y\rangle = \frac{1}{2}\operatorname{tr}(XY)$, $\mathbf{w} = \sum_{\alpha=1}^{3} w^\alpha t_\alpha$ and $(w^0)^2+|\mathbf{w}|^2 = 1$. The plaquette density is $a_p = 1 - w^0(W_{b,p})$, independent of the chosen side and base point. Thus

$$0 \le a_p \le 2, \qquad |\mathbf{w}(W_{b,p})|^2 \le 2a_p. \tag{6.ccclxv}$$

For a positive bond, define ∂_b^α by differentiating $U_b \mapsto e^{ist_\alpha}U_b$. The inverse bond changes by the inverse of this matrix. The same definition for an oriented negative bond is understood as a vector field on the positive bond coordinates. Since the four bonds in a plaquette are distinct, a derivative at one of its sides differentiates exactly one factor in the based holonomy.

Lemma 6.27 (The derivatives of the scalar and vector parts)**.** For a side b of p,

$$\partial_b^\alpha w^0_{b,p} = -w^\alpha_{b,p}, \qquad \partial_b^\alpha a_p = w^\alpha_{b,p}, \tag{6.ccclxvi}$$

$$\partial_b^\alpha w^\gamma_{b,p} = \delta_{\alpha\gamma} w^0_{b,p} + \sum_\delta \varepsilon_{\alpha\gamma\delta} w^\delta_{b,p}, \qquad \sum_\alpha \partial_b^\alpha w^\alpha_{b,p} = 3w^0_{b,p}. \tag{6.ccclxvii}$$

The derivatives of a_p vanish on bonds not in its boundary. ■

Proof. Write $W_{b,p} = U_b R$, where R has no dependence on that bond coordinate. Its derivative is $it_\alpha W_{b,p}$. Expand this product with $t_\alpha t_\gamma = \delta_{\alpha\gamma} I + i\sum_\delta \varepsilon_{\alpha\gamma\delta} t_\delta$. Its scalar part is $-w^\alpha$ and its vector part is the right side of eq. 6.ccclxvii. The alternating term vanishes when $\gamma = \alpha$, giving the final sum. □

6.14.2. *The displacement vector field.* For ρ different from the direction of b, let $p(b, \pm\rho)$ be the plaquette spanned by b and $\pm a e_\rho$, and abbreviate its based vector part by $\mathbf{w}_{b,\pm\rho}$. Put

$$\mathbf{u}_{b,\rho} = -\tfrac{1}{2}(\mathbf{w}_{b,+\rho} - \mathbf{w}_{b,-\rho}), \qquad \mathbf{u}_{b,\mu(b)} = 0,$$

$$\mathbf{v}_b[\eta] = a^{-1}\sum_\rho \eta^\rho(x_b)\mathbf{u}_{b,\rho}, \qquad \mathsf{D}_\eta = \sum_{b\in\mathcal{B}_+,\alpha} v_b^\alpha[\eta]\partial_b^\alpha. \tag{6.ccclxviii}$$

Only the finitely many values of η at bond midpoints are used. No regularity in the spatial variable is needed for this definition. Its coefficients are smooth functions of the group variables, even if η is merely a prescribed list of numbers.

For b a side of p define the elementary density

$$d_{b,p,\rho} = \langle \mathbf{u}_{b,\rho}, \mathbf{w}_{b,p}\rangle. \tag{6.ccclxix}$$

Then Lem. 6.27 gives

$$\mathsf{D}_\eta a_p = a^{-1}\sum_{b\subset\partial p,\rho} \eta^\rho(x_b) d_{b,p,\rho}. \tag{6.ccclxx}$$

All densities here are bounded functions on a compact configuration space, so every finite-cutoff derivative and integral used below exists.

6.14.3. *Gauge covariance and bond reversal.* A site gauge u acts by $U_b \mapsto u(b_-)U_b u(b_+)^{-1}$. Its intermediate factors cancel in a based loop, hence

$$W_{b,p}(U^u) = u(b_-)W_{b,p}(U)u(b_-)^{-1}. \tag{6.ccclxxi}$$

The same conjugation acts on $\mathbf{w}$, $\mathbf{u}$ and $\mathbf{v}$. Since the adjoint action preserves the colour inner product, $d_{b,p,\rho}$ is gauge invariant. The transformation rule for the bond derivative is the corresponding adjoint transformation of its direction. The two rules cancel in their contraction, so

$$\mathsf{D}_\eta(F\circ(\,\cdot\,)^u) = (\mathsf{D}_\eta F)\circ(\,\cdot\,)^u. \tag{6.ccclxxii}$$

The exact reversal relations are

$$W_{\bar b,p} = U_b^{-1}W_{b,p}^{-1}U_b, \qquad \mathbf{w}_{\bar b,p} = -\operatorname{Ad}(U_b^{-1})\mathbf{w}_{b,p},$$

$$\mathbf{u}_{\bar b,\rho} = -\operatorname{Ad}(U_b^{-1})\mathbf{u}_{b,\rho}, \qquad \mathbf{v}_{\bar b}[\eta] = -\operatorname{Ad}(U_b^{-1})\mathbf{v}_b[\eta]. \tag{6.ccclxxiii}$$

The first identity follows by following the inverse boundary from the other end of the same bond; the others use inversion and conjugation of the vector part. The midpoint is unchanged. At a fixed configuration, $\partial_{\bar b}^{X} = -\partial_b^{\mathrm{Ad}(U_b)X}$. It follows that $\mathbf{v}_{\bar b}\cdot\partial_{\bar b} = \mathbf{v}_b\cdot\partial_b$. Thus the vector field D_η is independent of which orientation is chosen for each unoriented bond, and $d_{\bar b,p,\rho} = d_{b,p,\rho}$.

For a signed permutation S of the spatial coordinates and a lattice translation, the image of a transverse positive direction can be negative. Extend $\mathbf{u}_b(\xi) = \sum_\rho \xi^\rho \mathbf{u}_{b,\rho}$ linearly to every $\xi\in\mathbb{R}^4$. Interchanging $+\rho$ and $-\rho$ changes its sign. Consequently, for the isometry $\mathsf{r}(x) = Sx + v$,

$$d_{\mathsf{r}b,\mathsf{r}p}(S\xi)(\mathsf{r}U) = d_{b,p}(\xi)(U), \qquad \mathsf{D}_{\mathsf{r}\cdot\eta}(F^{\mathsf{r}}) = (\mathsf{D}_\eta F)^{\mathsf{r}}, \tag{6.ccclxxiv}$$

where $(\mathsf{r}\cdot\eta)(x) = S\eta(\mathsf{r}^{-1}x)$. Bond reversals that arise in this formula are harmless by eq. 6.ccclxxiii. This verifies covariance under coordinate reflections as well as orientation-preserving permutations.

6.14.4. *The exact Haar divergence.* The divergence of a vector field written in left-invariant orthonormal frames is $\operatorname{div}\mathsf{D}_\eta = \sum_{b,\alpha}\partial_b^\alpha v_b^\alpha$. By eq. 6.ccclxvii,

$$\operatorname{div}\mathsf{D}_\eta = \frac{3}{2a}\sum_{b\in\mathcal{B}_+,\rho\neq\mu(b)} \eta^\rho(x_b)[a_{p(b,+\rho)} - a_{p(b,-\rho)}]. \tag{6.ccclxxv}$$

The coefficient three is the dimension of the colour algebra. The sign follows from $w^0 = 1 - a_p$ and the minus sign in the definition of $\mathbf{u}$.

Define the midpoint central difference by

$$\nabla_\rho^c\eta^\rho(x) = a^{-1}[\eta^\rho(x + \tfrac{a}{2}e_\rho) - \eta^\rho(x - \tfrac{a}{2}e_\rho)]. \tag{6.ccclxxvi}$$

A plaquette in the $\mu\nu$ plane occurs twice in eq. 6.ccclxxv for each of its two directions. For the direction ν, its lower μ side has midpoint $x_p - ae_\nu/2$ and sign plus; its upper μ side has midpoint $x_p + ae_\nu/2$ and sign minus. The other direction is identical. Regrouping the finite sum therefore gives

$$\operatorname{div}\mathsf{D}_\eta = -\tfrac{3}{2}\sum_{p\text{ in plane }\mu\nu} a_p[\nabla_\mu^c\eta^\mu(x_p) + \nabla_\nu^c\eta^\nu(x_p)]. \tag{6.ccclxxvii}$$

The notation in this formula sums over all plaquettes once; the two displayed directions are the directions of that plaquette and have no further implicit sum.

Proposition 6.28 (Integration by parts with the sourced Wilson measure)**.** For a smooth vector field D on the finite product of groups and a smooth function F,

$$\int \mathsf{D}F\,dU = -\int F\operatorname{div}\mathsf{D}\,dU. \tag{6.ccclxxviii}$$

For $A(c,U) = \sum_p c(p)a_p(U)$ and $Z(c) = \int e^{-A(c,U)}dU \neq 0$, the normalized, possibly complex, expectation satisfies

$$\langle \mathsf{D}A(c,\cdot)\rangle_c = \langle \operatorname{div}\mathsf{D}\rangle_c. \tag{6.ccclxxix}$$

■

Proof. Left multiplication preserves Haar measure, so $\int \partial_b^\alpha H\,dU = 0$ for smooth H. Apply it to each product $v_b^\alpha F$, expand by the product rule, and sum to prove eq. 6.ccclxxviii. Apply that identity to $F = e^{-A}$ and use $\mathsf{D}e^{-A} = -(\mathsf{D}A)e^{-A}$. Division by the stipulated nonzero integral proves eq. 6.ccclxxix. Compactness justifies differentiation under each integral. The proof works for complex coefficients by linearity; positivity is only needed later for estimates. □

6.14.5. *Orbital, tensor and remainder densities.* The four positive sides of a plaquette have lever arms $x_b - x_p = \pm a e_\mu/2, \pm a e_\nu/2$. Set

$$\begin{aligned} t_\rho(p) &= \sum_{b \subset \partial p} d_{b,p,\rho}, \\ s_{\lambda\rho}(p) &= \sum_{b \subset \partial p} a^{-1}(x_b - x_p)_\lambda d_{b,p,\rho}, \\ r_\rho(p) &= t_\rho(p) - \tfrac{1}{2}[a_{p+ae_\rho} - a_{p-ae_\rho}]. \end{aligned} \tag{6.ccclxxx}$$

These are local gauge-invariant polynomials. Under the signed-permutation isometries, s is a rank-two tensor and r a vector: this follows from eq. 6.ccclxxiv, the transformation of the lever arm by S, and the signed transformation of the central difference.

The sphere relation and $2ab \le a^2 + b^2$ give

$$|d_{b,p,\rho}| \le 1, \qquad |d_{b,p,\rho}| \le \tfrac{1}{2}[a_{p(b,+\rho)} + a_{p(b,-\rho)}] + a_p. \tag{6.ccclxxxi}$$

Indeed $|\mathbf{u}| \le 1$, while the product with $|\mathbf{w}_{b,p}|$ is bounded by $\frac{1}{4}(|\mathbf{w}_+|^2 + |\mathbf{w}_-|^2) + \frac{1}{2}|\mathbf{w}_{b,p}|^2$. If $N(p)$ includes the plaquettes sharing a side with p and the translates $p \pm a e_\rho$, these inequalities imply

$$|s_{\lambda\rho}(p)| + |t_\rho(p)| + |r_\rho(p)| \le C \sum_{p' \in N(p)} a_{p'}. \tag{6.ccclxxxii}$$

The constant is absolute and independent of a, ℓ. Each term depends only on bonds within $2a$ of the plaquette barycentre in the sup norm. These bounds identify the energy weight needed to estimate an insertion; they do not themselves supply decay of a connected correlation.

6.14.6. *A cutoff rotation and the product rule.* Let $\omega \in \mathfrak{so}(4)$. Choose a Lipschitz function χ supported in $(-\ell/2 + 2a, \ell/2 - 2a)^4$ and read it on the torus through representatives in $[-\ell/2, \ell/2)^4$. Define $\eta(x) = \chi(x)\omega x$. The support margin ensures that every shift used in a nonzero term is represented by its ordinary Euclidean shift. The linear field ωx alone is not periodic; this support condition is essential for the next identities.

Put

$$h_{\omega,\chi}(p) = a^{-1} \sum_{b \subset \partial p, \rho} [\chi(x_b) - \chi(x_p)](\omega x_b)_\rho d_{b,p,\rho}. \tag{6.ccclxxxiii}$$

Using $\omega x_b = \omega x_p + \omega(x_b - x_p)$ in eq. 6.ccclxx gives the exact product rule

$$\begin{aligned} \mathsf{D}_{\chi\omega x} a_p = {} & \chi(x_p) a^{-1} \sum_\rho (\omega x_p)_\rho t_\rho(p) \\ & + \chi(x_p) \sum_{\rho,\lambda} \omega_{\rho\lambda} s_{\lambda\rho}(p) + h_{\omega,\chi}(p). \end{aligned} \tag{6.ccclxxxiv}$$

Only the antisymmetric part of s contributes to its contraction with ω. This is an algebraic tensor statement and does not assume rotation symmetry of the quantum measure.

For a plaquette weight f define

$$(\nabla^s_\omega f)(p) = \sum_\rho (\omega x_p)_\rho \frac{f(p + a e_\rho) - f(p - a e_\rho)}{2a}. \tag{6.ccclxxxv}$$

For any weight c, define

$$\begin{aligned} \mathcal{S}_\chi[c] &= \sum_p c(p)\chi(x_p) \sum_{\rho,\lambda} \omega_{\rho\lambda} s_{\lambda\rho}(p), \\ \mathcal{K}_\chi[c] &= \sum_p c(p)\chi(x_p) a^{-1} \sum_\rho (\omega x_p)_\rho r_\rho(p). \end{aligned} \tag{6.ccclxxxvi}$$

Omit the subscript χ when its factor is absent.

The central-difference part of the first line of eq. 6.ccclxxxiv, summed against c, is

$$\sum_{p,\rho}(c\chi)(p)(\omega x_p)_\rho \frac{a_{p+ae_\rho}-a_{p-ae_\rho}}{2a} = -\mathcal{O}(\nabla^s_\omega(c\chi)). \tag{6.ccclxxxvii}$$

To verify it, shift the finite plaquette sum separately in its plus and minus terms. In direction ρ, the ρ component of ωx is unchanged by that shift because $\omega_{\rho\rho}=0$. The compact support margin removes every seam ambiguity. This proves the identity without a discrete product-rule approximation.

6.14.7. *The exact sourced identity.* Let w be a complex plaquette weight and $c=\beta-w$, with $\beta>0$. Assume $\chi=1$ on the Euclidean $2a$-neighborhood of the representatives of all plaquettes where $w\neq 0$. This implies $w\chi=w$ and $w(p)h_{\omega,\chi}(p)=0$. Define the source-independent shell insertion

$$\mathcal{B}_{\omega,\chi}=\beta\mathcal{O}(\nabla^s_\omega\chi)-\beta\sum_p h_{\omega,\chi}(p)+\operatorname{div}\mathsf{D}_{\chi\omega x}. \tag{6.ccclxxxviii}$$

For $Z(w)=\int e^{-A(\beta-w,U)}dU\neq 0$, denote the normalized expectation by $\langle\cdot\rangle_w$.

Proposition 6.29 (Finite-lattice rotational Ward identity)**.** Under the stated support and normalization hypotheses,

$$\langle\mathcal{O}(\nabla^s_\omega w)\rangle_w=-\langle\mathcal{S}_\chi[c]+\mathcal{K}_\chi[c]\rangle_w+\langle\mathcal{B}_{\omega,\chi}\rangle_w. \tag{6.ccclxxxix}$$

The divergence contribution has the explicit shell form

$$\operatorname{div}\mathsf{D}_{\chi\omega x}=-\tfrac{3}{2}\sum_{p\text{ in plane }\mu\nu}a_p\sum_{\rho\in\{\mu,\nu\}}(\omega x_p)_\rho\nabla^c_\rho\chi(x_p). \tag{6.cccxc}$$

■

Proof. Sum eq. 6.ccclxxxiv against c. Insert the definition of r and use eq. 6.ccclxxxvii. Since $c\chi=\beta\chi-w$ and $wh=0$, this gives

$$\mathsf{D}_{\chi\omega x}A(c,U)=\mathcal{S}_\chi[c]+\mathcal{K}_\chi[c]-\beta\mathcal{O}(\nabla^s_\omega\chi)+\mathcal{O}(\nabla^s_\omega w)+\beta\sum_p h_{\omega,\chi}(p).$$

Take normalized expectations and apply eq. 6.ccclxxix. Rearrangement proves eq. 6.ccclxxxix. For the divergence, substitute $\eta=\chi\omega x$ in eq. 6.ccclxxvii. Its component $(\omega x)_\rho$ is constant along the ρ direction, again because $\omega_{\rho\rho}=0$. The remaining central difference acts only on χ, proving eq. 6.cccxc. □

Every occurrence of χ in the flux is a difference of its values at points at distance at most a. In the first term of eq. 6.ccclxxxviii, split $\chi(x_p+ae_\rho)-\chi(x_p-ae_\rho)$ at x_p. The second term already has a bond-midpoint difference, and the last is eq. 6.cccxc. Thus a plaquette contributes nothing when χ is constant on its a-neighborhood. This local assertion does not license setting $\chi=1$ globally on a torus while treating ωx as periodic.

6.14.8. *Connected derivatives and the contact terms.* Choose weights $f_1,\dots,f_n$ and a single cutoff χ equal to one on the prescribed neighborhood of all their supports. Set $w(z)=\sum_i z_i f_i$. Since the group product is compact and $0\le a_p\le 2$, $Z(w(z))$ and every inserted numerator are entire functions of $z\in\mathbb{C}^n$. Also $Z(0)>0$. Continuity gives a common polydisc about zero on which Z is nonzero and all the preceding normalized identities hold holomorphically.

For a bounded insertion Y independent of z,

$$\partial_{z_1}\cdots\partial_{z_n}\langle Y\rangle_{w(z)}\big|_{z=0}=\langle Y;\mathcal{O}(f_1);\dots;\mathcal{O}(f_n)\rangle. \tag{6.cccxci}$$

This follows by adding one more source sY to Z and differentiating $\partial_s\log Z(s,z)$ at $s=0$. Boundedness justifies all derivatives under the integral, and local non-vanishing justifies the logarithm.

Differentiate eq. 6.ccclxxxix once in each of the n source variables. The source on its left gives n terms: differentiating its explicit factor z_i leaves a cumulant with the remaining $n-1$ sources.

The same product rule applies to $\mathcal{S}_\chi[\beta - w] + \mathcal{K}_\chi[\beta - w]$. Since $\chi = 1$ at the source plaquettes, its resulting contact insertions are $\mathcal{S}[f_i] + \mathcal{K}[f_i]$. Consequently

$$\begin{aligned}\sum_{i=1}^{n} & S_n^T(f_1, \dots, \nabla_\omega^s f_i, \dots, f_n) \\ &= -\beta\langle(\mathcal{S}_\chi + \mathcal{K}_\chi)[1]; \mathcal{O}(f_1); \dots; \mathcal{O}(f_n)\rangle \\ &\quad + \sum_{i=1}^{n}\langle(\mathcal{S} + \mathcal{K})[f_i]; (\mathcal{O}(f_j))_{j\neq i}\rangle \\ &\quad + \langle\mathcal{B}_{\omega,\chi}; \mathcal{O}(f_1); \dots; \mathcal{O}(f_n)\rangle. \end{aligned} \tag{6.cccxcii}$$

For $n = 1$ the contact term is an expectation. No assumption of disjoint supports is used for this exact finite-lattice identity. Such separation enters estimates of its connected terms, rather than the algebraic differentiation.

6.14.9. *The shell estimate and the continuum use.* For a cutoff χ_R equal to one on a ball of radius R and zero outside a ball of radius $2R$, assume $\operatorname{Lip}\chi_R \le C/R$, $a \le R/10$, and $2R+2a < \ell/2$, retaining the earlier torus support margin. The difference form of the flux, together with eq. 6.ccclxxxi, gives

$$|\mathcal{B}_{\omega,\chi_R}| \le C'(\beta+1)|\omega| \sum_{p:\, R-3a\le|x_p|\le 2R+3a} a_p. \tag{6.cccxciii}$$

To check the factors, a difference of χ_R contributes at most its point separation times C/R, cancelling the displayed a^{-1} in each term. In this shell $|x_p| + a \le 3R$, which cancels the remaining R^{-1}. The bounded neighbor multiplicity in eq. 6.ccclxxxi only changes C'. The divergence term has the same estimate with the factor β replaced by one.

This bound supplies integrability at fixed cutoff. It does not make the connected shell insertion tend to zero as $R \to \infty$: the shell contains an increasing number of plaquettes. A Ward proof of continuum rotation invariance must establish vanishing of the last line of eq. 6.cccxcii, as well as the stated ultraviolet estimates for the spin and orbital terms. Clustering without a rate sufficient for the shell sum is not such an estimate.

For $f \in C_c^3$ in a fixed bounded region, Taylor's integral formula yields

$$\|\nabla_\omega^s f - (\omega x)\cdot\nabla f\|_\infty \le Ca^2|\omega| \sup_{x\in\operatorname{supp} f + B_{2a}} (1+|x|)|D^3 f(x)|. \tag{6.cccxciv}$$

For $f \in C_c^4$ supported in a fixed ball of radius R_f, the same calculation after one spatial derivative gives

$$\|\nabla_\omega^s f - (\omega x)\cdot\nabla f\|_{C^1} \le Ca^2|\omega|(1+R_f+a)(\|D^3 f\|_\infty + \|D^4 f\|_\infty).$$

Indeed differentiation also acts on the linear coefficient $(\omega x)_\rho$, producing a central-difference error for f; the other term is the same error for a first derivative of f. Both have the displayed bound. The error is supported in $\operatorname{supp} f + B_a$. On any fixed separated tuple these enlarged supports remain separated for small a. The uniform correlation bound in the declared C^1 test norm, together with multilinearity, therefore passes the left side of the Ward identity to the infinitesimal rotation derivative for smooth tests. If the spin, orbital and shell terms all vanish on that same limiting route, the limiting functionals satisfy the infinitesimal rotation identity. Integrating along one-parameter rotations gives rotation covariance on the smooth test class, and continuity extends it to the declared test space. The exact finite-lattice calculation identifies all terms to be controlled; it does not replace their interacting estimates.

6.15. **Classical** SU(2) **invariants and the smooth Wilson action.** The rotational Ward calculation distinguishes a local density from its integral, and a classical identity from an estimate in the lattice measure. We make those distinctions explicit. First we classify the local gauge-invariant

polynomials through dimension six under the full hypercubic group. We prove the finite enumeration, its independence, and the quotients by divergences and by the field equation. We then derive the smooth-field Wilson expansion with the same SU(2) normalization as the lattice construction. Its pointwise coefficient contains a divergence which disappears only from an unweighted compact-support integral. None of these classical calculations bounds that coefficient under a rough interacting lattice measure.

6.15.1. *Conventions and the local polynomial spaces.* The Lie algebra consists of traceless Hermitian matrices. Write $X = \vec{x} \cdot \sigma$, using Pauli matrices with $\frac{1}{2}\,\mathrm{tr}(\sigma^a\sigma^b) = \delta_{ab}$, and set

$$\langle X, Y\rangle = \tfrac{1}{2}\,\mathrm{tr}(XY), \qquad \langle X, Y, Z\rangle = \tfrac{i}{2}\langle X, [Y, Z]\rangle. \tag{6.cccxcv}$$

Multiplication of the three Pauli matrices gives

$$XY = (\vec{x}\cdot\vec{y})I + i(\vec{x}\times\vec{y})\cdot\sigma, \quad i[X,Y] = -2(\vec{x}\times\vec{y})\cdot\sigma, \quad \langle X,Y,Z\rangle = -\det(\vec{x},\vec{y},\vec{z}). \tag{6.cccxcvi}$$

In particular the triple bracket is real and alternating. This fixes the sign of the cubic invariant below.

Let A_μ be a smooth connection on $\mathbb{R}^4$. Define

$$D_\alpha X = \partial_\alpha X + i[A_\alpha, X], \qquad F_{\mu\nu} = \partial_\mu A_\nu - \partial_\nu A_\mu + i[A_\mu, A_\nu], \qquad J^{\mathrm{c}}_\nu = \sum_\mu D_\mu F_{\mu\nu}. \tag{6.cccxcvii}$$

The superscript distinguishes this continuum field equation from a current defined as a positive action gradient. For $S_0 = \frac{1}{4}\int \sum_{\mu,\nu} |F_{\mu\nu}|^2$, a compactly supported variation gives $\delta S_0 = -\int \sum_\nu \langle J^{\mathrm{c}}_\nu, \delta A_\nu\rangle$. Thus its sign is the opposite of that positive gradient; the equation $J^{\mathrm{c}} = 0$ is unaffected.

Commuting $\partial_\alpha + iA_\alpha$ as operators, and using the Jacobi identity, proves

$$\begin{aligned} [D_\alpha, D_\beta]X &= i[F_{\alpha\beta}, X], \\ D_\alpha F_{\mu\nu} + D_\mu F_{\nu\alpha} + D_\nu F_{\alpha\mu} &= 0, \\ \partial_\alpha\langle X, Y\rangle &= \langle D_\alpha X, Y\rangle + \langle X, D_\alpha Y\rangle. \end{aligned} \tag{6.cccxcviii}$$

The same product rule holds for the triple bracket. Under a site gauge u, the connection is $A^u_\alpha = uA_\alpha u^{-1} + i(\partial_\alpha u)u^{-1}$. Conjugation of $\partial + iA$ shows that every iterated covariant derivative of F transforms by $X \mapsto uXu^{-1}$.

Give $D_{\alpha_1}\cdots D_{\alpha_k}F_{\mu\nu}$ dimension $k+2$. Let $\mathcal{V}_\delta$ be the real gauge-invariant polynomials in these variables which are homogeneous of dimension δ, identified as functions of (A, x). Constant polynomials form $\mathcal{V}_0$. No naked connection variable is admitted in these spaces. A total derivative of dimension six will mean

$$\partial\mathcal{V}_5 = \left\{ \sum_\rho \partial_\rho v_\rho : v_\rho \in \mathcal{V}_5 \right\}. \tag{6.cccxcix}$$

This is a quotient by local gauge-invariant currents, not a statement that a divergence vanishes pointwise. We keep the current ideal separate: $\mathcal{I}_6$ is spanned by

$$\langle J^{\mathrm{c}}_\nu, D_\alpha F_{\kappa\lambda}\rangle, \qquad \langle D_\alpha J^{\mathrm{c}}_\nu, F_{\kappa\lambda}\rangle. \tag{6.cd}$$

It contains all dimension-six gauge-invariant multiples of the field equation and its covariant derivatives in this polynomial algebra. Indeed a factor $D^k J^{\mathrm{c}}$ leaves dimension $3-k$ for its cofactor. For $k = 0, 1$ this gives precisely the two displayed families; $k = 2$ has no possible cofactor, and $k = 3$ is a linear colour expression, whose gauge average is zero.

An orthogonal map acts on a connection by $(R\cdot A)_\mu(x) = \sum_\nu R_{\mu\nu}A_\nu(R^{-1}x)$. All indices in an iterated derivative of F are tensor indices. The group W_4 consists of every signed coordinate permutation, including orientation-reversing ones. We write $\mathcal{V}_\delta^{W_4}$ for scalar invariants. For tensor channels, $\mathrm{Hom}_{W_4}(M, \mathcal{V}_\delta)$ denotes equivariant linear maps from the indicated real tensor space M.

6.15.2. *The finite invariant enumeration.*

Lemma 6.30 (Colour and index reduction)**.** The spaces below are spanned by the displayed families:

$$\begin{aligned}\mathcal{V}_4 &= \operatorname{span}\{\langle F_{\mu\nu}, F_{\kappa\lambda}\rangle\},\\ \mathcal{V}_5 &= \operatorname{span}\{\langle F_{\mu\nu}, D_\alpha F_{\kappa\lambda}\rangle\},\\ \mathcal{V}_6 &= \operatorname{span}\{\langle F_{\mu\nu}, D_\alpha D_\beta F_{\kappa\lambda}\rangle, \langle D_\alpha F_{\mu\nu}, D_\beta F_{\kappa\lambda}\rangle, \langle F_{\mu\nu}, F_{\kappa\lambda}, F_{\sigma\tau}\rangle\}.\end{aligned} \tag{6.cdi}$$

For $1 \le \delta \le 3$, $\mathcal{V}_\delta = 0$. For a tensor monomial with index tuple I, averaging over all coordinate signs kills it unless its set of odd-multiplicity indices matches the set prescribed by the output channel. A scalar requires the empty set; a vector component ρ requires $\{\rho\}$; an off-diagonal two-tensor component $\rho\sigma$ requires $\{\rho, \sigma\}$. ■

Proof. Each variable has dimension at least two, so through dimension six a monomial has at most three colour vectors. Average its coefficient tensor over constant SU(2) gauges. Conjugation acts as all of SO(3) on the colour vectors. Invariant coefficient tensors of ranks one, two and three are respectively zero, multiples of δ_{ab}, and multiples of ϵ_{abc}. Here is an elementary verification. Rotations through π about coordinate axes kill a rank-one invariant and all off-diagonal rank-two entries; quarter turns equate the remaining diagonal entries. For rank three, the same half turns require each of the three coordinate labels to occur an odd number of times. They therefore occur once each. Proper signed permutations make the remaining coefficients alternating, giving ϵ. These arguments classify coefficient tensors before evaluating any differential identities, so additional relations among the jets cannot enlarge the spanning space. The possible dimensions now give exactly eq. 6.cdi. Linear colour expressions, including a single high derivative of F, average to zero.

A coordinate sign vector ε multiplies a monomial by $\prod_j \varepsilon_j^{n_j}$, where n_j is its index count. Averaging this character against the scalar, vector, or two-tensor character gives the stated parity rule. Averaging subsequently over coordinate permutations gives orbit sums; for a fixed output component use the subgroup fixing its distinguished indices. This works with spanning families and does not assume that all formal monomials are independent. □

The central element $-I$ acts on $\mathcal{V}_\delta$ by $(-1)^\delta$. Hence odd-dimensional scalar invariants vanish, and the vector channel vanishes at even dimension. At dimension four the scalar parity patterns allow only squares of an individual $F_{\mu\nu}$; permutation averaging gives

$$\mathcal{V}_4^{W_4} = \mathbb{R}\sum_{\mu,\nu} |F_{\mu\nu}|^2, \qquad \mathcal{V}_5^{W_4} = 0. \tag{6.cdii}$$

Define the following three symmetric two-tensors and vectors:

$$\begin{aligned} T^1_{\alpha\beta} &= \sum_\kappa \langle F_{\alpha\kappa}, F_{\beta\kappa}\rangle, \quad T^2_{\alpha\beta} = \delta_{\alpha\beta}\sum_{\kappa,\lambda} |F_{\kappa\lambda}|^2,\\ T^3_{\alpha\beta} &= \delta_{\alpha\beta}\sum_\kappa |F_{\alpha\kappa}|^2, \qquad v^1_\rho = \partial_\rho \sum_{\alpha,\beta} |F_{\alpha\beta}|^2,\\ v^2_\rho &= \sum_\nu \langle F_{\rho\nu}, J^c_\nu\rangle, \qquad v^3_\rho = \partial_\rho \sum_\kappa |F_{\rho\kappa}|^2. \end{aligned} \tag{6.cdiii}$$

There is no sum on a repeated free index in T^3 or v^3.

Proposition 6.31 (The low-dimensional tensor channels)**.** The symmetric two-tensor channel of dimension four has basis T^1, T^2, T^3. Its antisymmetric channel is zero. The vector channel of dimension five has basis v^1, v^2, v^3, and

$$v^1_\rho = \sum_\alpha \partial_\alpha T^2_{\alpha\rho}, \quad v^3_\rho = \sum_\alpha \partial_\alpha T^3_{\alpha\rho}, \quad v^2_\rho = \sum_\alpha \partial_\alpha (T^1_{\alpha\rho} - \tfrac{1}{4} T^2_{\alpha\rho}). \tag{6.cdiv}$$

Moreover $\Lambda^2\mathbb{R}^4$ is irreducible for the full W_4, and has no equivariant image in $\mathbb{R}$, $\mathcal{V}_4$, or $\mathcal{V}_5$. ■

Proof. For a diagonal output component $\rho\rho$, sign parity requires even counts. In a product of two F's this leaves $\sum_\kappa |F_{\rho\kappa}|^2$ and the sum of the squares whose indices avoid ρ. These are the same span as the diagonal components of T^2 and T^3. For $\rho \neq \sigma$, the only nonzero parity pattern is $\rho\sigma\kappa\kappa$ with κ different from the two distinguished indices. Its orbit sum is $\sum_\kappa \langle F_{\rho\kappa}, F_{\sigma\kappa}\rangle$. It is symmetric in ρ, σ, so the antisymmetric channel is zero, and the full two-tensor space is the three-dimensional span claimed, subject to the independence verification below.

For the vector component ρ, a dimension-five monomial has five indices. The odd-set rule gives only multiplicities $(3,2)$ or $(1,2,2)$; (5) is zero by antisymmetry of F. Up to signs and orbit multiplicities the resulting list is

$$\begin{aligned} a_\rho &= \sum_\kappa \langle F_{\rho\kappa}, D_\rho F_{\rho\kappa}\rangle, \\ b^1_\rho &= \sum_{\sigma,\tau\neq\rho} \langle F_{\sigma\tau}, D_\rho F_{\sigma\tau}\rangle, \\ b^2_\rho &= \sum_{\sigma,\tau\neq\rho,\,\sigma\neq\tau} \langle F_{\rho\sigma}, D_\tau F_{\tau\sigma}\rangle, \\ b^3_\rho &= \sum_{\sigma,\tau\neq\rho,\,\sigma\neq\tau} \langle F_{\sigma\tau}, D_\sigma F_{\rho\tau}\rangle. \end{aligned} \tag{6.cdv}$$

This list is exhaustive: in the $(3,2)$ pattern the derivative has the distinguished index and both antisymmetric pairs contain it; in the $(1,2,2)$ pattern it either occurs on the derivative, or on one of the two curvature factors, giving the last three entries. The product rule and Bianchi identity give

$$v^3 = 2a, \qquad v^1 = 2b^1 + 4a, \qquad v^2 = a + b^2, \qquad \tfrac{1}{4}v^1 = a + b^3. \tag{6.cdvi}$$

For the last identity contract Bianchi with $F_{\kappa\lambda}$ and sum: the two terms with a derivative on an index of that curvature are equal, while the remaining one is half the derivative of $\sum |F|^2$. Explicitly

$$\sum_{\kappa,\lambda} \langle F_{\kappa\lambda}, D_\kappa F_{\rho\lambda}\rangle = \tfrac{1}{2}\sum_{\kappa,\lambda} \langle F_{\kappa\lambda}, D_\rho F_{\kappa\lambda}\rangle = \tfrac{1}{4} v^1_\rho. \tag{6.cdvii}$$

The left side is $a_\rho + b^3_\rho$. The same contracted identity, applied to the divergence of T^1, proves the third formula in eq. 6.cdiv; the other two are immediate product rules.

Independence can be checked on genuine connections rather than formal jets. Multiply all polynomials in the following tests by a smooth cutoff equal to one near zero, and set $A_\mu = q_\mu \sigma^3$. At zero, only the displayed q_μ are nonzero:

q	(v^1_1, v^2_1, v^3_1)
$q_2 = x_1 + x_1^2/2$	$(4,1,2)$
$q_3 = x_2 + x_1 x_2$	$(4,0,0)$
$q_2 = x_1 + x_3^2/2$	$(0,1,0)$

(6.cdviii)

The determinant is eight. For the tensor channel, the field $q_3 = x_1 + x_2$ has $T^1_{12} = 1$, while $T^2_{12} = T^3_{12} = 0$. The field $q_2 = x_1$ has $(T^1_{33}, T^2_{33}, T^3_{33}) = (0,2,0)$ and $(T^1_{11}, T^2_{11}, T^3_{11}) = (1,2,1)$. These three evaluations prove tensor independence.

Finally the sign subgroup acts on the six coordinate wedges by six distinct characters $\varepsilon_\rho\varepsilon_\sigma$. Averaging against one character projects onto its one-dimensional coordinate wedge. Any invariant subspace containing a nonzero vector therefore contains a coordinate wedge. Permutations act transitively on the six wedges, so it contains them all. This proves irreducibility. Its image in the trivial representation is zero, its dimension-four image is the antisymmetric channel already computed, and its dimension-five image is zero by the action of the central element $-I$. □

6.15.3. *Dimension six as densities.* Define

$$\begin{aligned} O_1 &= \sum_{\mu,\nu} |D_\mu F_{\mu\nu}|^2, & O_2 &= \sum_{\alpha,\mu,\nu} |D_\alpha F_{\mu\nu}|^2, \\ O_3 &= \sum_{\nu} |J^{\mathrm{c}}_\nu|^2, & O_F &= \sum_{\mu,\nu,\rho} \langle F_{\mu\nu}, F_{\nu\rho}, F_{\rho\mu}\rangle, \\ Q &= \sum_{\alpha} \partial_\alpha^2 \sum_{\mu} |F_{\alpha\mu}|^2, & d_i &= \sum_{\rho} \partial_\rho v^i_\rho. \end{aligned} \tag{6.cdix}$$

In O_1 the derivative index is tied to one curvature index before squaring. It is not O_3, which first sums the derivative contributions. In particular $d_3 = Q$.

Lemma 6.32 (An exact off-shell identity)**.** For every smooth connection, pointwise,

$$O_2 = 2O_3 - 4O_F + \tfrac{1}{2} d_1 - 2d_2. \tag{6.cdx}$$

■

Proof. Differentiate Bianchi and commute the two covariant derivatives:

$$\sum_{\rho} D_\rho D_\rho F_{\alpha\beta} = D_\alpha J^{\mathrm{c}}_\beta - D_\beta J^{\mathrm{c}}_\alpha + 2i \sum_{\rho} [F_{\rho\alpha}, F_{\rho\beta}]. \tag{6.cdxi}$$

Pair with $F_{\alpha\beta}$ and sum. Antisymmetry gives twice $T = \sum_{\alpha,\beta} \langle F_{\alpha\beta}, D_\alpha J^{\mathrm{c}}_\beta\rangle$ from the first two terms. The commutator term is $4O_F$ by eq. 6.cccxcv and relabeling the three indices. The product rules give

$$d_1 = 2O_2 + 4T + 8O_F, \qquad d_2 = O_3 + T. \tag{6.cdxii}$$

Eliminate T. No integration or field equation was used. □

Proposition 6.33 (Complete off-shell scalar basis)**.** The space $\mathcal{V}_6^{W_4}$ has basis

$$O_1,\ O_2,\ O_3,\ d_1,\ d_2,\ Q. \tag{6.cdxiii}$$

The cubic-in-F invariant subspace is exactly $\mathbb{R} O_F$. ■

Proof. We first give an exhaustive reduction. In a cubic curvature monomial regard each antisymmetric pair as an edge between its two coordinate labels. The sign rule requires even degree at every label. Three non-loop edges can then form only a triangle; the colour triple bracket gives its oriented contraction O_F. Permutation averaging changes only its multiplicity and sign. Thus the cubic subspace is at most one-dimensional.

For the $DF\,DF$ terms the six index counts are $(4,2)$ or $(2,2,2)$; the all-equal case is zero. The full orbit list, up to signs and factors, is

$$\begin{aligned} &O_1, \qquad S_1 = \sum_{a,b,c}^{\neq} |D_a F_{bc}|^2, \\ &S_2 = \sum_{a,b,c}^{\neq} \langle D_a F_{ac}, D_b F_{bc}\rangle, \qquad S_3 = \sum_{a,b,c}^{\neq} \langle D_a F_{bc}, D_b F_{ac}\rangle. \end{aligned} \tag{6.cdxiv}$$

Here the superscript means that the three labels are distinct. The $(4,2)$ pattern gives O_1. In $(2,2,2)$, either a derivative repeats a curvature index in each factor, giving S_2, or all three labels occur in each factor. Equal derivative labels then give S_1 and different ones give S_3. Expanding the sums and contracting Bianchi yields

$$O_2 = S_1 + 2O_1, \qquad O_3 = O_1 + S_2, \qquad S_1 = 2S_3. \tag{6.cdxv}$$

For the last equality multiply $D_a F_{bc} = D_b F_{ac} - D_c F_{ab}$ by $D_a F_{bc}$ and sum over distinct indices. Interchanging b, c makes the second cross term the negative of the first, giving exactly $2S_3$.

It remains to reduce $FDDF$. The pointwise identity

$$\langle F_{\mu\nu}, D_\alpha D_\beta F_{\kappa\lambda}\rangle = \partial_\alpha \langle F_{\mu\nu}, D_\beta F_{\kappa\lambda}\rangle - \langle D_\alpha F_{\mu\nu}, D_\beta F_{\kappa\lambda}\rangle \tag{6.cdxvi}$$

requires no commutation of D_α, D_β. After averaging over W_4, the first term is the divergence of an equivariant vector of dimension five. By Prop. 6.31 it lies in $\mathrm{span}\{d_1, d_2, Q\}$. The second term was just enumerated. The scalar space is therefore spanned by $O_1, O_2, O_3, O_F, d_1, d_2, Q$, and eq. 6.cdx reduces this to the six members in eq. 6.cdxiii.

We verify all six dimensions on actual compactly supported connections. Use the commuting cutoff connections of the previous proof. The following three choices give the indicated first three columns; since $F(0) = 0$, their last three columns are $(d_1, d_2, Q) = (2O_2, O_3, 2O_1)$:

q	O_1	O_2	O_3
$q_2 = x_1^2/2$	1	2	1
$q_3 = x_1 x_2$	0	4	0
$q_2 = (x_1^2 - x_3^2)/2$	2	4	0

(6.cdxvii)

Their three-by-three determinant is -8. Two further commuting tests, $q_2 = x_1 + x_1^3/6$ and $q_2 = x_1 + x_1 x_3^2/2$, have $DF(0) = 0$ and give respectively $(d_1, d_2, Q) = (4, 1, 2)$ and $(4, 1, 0)$. For the last test choose constant antisymmetric $f_{\mu\nu}$ with $f_{12} = \sigma^1$, $f_{23} = \sigma^2$, $f_{31} = \sigma^3$ and $f_{\mu 4} = 0$, and put $A_\mu = \frac{1}{2}\sum_\nu x_\nu f_{\nu\mu}$ near zero. Then $F(0) = f$, $DF(0) = 0$, and $O_F(0) = -6$. Moreover $D_\mu^2 F_{\mu\nu}(0) = 0$: the ordinary second derivative of $i[A_\mu, A_\nu]$ in the μ direction has a zero factor, and $A(0) = \partial_\mu A_\mu(0) = 0$. Thus $Q(0) = 0$. The curvature Laplacian and eq. 6.cdxii give $(d_1, d_2, Q) = (-12, 9, 0)$. These last three tests have $O_1 = O_2 = O_3 = 0$ and divergence matrix

$$\begin{pmatrix} 4 & 1 & 2 \\ 4 & 1 & 0 \\ -12 & 9 & 0 \end{pmatrix}, \qquad \det = 96. \tag{6.cdxviii}$$

The full six-by-six evaluation matrix is block triangular with determinant -768. This proves independence as functions of connections, and also shows $O_F \neq 0$. The spanning result is therefore a basis result, not merely a list of possible operators. □

6.15.4. *Rotational scalars, divergences and the field equation.*

Proposition 6.34 (The two density obstructions and the single integrated obstruction)**.** One has the direct sum

$$\mathcal{V}_6^{W_4} = \mathrm{span}\{O_2, O_3, d_1, d_2\} \oplus \mathbb{R}O_1 \oplus \mathbb{R}Q, \qquad \mathcal{V}_6^{\mathrm{O}(4)} = \mathrm{span}\{O_2, O_3, d_1, d_2\}. \tag{6.cdxix}$$

Modulo total derivatives the scalar space has basis O_1, O_2, O_3. Modulo rotational scalars and total derivatives its dimension is one, represented by O_1. This last obstruction remains nonzero after also quotienting by $\mathcal{I}_6$. Modulo divergences and $\mathcal{I}_6$ alone, a basis is given by the classes of O_1, O_2, with $O_2 \equiv -4O_F$. For the dimension-four symmetric tensor channel, a combination $c_1T^1 + c_2T^2 + c_3T^3$ is $\mathrm{O}(4)$-equivariant exactly when $c_3 = 0$. ■

Proof. Complete contraction of indices shows that O_2, O_3, O_F are rotational scalars and that T^1, T^2, v^1, v^2 have their stated full orthogonal tensor types. Their divergences d_1, d_2 are therefore scalars. To prove that no further linear combination is a scalar, fix a radial cutoff equal to one near zero and use

$$A_3(x) = \phi(p \cdot x)\sigma^3, \qquad A_\mu = 0 \quad (\mu \neq 3), \qquad |p| = 1,\ p_3 = 0 \tag{6.cdxx}$$

near zero. Rotations fixing e_3 take this family from p to Rp. At zero direct differentiation gives

$$O_1 = \phi''(0)^2 \sum_\alpha p_\alpha^4, \qquad Q = 2\{\phi''(0)^2 + \phi'(0)\phi'''(0)\} \sum_\alpha p_\alpha^4. \tag{6.cdxxi}$$

The factor $\sum p_\alpha^4$ changes from one to one half under a rotation taking e_1 to $(e_1+e_2)/\sqrt{2}$. For $\phi(t)=t^2/2$, invariance of aO_1+bQ would force $a+2b=0$; for $\phi(t)=t+t^3/6$ it would force $b=0$. Hence $a=b=0$. Together with the six-dimensional basis this proves eq. 6.cdxix.

The W_4-scalar part of $\partial\mathcal{V}_5$ equals $\operatorname{span}\{d_1,d_2,Q\}$. Indeed average a current over the finite group with its vector action; the divergence of the average is the scalar average of its divergence. The vector classification then applies. These three divergences are independent by the density basis. Quotienting gives the asserted three-dimensional basis. The off-shell identity also gives $O_2\equiv 2O_3-4O_F$ in this quotient.

The same sign and permutation enumeration in eq. 6.cd gives

$$\mathcal{I}_6^{W_4}=\operatorname{span}\{O_3,d_2\}. \tag{6.cdxxii}$$

For $\langle J_\nu^{\mathrm{c}}, D_\alpha F_{\kappa\lambda}\rangle$ the only nonzero even index pattern contracts ν with one curvature index and α with the other, yielding O_3. For $\langle D_\alpha J_\nu^{\mathrm{c}}, F_{\kappa\lambda}\rangle$ the same pattern yields d_2-O_3 by the product rule. The alternative pairing sets the two curvature indices equal and is zero. Both surviving invariants are rotational scalars. If an invariant belonged to a sum of the rotation, divergence and current subspaces, averaging that membership over W_4 would give precisely these invariant subspaces. Thus the extra quotient cannot remove the class of O_1. This proves the on-shell quotient assertion without setting J^{c} to zero inside an off-shell density identity. The divergence subspace together with the current ideal has basis d_1,d_2,Q,O_3, by the six-density basis. Its quotient is therefore two-dimensional, with basis O_1,O_2; the exact off-shell relation reduces there to $O_2=-4O_F$. In particular O_F is not a divergence, even after the field-equation quotient.

For the tensor assertion, T^1,T^2 already have full orthogonal covariance. In the test family with $\phi'(0)=1$, $T^3_{\alpha\alpha}=p_\alpha^2+\delta_{\alpha 3}$ and every off-diagonal entry is zero. At $p=e_1$, rotating the tensor $\operatorname{diag}(1,0,1,0)$ by $\pi/4$ in the first two coordinates produces a nonzero off-diagonal entry. The tensor T^3 evaluated on the rotated connection still has zero off-diagonal entries. It is therefore not equivariant, and subtracting the equivariant T^1,T^2 proves the claim. □

The conclusion has three distinct meanings. There are two nonrotational directions as local densities, represented by O_1 and Q. In the integral modulo the specified divergences only O_1 remains. In the further algebraic quotient by the field equation it still remains. None of these statements removes a weighted divergence: for a compactly supported test h,

$$\int hQ=\sum_\alpha\int(\partial_\alpha^2 h)\sum_\mu|F_{\alpha\mu}|^2. \tag{6.cdxxiii}$$

This term must be retained when the local Ward calculation uses a nonconstant cutoff.

6.15.5. *Parallel transport and centred plaquettes.* For a piecewise C^1 path $\gamma:[0,T]\to\mathbb{R}^4$, define its transport by the right-ordered differential equation

$$P'(t)=iP(t)\eta(t),\qquad P(0)=I,\qquad \eta(t)=\sum_\mu A_\mu(\gamma(t))\dot\gamma_\mu(t). \tag{6.cdxxiv}$$

Its value at T is denoted $\Pi_\gamma[A]$. Iterating the integral equation gives the absolutely convergent series

$$\Pi_\gamma=I+\sum_{n\ge1}i^n\int_{0<t_1<\cdots<t_n<T}\eta(t_1)\cdots\eta(t_n)\,dt_1\cdots dt_n. \tag{6.cdxxv}$$

The nth term is bounded by $(\int|\eta|)^n/n!$, proving existence and allowing termwise differentiation for smooth finite parameter families on compact parameter sets. Uniqueness follows by iterating the integral equation for a difference, with the same factorial bound. Since η is Hermitian and traceless, $(PP^*)'=0$ and $(\det P)'=i\operatorname{tr}(\eta)\det P=0$. Thus the transport is in SU(2).

Concatenation multiplies transports in path order; reversing a path inverts its transport. These follow either from uniqueness or by reversing the integral equation. Differentiating $u(\gamma(0))P(t)u(\gamma(t))^{-1}$ shows that

$$\Pi_\gamma[A^u] = u(\gamma(0))\Pi_\gamma[A]u(\gamma(T))^{-1}. \tag{6.cdxxvi}$$

The sign in A^u is thereby checked against the transport ordering, rather than chosen independently. The same differentiation gives

$$\frac{d}{dt}\{P(t)X(\gamma(t))P(t)^{-1}\} = P(t)\left(\sum_\mu \dot\gamma_\mu(t)D_\mu X(\gamma(t))\right)P(t)^{-1}. \tag{6.cdxxvii}$$

Fix $\mu < \nu$. Let $c(t)$, $0 \le t \le 4$, traverse the boundary of the unit square centred at zero in the (μ,ν) plane, starting at $-(e_\mu + e_\nu)/2$ and following $+e_\mu, +e_\nu, -e_\mu, -e_\nu$ at unit speed. Extend it periodically. Thus $c(t+2) = -c(t)$. Define

$$W_{\mu\nu}(s,y) = \Pi_{y+sc}[A], \qquad G_{\mu\nu}(s,y) = 1 - \tfrac{1}{2}\operatorname{tr} W_{\mu\nu}(s,y). \tag{6.cdxxviii}$$

These are smooth functions of (s,y) for real s, including $s=0$. Apply the ODE separately on the four sides to see the smooth parameter dependence despite the corners. The trace is real for SU(2). Gauge transformations conjugate W at its base point, so G is gauge invariant.

The centred plaquette has the exact parity

$$G_{\mu\nu}(-s,y) = G_{\mu\nu}(s,y). \tag{6.cdxxix}$$

Indeed changing s to $-s$ starts the same oriented square halfway round its boundary. If its two half-transports are P_1, P_2, the two full transports are P_1P_2 and P_2P_1, whose traces are equal. This is parity of the centred traced plaquette; it does not assert that a matrix-valued transport based at a fixed corner is itself even.

Lemma 6.35 (The pointwise plaquette coefficients)**.** For every smooth connection,

$$G_{\mu\nu}(s,y) = \frac{s^4}{2}|F_{\mu\nu}(y)|^2 + \frac{s^6}{24}\langle F_{\mu\nu}, (D_\mu^2 + D_\nu^2)F_{\mu\nu}\rangle(y) + O(s^8). \tag{6.cdxxx}$$

On a compact set of y the remainder is uniform. For a compactly supported connection it has a common compact support when $|s| \le 1$. ∎

Proof. Use radial gauge about the selected point y. Let $u(y+z)$ be the transport of A along the straight segment from y to $y+z$, and put $B = A^u$. By eq. 6.cdxxvi, every radial segment for B has transport one. Hence

$$z \cdot B(y+z) = 0, \qquad B(y) = 0, \qquad \partial_\lambda B_\kappa(y) = \tfrac{1}{2}F_{\lambda\kappa}(y). \tag{6.cdxxxi}$$

The last two conclusions follow by differentiating the first identity once and twice, and then using the definition of F. This gauge need not be compactly supported; it is used only to identify coefficients at y. The uniform remainder will be estimated using the original plaquette function.

Put $f = F_{\mu\nu}(y)$. In the series eq. 6.cdxxv, the coefficient on the square is

$$\eta_s(t) = s\sum_\kappa B_\kappa(y+sc(t))\dot c_\kappa(t) = s^2\eta_0(t) + O(s^3), \qquad \eta_0(t) = \tfrac{1}{2}(c_\mu\dot c_\nu - c_\nu\dot c_\mu)f. \tag{6.cdxxxii}$$

All leading matrices are multiples of the single f. Let $H = \int_0^4 \eta_s(t)\,dt$ and let W_n denote the ordered integral of n coefficient factors, without i^n. The trace of H is zero. Symmetry of $\mathrm{tr}(XY)$ gives $\operatorname{tr} W_2 = \frac{1}{2}\operatorname{tr} H^2$. The order-$s^6$ part of $\operatorname{tr} W_3$ is zero, because it is proportional to $\operatorname{tr} f^3 = 0$; replacing one leading coefficient by its $O(s^3)$ remainder costs $O(s^7)$. All $n \ge 4$ terms cost $O(s^8)$ by the factorial estimate. Consequently

$$G_{\mu\nu}(s,y) = \tfrac{1}{2}|H|^2 + O(s^7). \tag{6.cdxxxiii}$$

This is where the SU(2) trace algebra is used.

Ordinary Stokes' formula in the square gives $H = \int_{[-s/2,s/2]^2} \psi(y + z_\mu e_\mu + z_\nu e_\nu)\, dz_\mu dz_\nu$, where $\psi = \partial_\mu B_\nu - \partial_\nu B_\mu$. Taylor expansion on the symmetric square yields

$$H = s^2\psi(y) + \frac{s^4}{24}(\partial_\mu^2 + \partial_\nu^2)\psi(y) + O(s^6). \tag{6.cdxxxiv}$$

The odd moments vanish and each quadratic moment equals $s^4/12$. At y one has $\psi = f$. Also, for $i = \mu$ or ν, $\partial_i^2[B_\mu, B_\nu](y) = 0$: both potentials vanish, and in the remaining product one factor is $\partial_i B_i(y) = 0$. For the same reason $D_i^2 F_{\mu\nu}(y) = \partial_i^2 F_{\mu\nu}(y)$. Therefore

$$H = s^2 f + \frac{s^4}{24}(D_\mu^2 + D_\nu^2)F_{\mu\nu}(y) + O(s^6). \tag{6.cdxxxv}$$

Insert this into eq. 6.cdxxxiii. It identifies the coefficients of orders four and six, with an initial $O(s^7)$ remainder. The original function $G(s, y)$ is smooth and even. Thus all odd Taylor coefficients vanish and Taylor's theorem gives an $O(s^8)$ remainder, bounded by $|s|^8 \sup_{|t|\le 1} |\partial_s^8 G(t, y)|/8!$ on $|s| \le 1$. On compact sets this supremum is finite. If A has compact support, any square of side at most one sufficiently far from that support has all its transports equal to one. The plaquette function and all coefficients then vanish. The required uniform support and remainder follow on the fixed enlarged compact set. □

There is a direct noncommuting check on both coefficients. For a connection constant near the square, with $A_1 = r\sigma^1$, $A_2 = r\sigma^2$ and the other components zero, multiplication of the four exponentials gives

$$G_{12}(s, y) = 2\sin^4(sr) = 2r^4 s^4 - \tfrac{4}{3} r^6 s^6 + O(s^8). \tag{6.cdxxxvi}$$

Here $F_{12} = -2r^2\sigma^3$ and $D_1^2 F_{12} = D_2^2 F_{12} = -4r^2 F_{12}$, giving exactly the two coefficients in eq. 6.cdxxx. Ordinary derivatives of F vanish in this test, so replacing the covariant derivatives by ordinary ones would fail the check.

6.15.6. *Summing over the lattice with a controlled remainder.* For a compactly supported connection let its support lie inside $(-\ell/2 + 1, \ell/2 - 1)^4$. Assume $0 < a \le 1$ and $\ell/(2a) \in \mathbb{N}$. Define the torus link variables by transport along each positive bond. Since A vanishes in the boundary collar, a plaquette crossing a torus face agrees with the corresponding square in $\mathbb{R}^4$. The complete unweighted action is therefore exactly

$$A(U) = \sum_{\mu<\nu} \sum_{x \in a\mathbb{Z}^4} G_{\mu\nu}\left(a, x + \tfrac{a}{2}(e_\mu + e_\nu)\right). \tag{6.cdxxxvii}$$

Only finitely many summands are nonzero. The same formula with a weight at the barycentre defines $A(h, U)$.

We record the quadrature estimate so the error in the action is quantitative. For $\varphi \in C_c^\infty(\mathbb{R}^4)$ and any offset $v \in \mathbb{R}^4$,

$$\left| a^4 \sum_{n \in \mathbb{Z}^4} \varphi(a(n + v)) - \int \varphi \right| \le C a^5 \max_i \|\partial_i^5 \varphi\|_{L^1}. \tag{6.cdxxxviii}$$

To prove it, periodize $r \mapsto \varphi(ar)$ on the unit torus. Its Fourier coefficient at $k \in \mathbb{Z}^4$ is $a^{-4}\widehat{\varphi}(2\pi k/a)$, with $\widehat{\varphi}(\xi) = \int e^{-i\xi\cdot x}\varphi(x)\, dx$. The Fourier series converges absolutely after five integrations by parts. Evaluating it at v gives

$$a^4 \sum_n \varphi(a(n + v)) = \sum_{k \in \mathbb{Z}^4} e^{2\pi i k\cdot v}\widehat{\varphi}(2\pi k/a). \tag{6.cdxxxix}$$

For $k \ne 0$ choose a coordinate with $|k_i| = |k|_\infty$ and integrate five times in that coordinate. The term is bounded by $(a/(2\pi|k|_\infty))^5 \|\partial_i^5\varphi\|_1$. The number of points in the shell $|k|_\infty = m$ is $O(m^3)$, so the nonzero-frequency sum converges and proves eq. 6.cdxxxviii. The offset occurs only in phases, giving the asserted uniformity.

Proposition 6.36 (The weighted and unweighted smooth Wilson expansion)**.** For a fixed smooth compactly supported A and a smooth weight h, bounded with its derivatives near that support, one has

$$A(h,U)=\frac{1}{4}\int h\sum_{\mu,\nu}|F_{\mu\nu}|^2+a^2\int h\left(-\frac{O_1}{24}+\frac{Q}{48}\right)+\mathcal{E}_{A,h}(a),\qquad |\mathcal{E}_{A,h}(a)|\le C_{A,h}a^4. \tag{6.cdxl}$$

The constant depends on finitely many smooth norms and a support bound for A,h, and is independent of the torus side, the number of sites and the coupling. In particular,

$$\beta A(U)=\frac{\beta}{4}\int\sum_{\mu,\nu}|F_{\mu\nu}|^2-\frac{a^2\beta}{24}\int O_1+O_A(\beta a^4). \tag{6.cdxli}$$

The divergence is removed only in this unweighted formula. ■

Proof. Denote the coefficients in eq. 6.cdxxx by $c_4^{\mu\nu}$ and $c_6^{\mu\nu}$. They and the remainders have support in one fixed compact set K. There are at most $C(\operatorname{diam}K+1)^4a^{-4}$ relevant mesh points. The sum of the pointwise $O(a^8)$ remainders is consequently $O_{A,h}(a^4)$.

Apply eq. 6.cdxxxviii to $hc_4^{\mu\nu}$ and $hc_6^{\mu\nu}$, with $v=(e_\mu+e_\nu)/2$. The errors in replacing their sums by integrals are $O_{A,h}(a^5)$ and $O_{A,h}(a^7)$ after the additional a^2 factor. Both are bounded by $C_{A,h}a^4$. The leading coefficient satisfies $\sum_{\mu<\nu}c_4^{\mu\nu}=\frac{1}{4}\sum_{\mu,\nu}|F_{\mu\nu}|^2$. For the next coefficient set

$$Y=\sum_{\mu,\nu}\langle F_{\mu\nu},D_\mu^2F_{\mu\nu}\rangle. \tag{6.cdxlii}$$

Pairing the two ordered orientations gives $\sum_{\mu<\nu}c_6^{\mu\nu}=Y/24$ exactly. Applying the product rule twice gives $Q=2O_1+2Y$. Thus the summed pointwise coefficient is $-O_1/24+Q/48$, proving eq. 6.cdxl. For $h=1$, the compact support makes $\int Q=0$. Multiplication by β proves eq. 6.cdxli with its stated dependence on β. □

Equivalently the weighted second coefficient is

$$-\frac{1}{24}\int hO_1+\frac{1}{48}\sum_\mu\int(\partial_\mu^2h)\sum_\nu|F_{\mu\nu}|^2. \tag{6.cdxliii}$$

This displays the source or shell contribution explicitly. It is an integration-by-parts identity for smooth fields, not a reason to omit Q before localizing the action.

The expansion may be differentiated for a specified smooth finite parameter family, but not by differentiating a bare big-O inequality. Suppose $A(t,x),h(t,x)$ are smooth for t in a compact interval, have a common support bound for the connections, and the derivatives used above are uniformly bounded. Apply the Taylor proof directly to $\partial_t^mG(s,y;t)$: this function is still even in s, and its eighth s derivative is uniformly bounded on the compact parameter set. The quadrature proof applies to the differentiated coefficients as well. It follows that for each fixed m,

$$\left|\partial_t^m\mathcal{E}_{A(t),h(t)}(a)\right|\le C_ma^4. \tag{6.cdxliv}$$

The hypotheses are smooth classical family bounds; they are not uniform bounds on fields distributed by the lattice Gibbs law.

6.15.7. *What the classical calculation supplies to the Ward problem.* The classification excludes scalar, antisymmetric and vector partners in the stated dimensions by finite colour and coordinate algebra. It proves that the dimension-six rotational obstruction has two directions as a density, one after the specified divergences are removed, and still one after the field-equation quotient. The Wilson expansion identifies the coefficient of that last direction as $-a^2\beta/24$, while retaining the weighted divergence with coefficient $a^2\beta/48$. These conclusions are off-shell identities or controlled classical asymptotics in their declared test spaces.

To make the bulk term of the interacting rotational Ward identity vanish, one still needs the actual typed insertion estimates, their source formation and normalization, the required treatment of equation-of-motion insertions under the measure, and the shell or volume transfer bounds. A smooth-field expansion is not uniform on the rough lattice fields in that measure. The factors a^2 and the absence of lower-dimensional partners do not, by themselves, prove the quantum estimate. The finite exact Ward identity and the interacting bounds remain distinct parts of that argument.

6.16. **Euclidean evolution from separated moments.** This section proves a conditional reconstruction on compactly supported separated test tuples. The time contraction follows from a bound which is uniform in the positions of finitely many supports. No estimate on arbitrary Schwartz sequences, and no bound uniform in the number of fields, enters that argument. A further lattice approximation hypothesis gives a spectral cone with a cubical spatial section. The round cone and continuous rotations require additional input.

6.16.1. *The precise compact test domain.* Put $\mathcal{D} = C_c^1(\mathbb{R}^4;\mathbb{C})$ and use the norm

$$\|f\|_1 = \max\{\|f\|_\infty, \|\nabla f\|_\infty\}.$$

A separated tuple $X = (f_1, \dots, f_n)$ has compact supports at pairwise positive distance. The empty tuple is denoted by 1. Write $\mathscr{V}$ for the complex vector space of finite formal linear combinations of these tuples. Multilinear and permutation relations may be imposed at the outset; equivalently they will be null relations in the forms below. Concatenation $X \cdot Y$ is used only if the supports of all its entries remain separated. There is no claim that $\mathscr{V}$ is an algebra under unrestricted concatenation.

Our translation convention is $\tau_v f(x) = f(x - v)$, so its support is translated by v. For the time reflection $\theta(x_1, x_2, x_3, x_4) = (x_1, x_2, x_3, -x_4)$ put $\theta f = f \circ \theta$. These maps act entrywise on tuples and linearly on formal combinations. The bar conjugates both the coefficients and the test functions. Let $\mathscr{V}_+$ consist of combinations whose entries have supports compactly contained in $\mathbb{E}_+ = \{x_4 > 0\}$.

Assume normalized symmetric multilinear moments S_n on this separated domain. Write $\sigma(X) = S_n(f_1, \dots, f_n)$, $\sigma(1) = 1$, and extend linearly. They obey the following hypotheses. They preserve conjugation, are translation invariant, and are invariant under the coordinate reflections. Their reflection-positive form satisfies

$$q(F, F) := \sigma(\overline{\theta F} \cdot F) \geq 0 \qquad (F \in \mathscr{V}_+). \tag{6.cdxlv}$$

This is positivity for every finite linear combination, including the empty tuple, rather than just for individual monomials. The concatenations in eq. 6.cdxlv and its polarized form are separated: reflected supports lie strictly below time zero, and the others strictly above it.

For every integer $n \geq 1$, $R < \infty$ and $d > 0$, assume a finite number $M_n(d, R)$ such that

$$|S_n(f_1, \dots, f_n)| \leq M_n(d, R) \prod_{i=1}^{n} \|f_i\|_1, \tag{6.cdxlvi}$$

whenever each support is in a ball of radius R, centered anywhere, and their pairwise distances are at least d. The centers need not lie in a common bounded region. For one entry the separation condition is empty. These are moment bounds, not merely cumulant bounds. Bounds on cumulants give eq. 6.cdxlvi after the finite moment–cumulant sum, if the needed one-point bound is included. There is no restriction here on the growth of M_n as n increases or d decreases.

Proposition 6.37 (Compact-tuple Euclidean reconstruction)**.** Under eq. 6.cdxlv–eq. 6.cdxlvi and the stated invariances, the completion of $\mathscr{V}_+$ by its reflection form is a separable Hilbert space $\mathcal{H}$. The empty tuple has class Ω of norm one. The formulas

$$\begin{gathered} T_t[F] = [\tau_{te_4} F] \\ (t \geq 0), \\ U_x[F] = [\tau_{(x,0)} F] \\ (x \in \mathbb{R}^3) \end{gathered} \tag{6.cdxlvii}$$

define, respectively, a strongly continuous semigroup of positive self-adjoint contractions and a strongly continuous unitary representation. They commute and fix Ω. There is a unique nonnegative self-adjoint operator H with $T_t = e^{-tH}$. Each T_t, $t > 0$, is injective. The spatial generators P_i and H commute strongly. ∎

6.16.2. *The quotient and the contraction proof.* Positivity of the quadratic form gives Hermiticity by polarization and the Cauchy–Schwarz inequality $|q(F,G)|^2 \leq q(F,F)q(G,G)$. Thus $\mathscr{N} = \{F : q(F,F) = 0\}$ is a linear subspace orthogonal to everything. The quotient $\mathscr{V}_+/\mathscr{N}$, with inner product q, is pre-Hilbert; its completion defines $\mathcal{H}$. In particular $\|\Omega\|^2 = \sigma(1) = 1$ and $\langle \Omega, [F] \rangle = \sigma(F)$.

Time and spatial translations in eq. 6.cdxlvii preserve their positive-time domain. Translation invariance and $\theta \tau_{te_4} = \tau_{-te_4} \theta$ give

$$\begin{aligned} q(F, \tau_{te_4} G) &= q(\tau_{te_4} F, G), \\ q(\tau_{(x,0)} F, \tau_{(x,0)} G) &= q(F,G). \end{aligned} \tag{6.cdxlviii}$$

The second identity proves that spatial translations preserve null vectors and induce isometries with inverse U_{-x}. For the first identity, boundedness of the induced time maps remains to be proved; symmetry alone would not suffice.

Fix $F = \sum_\alpha c_\alpha X_\alpha \in \mathscr{V}_+$. There are $\delta > 0$, $d > 0$ and $R < \infty$ such that every entry has time coordinate at least δ, every individual tuple has internal separation at least d, and each entry has support in a ball of radius R. For every $s \geq 0$, every concatenation $\overline{\theta \tau_{se_4} X_\alpha} \cdot \tau_{se_4} X_\beta$ has internal separation at least $d_* = \min\{d, 2\delta\} > 0$. Indeed its two groups lie below $-\delta - s$ and above $\delta + s$. Moving the groups apart changes their centers but not their radii, norms or internal separations. Applying eq. 6.cdxlvi to the finitely many pairs gives

$$\sup_{s \geq 0} \|\tau_{se_4} F\|_q \leq C_F < \infty. \tag{6.cdxlix}$$

The same assertion covers empty entries and constants by normalization. Its essential hypothesis is that the bound is independent of support positions. A bound with a growing enclosing-volume factor would not prove eq. 6.cdxlix.

Write $a(s) = \|\tau_{se_4} F\|_q$. Symmetry and Cauchy–Schwarz give

$$a(t)^2 = q(F, \tau_{2te_4} F) \leq a(0) a(2t).$$

Iteration yields

$$a(t) \leq a(0)^{1-2^{-k}} a(2^k t)^{2^{-k}} \leq a(0)^{1-2^{-k}} C_F^{2^{-k}}. \tag{6.cdl}$$

If $a(0) = 0$, the first inequality already proves $a(t) = 0$. Otherwise let $k \to \infty$ to obtain $a(t) \le a(0)$. Consequently time translations preserve $\mathscr{N}$ and extend to contractions on $\mathcal{H}$. Their symmetry in eq. 6.cdxlviii makes each bounded extension self-adjoint. Moreover

$$q(F, \tau_{te_4} F) = q(\tau_{(t/2)e_4} F, \tau_{(t/2)e_4} F) \ge 0,$$

so every T_t is positive. The semigroup law is inherited from the exact translation law on the dense domain.

6.16.3. *Continuity, generators and elementary consequences.* For $f \in C^1_c$, uniform continuity of ∇f gives

$$\|\tau_h f - f\|_1 \le \max\left\{ |h| \|\nabla f\|_\infty, \sup_{|x-y|\le|h|} |\nabla f(x) - \nabla f(y)| \right\} \longrightarrow 0. \tag{6.cdli}$$

This statement need not hold in the Lipschitz norm for a merely Lipschitz function. To apply it to a moment, enclose the old and slightly moved supports of each entry in one common neighborhood. For sufficiently small shifts these neighborhoods retain half their original positive separation. The multilinear telescoping identity and eq. 6.cdxlvi then bound the change of a moment by a constant times the sum of the C^1 changes of its entries. Differences of functions are evaluated only on those fixed neighborhoods.

Expanding $\|[\tau_h F] - [F]\|^2$ into its finitely many moment terms and using this observation proves convergence to zero for $h = te_4$, $t \downarrow 0$, and for spatial $h \to 0$. The contraction and unitary bounds extend this continuity from the dense quotient domain to all of $\mathcal{H}$. The semigroup and group laws then give strong continuity at every parameter.

Here is a construction of the generator which also rules out a hidden zero-transfer subspace. If $T_1 v = 0$, positivity and $T_1 = T_{1/2}^2$ give $T_{1/2} v = 0$. Repeated halving and strong continuity at zero imply $v = 0$. Thus the spectral measure of T_1 has no atom at zero. Define the densely defined self-adjoint operator $H = -\log T_1$ by functional calculus; its spectrum is nonnegative. Uniqueness of positive roots gives $T_{m/n} = T_1^{m/n}$ for nonnegative rationals, and strong continuity gives $T_t = e^{-tH}$ for all $t \ge 0$. Functional calculus also proves uniqueness of H and injectivity of every T_t, $t > 0$. Since translations fix the empty tuple, $H\Omega = 0$ and $U_x \Omega = \Omega$.

The commuting spatial unitaries have self-adjoint generators $U_x = e^{i \sum_i x_i P_i}$. They commute with T_1 and hence with its spectral projections and with H. The joint spectral theorem, equivalently the spectral theorem for the strongly continuous abelian unitary group $(s, x) \mapsto e^{isH} U_x$, supplies one projection-valued measure E on $[0, \infty) \times \mathbb{R}^3$. Here and below strong commutation means commutation of these spectral projections. For $F, G \in \mathscr{V}_+$, $t \ge 0$ and $x \in \mathbb{R}^3$ the dictionary is

$$\begin{aligned} \sigma(\overline{\theta F}\, \tau_{(x,t)} G) &= \langle [F], e^{-tH} U_x [G] \rangle \\ &= \int e^{-tE + ix\cdot p} \langle [F], \mathsf{E}(dE\, dp)[G] \rangle. \end{aligned} \tag{6.cdlii}$$

For completeness, the quotient is separable. Cover compact positive-time supports by finite unions of rational boxes with closures still in $\mathbb{E}_+$; choose these unions separately for each entry so that they remain separated. There are countably many such finite systems. On each fixed bounded union, the C^1 space is separable: restriction of a function and its four derivatives embeds it isometrically in a finite product of separable continuous-function spaces. Choose countable dense subsets inside the supported C^1 spaces, and rational complex coefficients for formal combinations. Telescoping with eq. 6.cdxlvi, on the fixed separated neighborhoods, shows that the resulting countable set is total in $\mathcal{H}$.

The formal description does not create extra vectors from zero tensors. For a finite homogeneous relation $\sum_\alpha c_\alpha f_{\alpha,1} \otimes \cdots \otimes f_{\alpha,n} = 0$ whose tuples are separated, choose $d > 0$ below all their separations. Localize every entry with one finite smooth partition covering their supports, whose sets have diameter less than $d/8$. In a product of partition sets, either two sets have distance less than $d/2$, in which case every original tensor has a zero factor there, or all the slot sets remain separated. In the latter case the moment is multilinear on the product of their supported function spaces and hence is a linear functional on their algebraic tensor product. The map from this tensor product into functions on the Cartesian product is injective: on the finitely many function spans involved, independent functions can be distinguished by finitely many point evaluations, and the corresponding evaluation matrices invert each slot. Thus the localized zero tensor has zero moment. Summing proves the assertion. Applying it also after concatenation with a reflected test shows that a zero tensor is a reflection-null vector. This is an algebraic compact-support fact, distinct from the Schwartz density input below.

Any realization with a dense image of the same test domain and the same scalar products is therefore canonically unitarily equivalent, by sending each test class to its other realization; the generators intertwine by density. The construction can use any coordinate as time if its RP hypothesis is supplied. For $c \geq 0$ and F supported strictly above time c, the exact identity is $[F] = T_c[\tau_{-ce_4}F]$.

Any further linear symmetry of the moments which preserves positive time and commutes with θ acts isometrically on this quotient. In particular, if the moments also have the spatial signed-permutation symmetry W_3, then $V_w[F] = [wF]$ is unitary, $V_w T_t = T_t V_w$ and $V_w U_x V_w^{-1} = U_{wx}$. Uniqueness of the joint spectral measure gives the corresponding covariance under $(E, p) \mapsto (E, wp)$ and hence W_3 symmetry of the joint spectrum. This optional finite symmetry is not continuous rotation invariance.

Spectral dominated convergence gives $T_t \to P_0 = 1_{\{0\}}(H)$ strongly as $t \to \infty$. Hence the large-time reflected correlations equal the matrix elements of P_0. In particular, $\ker H = \mathbb{C}\Omega$ exactly when their limits, or their Cesàro limits, equal $\overline{\sigma(F)}\sigma(G)$ for every positive-time F, G. If $\sigma(f) = 0$ and $S_2(\theta\bar{f}, f) > 0$ for one positive-time test, then $[(f)]$ is a nonzero vector orthogonal to Ω, so $\dim \mathcal{H} \geq 2$; this requires an actual positive two-point input.

A shift of the fields does not change this representation. More precisely, let m be a complex linear, translation- and reflection-invariant functional on $\mathcal{D}$, satisfying $m(\bar{f}) = \overline{m(f)}$ and bounded on each fixed compact support. Define

$$C_m(f_1, \ldots, f_n) = \sum_{A \subset \{1,\ldots,n\}} \prod_{i \notin A} [-m(f_i)]\, (f_i)_{i \in A},$$

$$\sigma^{\mathrm{c}}(F) = \sigma(C_m F).$$

Then C_{-m} is the inverse of C_m, and on every admissible concatenation $C_m(FG) = C_m(F)C_m(G)$. It commutes with the bar, reflections and translations. Therefore $[F]_{\sigma^{\mathrm{c}}} \mapsto [C_m F]_\sigma$ is a unitary intertwining the two evolutions. Its finite expansion also transfers in eq. 6.cdxlvi, since local boundedness and translation invariance bound m uniformly on balls of each fixed radius. This algebraic statement does not estimate the size of the one-point difference between two cutoff states.

In the particular unweighted Wilson-density normalization, the one-point calibration can be written explicitly. Let two states ρ_j, ν_j on spacing a_j be translation and hypercubic invariant, and put $\mathcal{O}_j(f) = \sum_p f(x(p))a_p$. Their plaquette mean difference $d_j = \rho_j(a_p) - \nu_j(a_p)$ is independent of p. Define

$$R_j(f) = \frac{a_j^4}{6} \sum_p f(x(p)),$$

$$c_j = 6a_j^{-4} d_j.$$

Then $\rho_j(\mathcal{O}_j(f)) - \nu_j(\mathcal{O}_j(f)) = c_j R_j(f)$ exactly, and the six shifted Riemann sums give $R_j(f) \to \int f$. If these one-point differences converge to $m(f)$ on all compact C^1 tests, choose one f_0 with $\int f_0 = 1$. The ratio at f_0 shows $c_j \to m(f_0) = c$, and consequently $m(f) = c \int f$ for every test. A uniform one-point bound at f_0 bounds $|c|$; this bound is an input, not a consequence of translation invariance alone. When the two states coincide, $c_j = c = 0$.

6.16.4. *Coarse lattice inequalities and the continuum cube cone.* The spectral cone needs additional information. Assume infinite-lattice probability measures ν_j at spacings $a_j \downarrow 0$, invariant under lattice translations and reflection positive on the closed side of all coordinate and diagonal lattice mirrors. Their moment forms will be denoted by $S_n^{(j)}$. For periodic Wilson DLR states these hypotheses are proved in Prop. A.11. For other lattice measures they remain explicit assumptions. The normal transfer T_j and tangential translation $V_{j,i}$ in their reflection Hilbert spaces then have the carrier established in the plateau argument:

$$\begin{aligned} \sinh(E/2) &\geq |\sin(p/2)|, \\ T_j &= e^{-E}, \\ V_{j,i} &= e^{ip}. \end{aligned} \tag{6.cdliii}$$

Here E is dimensionless and may be infinity on $\ker T_j$, while p is a circle variable. Only this lattice carrier, rather than a round relativistic cone, is assumed from that argument.

One lattice distinction is useful. For spacing a, the site mirror at zero and the link mirror at $-a/2$ have the same positive-side lattice algebra. Their forms obey $q_{\text{link}}(A, B) = q_{\text{site}}(A, TB)$, by translation invariance. Consequently $[A]_{\text{link}} \mapsto T^{1/2}[A]_{\text{site}}$ is an isometry onto the closure of $\operatorname{Ran} T^{1/2}$, namely $(\ker T)^\perp$. It intertwines the two normal transfers, since this holds on the common local domain. Thus the link transfer is injective, even if the site transfer has a kernel. This proves the relation between the two pictures without discarding site-kernel contributions in eq. 6.cdlv.

For every integer $k \geq 1$, convexity of sinh and the elementary inequality $|\sin(kv)| \leq k|\sin v|$ give

$$\sinh(kE/2) \geq k \sinh(E/2) \geq k|\sin(p/2)| \geq |\sin(kp/2)|. \tag{6.cdliv}$$

The sine inequality follows by induction from the addition formula and $|\cos v| \leq 1$. Thus functional calculus gives the bounded operator inequality

$$(I - T_j^k)^2 \geq T_j^k (2I - V_{j,i}^k - V_{j,i}^{-k}). \tag{6.cdlv}$$

At $T_j = 0$ this inequality holds directly, so no division by a transfer eigenvalue is required. Its quadratic form is a five-point inequality. If $s = ka_j$ and $\Phi_{j,F}(v) = \nu_j(\overline{\theta F_j}\, \tau_v F_j)$, it reads

$$\Phi_{j,F}(0) - 4\Phi_{j,F}(se_4) + \Phi_{j,F}(2se_4) + \Phi_{j,F}(se_4 + se_i) + \Phi_{j,F}(se_4 - se_i) \geq 0. \tag{6.cdlvi}$$

To pass to the limit, use the following approximation between cutoffs. Assume linear local lattice bounded Borel representatives $\iota_j(f)$ for compact C^1 tests. Their supports lie within distance $\epsilon_j \to 0$ of $\operatorname{supp} f$. They commute with coordinate reflection and with translations by $a_j\mathbb{Z}^4$. Let F_j be the product representative of each tuple, extended linearly, and let $S_n^{(j)}$ be its moments. Assume convergence on every fixed separated compact tuple to S_n, and assume eq. 6.cdxlvi for these lattice moments with constants independent of j once j is sufficiently large for the fixed n, d, R. For $\operatorname{tr}(F^2)$ representatives their supremum norms may depend on j; the asserted uniform control is on these moments.

If $v_j \to v$, the supports of $\tau_{v_j} f$ and $\tau_v f$ lie in fixed slightly enlarged sets. Whenever the limiting tuple is separated, these sets retain a positive separation. Telescoping and the uniform moment bound give

$$S_n^{(j)}(f_{1,j}, \dots, f_{n,j}) - S_n^{(j)}(f_1, \dots, f_n) \longrightarrow 0 \tag{6.cdlvii}$$

for such translated tests, by eq. 6.cdli. Together with fixed-tuple convergence, this proves convergence at the moving arguments.

The same argument also explains inheritance of the Hilbert hypotheses from these approximants, when it is needed. A continuum translation is approached by lattice vectors v_j; exact lattice covariance and eq. 6.cdlvii pass its moment identity to the limit. Coordinate reflections through the origin need no rounding. For any fixed $F \in \mathscr{V}_+$ the representatives F_j lie on the positive side for large j, so their finite quadratic RP inequalities pass directly to eq. 6.cdxlv. Normalization, conjugation, multilinearity and the uniform moment bounds pass by their finite defining relations. The lattice mirror hypotheses themselves are supplied by Prop. A.11 in the periodic Wilson application.

There is also a finite-torus scalar-product statement, with a narrower conclusion. If fixed separated moments converge from growing periodic tori and satisfy uniform C^1 bounds on the fixed neighborhoods under consideration, RP at the link mirror $x_4 = a_j/2$ gives

$$q(F, G) = \lim_j \nu_j(\overline{\theta_{a_j/2} F_j}\, G_j).$$

Indeed $\theta_{a_j/2} f = \tau_{a_j e_4} \theta f$, whose difference from θf tends to zero in C^1, and the same telescoping estimate applies. This compares scalar products as numbers; it asserts no maps between the cutoff Hilbert spaces. Finite-torus positivity of this kind does not by itself supply the global lattice semigroup or eq. 6.cdliii.

Fix $t > 0$ and choose integers $k_j \geq 1$ with $k_j a_j \to t$. For positive-time F, its lattice representative is supported on the positive side of the fixed site mirror for large j. All five moment expressions in eq. 6.cdlvi are separated uniformly: the negative reflected group and every translated positive group retain their original positive-time margin. Internal separations are unchanged. Therefore eq. 6.cdlvii passes eq. 6.cdlvi to its continuum version. In $\mathcal{H}$ this is

$$B_{t,i} := (I - T_t)^2 - T_t(2I - U_{te_i} - U_{-te_i}) \geq 0. \tag{6.cdlviii}$$

Initially its form is nonnegative on the dense compact-tuple domain; since $B_{t,i}$ is bounded and self-adjoint, the inequality holds on all of $\mathcal{H}$. No differentiation of a cutoff correlation at $t = 0$ has been used. The fixed-time coarse inequality is passed first.

In the joint functional calculus its multiplier is

$$b_{t,i}(E, p) = 1 - 4e^{-tE} + e^{-2tE} + 2e^{-tE}\cos(tp_i) = 2e^{-tE}[\cosh(tE) + \cos(tp_i) - 2]. \tag{6.cdlix}$$

Take a countable sequence $t_m \downarrow 0$, for example $t_m = 1/m$. Positivity of eq. 6.cdlviii means that the joint projection-valued measure gives zero mass to $\{b_{t_m,i} < 0\}$. Remove the countable union of those sets for the three spatial indices. At every remaining spectral point,

$$0 \leq \lim_{m\to\infty} \frac{\cosh(t_m E) + \cos(t_m p_i) - 2}{t_m^2} = \tfrac{1}{2}(E^2 - p_i^2).$$

Since $E \geq 0$, this proves

$$\mathsf{E}\{(E, p) : E < \max_i |p_i|\} = 0. \tag{6.cdlx}$$

In particular $\operatorname{Dom} H \subset \operatorname{Dom} P_i$ and $\|P_i\psi\| \le \|H\psi\|$ on that domain. The corresponding form-domain statement follows by integrating $|p_i| \le E$ rather than their squares. Zero-energy vectors are spatially invariant. Consequently vectors fixed by all Euclidean time and spatial translations are exactly $\ker H$. This statement concerns invariant Hilbert vectors; identifying them with an ergodic decomposition of correlation states needs the separate phase argument. The cone in eq. 6.cdlx has a cubical spatial section. Nothing here proves $E \ge |p|_2$ or supplies an O(4) action. Finite periodic torus laws cannot simply be substituted for the infinite lattice hypotheses at arbitrarily large separations; any required infinite-volume reflection-positive state must first be obtained.

6.16.5. *What the full Schwartz sequence domain additionally needs.* The compact-tuple construction above does not establish the claimed Schwartz-domain growth property. Here is a precise sufficient additional input for that extension. For $n \ge 2$ put $\Delta_n = \bigcup_{i<j}\{x_i = x_j\}$ and let $\mathcal{S}_{\Delta,n}$ be the Schwartz functions on $\mathbb{R}^{4n}$ whose derivatives of every order vanish on Δ_n. Use $\mathcal{S}_{\Delta,0} = \mathbb{C}$ and the usual Schwartz space for $n = 1$. Define the seminorms

$$p_k(\varphi) = \max_{|\alpha|\le k} \sup_x (1 + |x|^2)^{k/2} |\partial^\alpha \varphi(x)|.$$

The positive-time subspace $\mathcal{S}_{\Delta,+,n}$ consists of functions all of whose derivatives vanish outside $\{x_{1,4} > 0, \dots, x_{n,4} > 0\} \setminus \Delta_n$. This includes flatness at the time boundary, as well as at the diagonals.

The separate continuity/growth input, called H1 here, supplies continuous linear moment functionals Σ_n on these full diagonal-flat spaces, agreeing with the compact smooth separated tensors, and constants $c, C < \infty$, $k \in \mathbb{N}$, $\varkappa < \infty$ such that

$$|\Sigma_n(\varphi)| \le c C^n (n!)^{\varkappa} p_{kn}(\varphi). \tag{6.cdlxi}$$

This is a condition on moments, not just connected functions. It is not a consequence of having a finite $M_n(d, R)$ for every fixed triple of parameters. The Density lemma of § 7.14 proves that finite linear combinations of smooth compact separated tensors are dense in $\mathcal{S}_{\Delta,n}$, and those with strictly positive-time supports are dense in $\mathcal{S}_{\Delta,+,n}$, in their Schwartz subspace topologies. These assertions include the necessary cutoffs at infinity, at the time boundary, and near the diagonals. They cannot be replaced by ordinary tensor density without those constraints.

Using H1 and that density lemma, the finite Schwartz sequence space $\bigoplus_{n\ge 0} \mathcal{S}_{\Delta,+,n}$ has form $\sum_{m,n} \Sigma_{m+n}(\overline{\theta F_m} \otimes G_n)$. The tensor here lies in the diagonal-flat space: an internal coincidence is killed by the corresponding factor, and a coincidence between a negative and a positive time argument forces the common time to zero, where the factors are flat. Tensor multiplication is continuous in the Schwartz topologies. Thus H1 and tensor density transfer the compact reflection positivity and show that its quotient completion is canonically the same $\mathcal{H}$. Compact C^1 tuples themselves are approximated by compact smooth ones inside the same separated positive-time neighborhoods, using eq. 6.cdxlvi. The already proved contraction and unitary groups then extend by this identification. The use of H1 here is its continuity on the enlarged domain; eq. 6.cdlxi also records the additional quantitative growth claim needed when that OS hypothesis is asserted. The compact construction does not supply the factorial constants in H1; the constrained tensor-density proof is given in the cited section.

7. Reconstruction and canonical components

This section passes from the Euclidean functionals to scalar quantum fields. We first construct the spectral and common-domain objects and compare their moments with the reconstructed theory. The compact decomposition then identifies the canonical components and their vacuum spaces. The final reconstruction statement records the precise growth, positivity, covariance and clustering

hypotheses. The intervening observable-algebra results specify the information carried by the scalar field and the additional requirements for extending it to gauge observables.

7.1. **Complex translations and reconstruction domains.** The diagonal-flat growth theorem controls the order of the moment functionals. The Euclidean Hilbert construction gives the Hilbert space and its evolution. We match their domains here, prove the round spectral cone and a joint complex translation theorem for that evolution, and specify the field domain obtained once the Minkowski distributions have been constructed. The translation theorem here has fixed-vector scope. The actual field-product continuation is constructed in § 7.2; the explicit reconstruction norm estimates and the locality theorem are matched in § 7.3.

The exact test-space match. Let $\mathcal{S}_{\Delta,n}$ be the Schwartz functions on $\mathbb{R}^{4n}$ whose every derivative vanishes whenever two four-dimensional arguments coincide. Write

$$p_j(f) = \max_{|\alpha|\le j} \sup_x (1+|x|^2)^{j/2} |\partial^\alpha f(x)|. \tag{7.i}$$

The quantitative flat-extension theorem gives, under its actual source hypotheses, normalized symmetric moments with

$$|S_n(f)| \le A B^n (n!)^{k+32} p_{20n}(f). \tag{7.ii}$$

This is the diagonal-flat version of the growth requirement. If $B_+ = \max(1, B)$, the elementary inequality $n! \ge 2^{n-1}$ gives

$$B^n \le B_+ (n!)^{\log_2 B_+}, \qquad \sigma_n = A B_+ (n!)^{k+32+\lceil \log_2 B_+ \rceil}. \tag{7.iii}$$

Thus $|S_n(f)| \le \sigma_n p_{20n}(f)$, with one linear order coefficient and factorial σ_n. No unquantified change of seminorm order has occurred.

The applicable external result is the corrected scalar theorem $E' \to R'$ with $E0'$, in [OS75, Section IV.1, pp. 287–289]. The exact diagonal-flat seminorm comparison is given in Prop. 7.5. In particular the proved weighted order $20n$ and factorial exponent $k+32$ imply the safe total-monomial order $40n$, with an explicit additional factorial exponent twenty and exponential constant. Thus the actual growth is sufficient without identifying two seminorm conventions by an unspecified dimension-dependent constant. We retain its Euclidean covariance, positivity, symmetry, reality and clustering requirements. The argument here does not replace that result by an assertion about independently continuous correlations or assign an ordinary Euclidean contact prescription.

The positive-time space already used in § 6.16 is denoted by $\mathcal{S}_{\Delta,+,n}$. Its functions are flat outside the region of distinct arguments with all times positive. Define also

$$\begin{aligned} O_n &= \{0 < t_1 < t_2 < \cdots < t_n\}, \\ \mathcal{S}_{\mathrm{ord},n} &= \{f \in \mathcal{S}(\mathbb{R}^{4n}) : \partial^\alpha f = 0 \text{ on } O_n^c \text{ for every } \alpha\}. \end{aligned} \tag{7.iv}$$

The ordered spaces, used in the historical positivity convention [OS73, Sections 2–3], are subspaces of $\mathcal{S}_{\Delta,+,n}$. Set both degree-zero spaces to $\mathbb{C}$, and use finite direct-sum sequences throughout.

Let $\mathcal{K}$ be the completed full positive-time quotient, with its proved form

$$q(F,G) = \sum_{m,n} S_{m+n}(\Theta \overline{F_m} \otimes G_n). \tag{7.v}$$

The historical reflected form also reverses the first group of arguments. Scalar permutation symmetry makes the two forms equal on the ordered subspace. Restriction of eq. 7.v consequently gives an isometry of its ordered quotient into $\mathcal{K}$. Denote its closed range by $\mathcal{K}_{\mathrm{ord}}$.

Proposition 7.1 (The ordered sector and its inherited evolution)**.** The subspace $\mathcal{K}_{\mathrm{ord}}$ contains the vacuum and reduces the positive-time contractions $T_t = e^{-tH}$ and all spatial translations $U_a = e^{ia\cdot P}$. Their restrictions are strongly continuous, have the restricted joint spectral measure, and have the same nonnegative Hamiltonian in functional calculus. Separability, spatial clustering and a one-dimensional kernel of H, when established on $\mathcal{K}$, pass to this sector. ∎

Proof. Simultaneous positive-time translation preserves strict time ordering, as do all simultaneous spatial translations. The corresponding operators therefore preserve the ordered core and its closed range. For a bounded self-adjoint T_t, invariance of a closed subspace M also makes $M^\perp$ invariant: if $x \perp M$ and $y \in M$, then $\langle T_t x, y\rangle = \langle x, T_t y\rangle = 0$. Thus its projection commutes with every T_t, and hence with the spectral projections of H. Both signs of each spatial translation preserve the range, so its projection commutes with the spatial unitaries and their spectral projections as well. This proves the joint spectral restriction and the domain identity

$$\operatorname{Dom} H_{\mathrm{ord}} = \operatorname{Dom} H \cap \mathcal{K}_{\mathrm{ord}}, \qquad H_{\mathrm{ord}} = H|_{\operatorname{Dom} H_{\mathrm{ord}}}. \tag{7.vi}$$

Strong continuity restricts. The degree-zero vector belongs to the ordered sector and still has norm one. A closed subspace of a separable Hilbert space is separable. A clustering matrix-element limit restricts to any pair of its vectors. Finally, a vector annihilated by the restricted Hamiltonian lies in $\ker H$; if the latter is $\mathbb{C}\Omega$, the restricted kernel is exactly that line. □

Equality $\mathcal{K}_{\mathrm{ord}} = \mathcal{K}$ is not needed in this theorem or for these transfers to the reconstructed sector. It is not a Schwartz density statement: evaluation at a configuration with equal positive times and distinct spatial points vanishes on every ordered test, while it need not vanish on a test in $\mathcal{S}_{\Delta,+,n}$. A claim of equality of the completed Hilbert spaces would require an additional argument in the Hilbert seminorm. The imported reconstruction supplies fields on its ordered realization. The theorem above does not extend their field operators or their Lorentz boosts to a larger space.

Implementing spatial rotations on the actual quotient. Suppose now that the established Euclidean functional has spatial SO(3) covariance. This is an explicit input from the full covariance route. Neither the finite hypercubic group nor reflection positivity alone supplies it. For $R \in \mathrm{SO}(3)$ let

$$(r_R f)(\mathbf{x}_1, t_1, \dots, \mathbf{x}_n, t_n) = f(R^{-1}\mathbf{x}_1, t_1, \dots, R^{-1}\mathbf{x}_n, t_n). \tag{7.vii}$$

The pullback preserves all the flat and positive-time spaces, commutes with reflection, and preserves the form in eq. 7.v. It consequently preserves its null space and gives an isometry $V_R[F] = [r_R F]$ with inverse $V_{R^{-1}}$. This defines unitaries on the actual completed quotient.

We check their continuity. For each fixed n, j, the chain rule and the orthogonality of R bound $p_j(r_R f)$ locally uniformly by a constant times $p_j(f)$. Near identity write $R = e^A$, where A is skew and $\|A\| \le C\|R - I\|$. Differentiation along e^{sA} inserts $\sum_i (A\mathbf{x}_i)\cdot\nabla_{\mathbf{x}_i}$, up to the pullback sign. Its coordinate factors consume one weight and its derivative consumes one derivative. Thus

$$p_j(r_R f - f) \le C_{n,j}\|R - I\| p_{j+1}(f) \tag{7.viii}$$

for R in a fixed neighbourhood of identity. Continuity at every rotation follows by composition. Tensor multiplication is continuous in the Schwartz topology, and each S_{m+n} is continuous on its flat domain. Expanding $\|[r_R F] - [F]\|^2 = q(r_R F - F, r_R F - F)$ therefore gives convergence to zero for each finite-sequence class. These classes are dense; unitarity extends the convergence to every vector of $\mathcal{K}$. Hence $R \mapsto V_R$ is a strongly continuous unitary representation. The same proof applies to $\mathcal{K}_{\mathrm{ord}}$, since rotations preserve its core.

On the dense core, the exact coordinate identities are

$$V_R T_t = T_t V_R, \qquad V_R U_a V_R^{-1} = U_{Ra}. \tag{7.ix}$$

They extend to the Hilbert space by boundedness. Uniqueness of the self-adjoint generators gives the unbounded-operator statements

$$\begin{aligned} V_R \operatorname{Dom} H &= \operatorname{Dom} H, & V_R H V_R^{-1} &= H, \\ V_R \operatorname{Dom}(a\cdot P) &= \operatorname{Dom}((Ra)\cdot P), & V_R (a\cdot P) V_R^{-1} &= (Ra)\cdot P. \end{aligned} \tag{7.x}$$

The last form states the convention without an ambiguity about whether a matrix acts on momentum components or on the translating vector. It also identifies the transformed spectral projections.

Proposition 7.2 (The round cone on the Euclidean Hilbert space)**.** Suppose the joint spectral measure E of (H, P) has the established cube carrier $E \geq \max_i |p_i|$. Under the spatial covariance just implemented,

$$\mathsf{E}\{(E,p) : E < |p|_2\} = 0. \tag{7.xi}$$

This holds on the full $\mathcal{K}$ and on its reducing ordered sector. In particular $\mathrm{Dom}\, H \subset \mathrm{Dom}\, |P|$, and $\||P|\psi\| \leq \|H\psi\|$ on that domain. ∎

Proof. Rotating the first coordinate carrier with eq. 7.x gives $\mathsf{E}\{E < |n \cdot p|\} = 0$ for every unit vector $n = Re_1$. Choose a countable dense set n_j on the unit sphere, and remove the countable union of these spectral null sets. At every remaining point, $|n_j \cdot p| \leq E$ for every j. Continuity in n and $\sup_{|n|=1} |n \cdot p| = |p|_2$ prove eq. 7.xi. Integrating $|p|_2^2 \leq E^2$ against a vector's spectral measure gives the stated domain inclusion and norm bound. Integrating $|p|_2 \leq E$ also gives the corresponding form-domain statement. Restriction to a reducing subspace restricts the same measure. □

This argument uses spatial rotations and the already constructed joint spectrum. It does not construct a Lorentz boost.

A joint tube of bounded complex translations. Use the joint measure just proved, and define the open parameter tube

$$\mathcal{T} = \{(z,w) \in \mathbb{C} \times \mathbb{C}^3 : \delta(z,w) := \mathrm{Re}\, z - |\,\mathrm{Im}\, w|_2 > 0\}. \tag{7.xii}$$

Joint functional calculus defines

$$\mathcal{V}(z,w) = \int e^{-zE+iw\cdot p}\, \mathsf{E}(dE\, dp). \tag{7.xiii}$$

On the carrier eq. 7.xi its multiplier has modulus at most $e^{-\delta(z,w)E}$. Thus it is a bounded operator of norm at most one. The notation $e^{-zH+iw\cdot P}$ will mean precisely this bounded operator.

Proposition 7.3 (Complex translations and their boundary)**.** The map $\mathcal{V}$ is jointly holomorphic in operator norm on $\mathcal{T}$. For $a \geq 0$, a three-dimensional multiindex α, and $m = a + |\alpha|$,

$$\|\partial_z^a \partial_w^\alpha \mathcal{V}(z,w)\| \leq m!\, \delta(z,w)^{-m}. \tag{7.xiv}$$

It obeys the addition law and its unitary real boundary is

$$\lim_{\substack{s,y\to 0 \\ s>|y|_2}} \mathcal{V}(s+it, x+iy) = e^{-itH} U_x \quad \text{strongly}. \tag{7.xv}$$

For every pair of Hilbert vectors its matrix coefficients have tempered boundary values in (t,x), with Fourier carrier $E \geq |p|_2$ in the convention $e^{-itE+ix\cdot p}$. Every assertion also holds on $\mathcal{K}_{\mathrm{ord}}$. ∎

Proof. The differentiated multiplier is $(-E)^a (ip)^\alpha e^{-zE+iw\cdot p}$. Its absolute value is at most $E^m e^{-\delta E}$, and

$$E^m e^{-\delta E} \leq m! \delta^{-m}, \tag{7.xvi}$$

as follows from the m-th term of the exponential series. This gives eq. 7.xiv. It also justifies norm differentiation: on a small parameter ball with $\delta \geq \delta_0 > 0$, the scalar exponential Taylor remainder after its linear term is bounded by $C|h|^2 E^2 e^{-\delta_0 E/2}$. Its spectral supremum tends to zero quadratically in $|h|$. The same argument after any fixed number of derivatives proves joint complex differentiability and local norm-convergent Taylor series.

Multipliers multiply, so $\mathcal{V}(z,w)\mathcal{V}(z',w') = \mathcal{V}(z+z', w+w')$; the sum stays in the tube. For the boundary in eq. 7.xv, the multipliers converge pointwise on the spectrum and remain bounded by one. Spectral dominated convergence proves strong convergence for every vector, along every such approach. In particular there is no choice of regulator path in this bounded-operator statement.

For fixed ξ, η, let $\mu_{\xi,\eta}(A) = \langle \xi, \mathsf{E}(A)\eta\rangle$. Its total variation is at most $\|\xi\|\|\eta\|$: for a finite disjoint partition, apply Cauchy–Schwarz to $\sum_j \|\mathsf{E}(A_j)\xi\|\|\mathsf{E}(A_j)\eta\|$. Therefore

$$\langle \xi, e^{-itH} U_x \eta\rangle = \int e^{-itE+ix\cdot p}\, d\mu_{\xi,\eta}(E,p) \tag{7.xvii}$$

is bounded and continuous. For a Schwartz test g on $\mathbb{R}^4$, its distributional pairing has absolute value at most

$$\|\xi\|\|\eta\| \int |g(a)|\, da \le C\|\xi\|\|\eta\| p_5(g). \tag{7.xviii}$$

Dominated convergence with this integrable majorant proves the boundary convergence in $\mathcal{S}'$ as well. The measure in eq. 7.xvii is supported on the forward cone, proving its stated carrier. The reducing-subspace result follows from the common restricted spectral calculus. □

There is also an explicit dense domain for the translation generators:

$$\mathcal{D}_{\text{heat}} = \bigcup_{s>0} \operatorname{Ran} e^{-sH}. \tag{7.xix}$$

The ranges are nested, so this is a linear space; strong continuity at zero makes it dense. The cone and eq. 7.xvi give, for $v = e^{-sH}\eta$,

$$v \in \operatorname{Dom}(H^a P^\alpha), \qquad \|H^a P^\alpha v\| \le m! s^{-m} \|\eta\|. \tag{7.xx}$$

It is invariant under the real translations and spatial rotations. It is also invariant under each generator: reserve half of the heat factor and apply the bound to the other half. Thus generator and domain assertions in this bridge do not depend on a formal exponential with an unspecified domain. Field invariance of this heat domain is not asserted.

The field-product reconstruction beyond this lemma. The coefficients in eq. 7.xvii have a finite measure and hence a simple boundary. The fixed-vector translation theorem alone does not construct arbitrary field products. In particular the strict-gap insertion bound in eq. 6.ccxlii does not permit globally undoing e^{-sH} or putting $s = 0$ in an unbounded field formula.

§ 7.2 supplies the additional construction under the actual UI/PD inputs. It defines the bounded sharp-time Riesz family, removes its heat factors only on finite energy bands, and constructs the spacetime fields on a common energy domain. Its exact sewing, simultaneous forward-tube continuation and full cone tempered boundary apply to arbitrary field products. It also derives Lorentz covariance from actual G2. These results extend the fixed-vector statement in eq. 7.xiv to field products.

§ 7.3 checks the hypotheses of the corrected reconstruction theorem by explicit seminorm estimates. Analytic uniqueness identifies the constructed moments with those of the theorem, giving local commutativity and the stronger linear output-order estimate. The theorem does not assert preservation of the Euclidean factorial exponent. Nor does either construction assign ordinary Euclidean contact values: the diagonal-flat input continues to have its stated domain.

The common field domain after a Minkowski boundary exists. We state the operator hypotheses explicitly. Suppose the continuation step has produced tempered distributions W_n on all of $\mathcal{S}(\mathbb{R}^{4n})$, with $W_0 = 1$, and the positive Wightman form. This is a new assumption in the rest of this section. Let

$$\begin{aligned} \mathcal{B} &= \bigoplus_{n\ge 0}^{\text{finite}} \mathcal{S}(\mathbb{R}^{4n}), \qquad (FG)_n = \sum_{r+s=n} F_r \otimes G_s, \\ F_n^*(x_1,\dots,x_n) &= \overline{F_n(x_n,\dots,x_1)}, \qquad \omega(F) = \sum_n W_n(F_n). \end{aligned} \tag{7.xxi}$$

The empty component is the unit. Positivity means $\omega(F^*F) \ge 0$ for every finite sequence, with no separation restriction. Its polarized form is $\langle F, G\rangle = \omega(F^*G)$, and its null space is $\mathcal{N}_W = \{F : \omega(F^*F) = 0\}$.

Proposition 7.4 (The field-domain construction)**.** The completion of $\mathcal{B}/\mathcal{N}_W$ has a common dense invariant field domain $\mathcal{D} = \mathcal{B}/\mathcal{N}_W$. For a one-variable Schwartz test f, left multiplication by its degree-one sequence defines $\phi(f)$ there. It is linear in f, satisfies $\phi(f) \subset \phi(\bar{f})^*$, and is closable. For each $\eta \in \mathcal{D}$, the map $f \mapsto \phi(f)\eta$ is continuous from Schwartz space to the Hilbert space. The vacuum is cyclic for the field polynomials. Distributional Poincare covariance and spacelike commutativity of W, when supplied, give the corresponding operator identities on $\mathcal{D}$. ■

Proof. Positivity gives Cauchy–Schwarz. A null element A is therefore orthogonal to every element. For arbitrary B,

$$\|BA\|^2 = \omega(A^*B^*BA) = \langle A, B^*BA\rangle = 0. \tag{7.xxii}$$

All expressions are finite algebra products. Thus $\mathcal{N}_W$ is a left ideal, which is exactly what is required for left multiplication to be well-defined on the quotient. Let $\iota(f)$ denote the degree-one sequence. Then

$$\phi(f)[G] = [\iota(f)G], \qquad \langle [F], \phi(f)[G]\rangle = \langle \phi(\bar{f})[F], [G]\rangle. \tag{7.xxiii}$$

The domain is dense by construction and invariant under every such left multiplication. The adjoint domain of $\phi(f)$ contains this same dense domain, by the second identity. Hence $\phi(f)$ is closable. For real f it is symmetric on $\mathcal{D}$; essential self-adjointness has not been inferred.

Fix $\eta = [G]$, with finitely many nonzero degrees. Its image norm squared is a finite sum of terms

$$W_{r+s+2}(G_r^* \otimes \bar{f} \otimes f \otimes G_s). \tag{7.xxiv}$$

Temperedness of each distribution and continuity of tensor multiplication give, for this fixed G, an integer j and constant C_G such that the absolute sum is at most $C_G p_j(f)^2$. Thus $\|\phi(f)\eta\| \le C_G^{1/2} p_j(f)$, proving the asserted Hilbert-valued distribution continuity. The order and constant here may depend on the fixed vector; no degree-independent operator norm has been postulated.

Finite sums of ordinary Schwartz tensors are dense in every $\mathcal{S}(\mathbb{R}^{4n})$. This can be seen directly by cutting off infinity and using Fourier series on a product box, whose partial sums converge in every Schwartz seminorm. The norm of a homogeneous degree-n vector is continuous under this convergence, because its squared norm uses the single tempered distribution W_{2n} and a tensor product. Consequently the polynomial vectors $\phi(f_1)\cdots\phi(f_n)\Omega$ have dense span. Their span is itself a common dense invariant domain if that smaller domain is preferred.

A scalar Poincare pullback α_g is an algebra automorphism of $\mathcal{B}$ commuting with the involution. If $\omega \circ \alpha_g = \omega$, the prescription $\mathcal{U}_g[F] = [\alpha_g F]$ gives a unitary with its exact inverse. The usual Schwartz continuity of affine pullbacks and the same finite form expansion prove strong continuity. On the common domain the algebra identity gives

$$\mathcal{U}_g \phi(f) \mathcal{U}_g^{-1} = \phi(\alpha_g f). \tag{7.xxv}$$

This derives the implementation once distributional covariance has been supplied; it does not derive a Lorentz identity from the spatial rotation argument.

Finally suppose the Minkowski distributions give the adjacent commutator identity for tests f, h with spacelike-separated supports and arbitrary spectator tests. Its pairing with F^* and G says

$$\langle [F], [\phi(f), \phi(h)][G]\rangle = 0 \quad (F, G \in \mathcal{B}). \tag{7.xxvi}$$

The commutator maps the common domain into itself. Density of the test classes therefore makes it zero there. This proves operator locality from that distributional identity. □

7.2. **Tempered fields from analytic insertions.** We construct spacetime-smeared fields from the actual Euclidean insertion estimates. The construction starts with the bounded analytic density of § 6.10, derives a compatible sharp-time Riesz family, and removes its heat factors only on finite energy bands. Temporal smearing then gives a common invariant dense field domain and positive tempered vacuum moments. Exact Euclidean sewing also gives a joint positive-gap continuation

and its tempered real-time boundary. No unrestricted Minkowski moment sequence is assumed in this construction.

The hypotheses are those already declared for UI and PD: the actual ordinary-source and symmetry inputs, the separated-moment continuity, and the reflection-positive Hilbert evolution with its exact cube cone. Write $T_s = e^{-sH}$, $U_x = e^{ix\cdot P}$, and let $\mathcal{K}_{\mathrm{ord}} \subset \mathcal{K}$ be the reducing ordered sector of § 7.1. The round cone is available when the spatial rotation hypothesis of that section is supplied. All estimates below can first be made on $\mathcal{K}$ and then restricted to $\mathcal{K}_{\mathrm{ord}}$. The field's cyclic space will be identified with this ordered sector.

The sharp family is a defined bounded form. The PD input is an actual operator-norm analytic function $V_\eta(t,x)$, uniform in real $x \in \mathbb{R}^3$, with

$$\|V_\eta(t,x)\| \le C\eta^{-N}, \qquad N = p+5 = 9, \tag{7.xxvii}$$

on its retained complex neighbourhood. The value $N = 9$ uses the proved UI exponent $p = 4$. eq. 6.cclv identifies this density with the original insertion form between pulled-down outside polynomials. For $0 < s \le 1/4$ and $h \in L^1(\mathbb{R}^3)$, define

$$\Phi_s(h) = \int h(x) V_{4s}(0,x)\, d^3x, \qquad \|\Phi_s(h)\| \le C s^{-N} \|h\|_1. \tag{7.xxviii}$$

The weak integral is defined by bounded sesquilinear forms and Riesz representation. Norm continuity of the density also permits a Bochner integral. This definition uses no unsandwiched sharp-time operator.

We verify the identification and consistency needed later. Choose a fixed nonnegative even real $\chi \in C_c^\infty(\mathbb{R})$, with integral one, and set $\chi_\epsilon(t) = \epsilon^{-1}\chi(t/\epsilon)$. This temporal approximate identity has $\|\chi_\epsilon\|_1 = 1$ and support shrinking to zero. For compact smooth h, the actual regularized insertion operator for $k_\epsilon(t,x) = \chi_\epsilon(t)h(x)$ has core form

$$\langle [A], \Phi_s(k_\epsilon)[B]\rangle = I(\tau_s A; k_\epsilon; \tau_s B), \qquad \Phi_s(k_\epsilon)[B] = [(\tau_s k_\epsilon)\cdot \tau_{2s} B]. \tag{7.xxix}$$

Here $\tau_s = \tau_{se_4}$, and the second identity is exactly the eq. 6.ccxlvi vector identity, extended to a compact spatial profile by its proved density formula. The two time supports in the displayed product are separated for small ϵ. eq. 6.cclv gives $\Phi_s(k_\epsilon) = \int \chi_\epsilon(t)h(x)V_{4s}(t,x)\, dt, dx$. A temporal Cauchy derivative of eq. 7.xxvii is bounded uniformly in real x, so

$$\|\Phi_s(k_\epsilon) - \Phi_s(h)\| \le C s^{-N-1}\epsilon \|h\|_1. \tag{7.xxx}$$

Thus the sharp limit is an operator-norm limit of actual core insertions. Approximation in spatial L^1 extends this conclusion to the domain in eq. 7.xxviii.

Testing eq. 7.xxix after an additional time shift of both outside polynomials gives

$$\Phi_{s+r}(h) = T_r \Phi_s(h) T_r \quad (0 < s < s+r \le 1/4). \tag{7.xxxi}$$

Indeed $\langle A, T_r\Phi_s(k)T_r B\rangle$ is the insertion form with outside entries shifted by $s+r$. PD's compatibility on the overlapping pulled-down domains identifies it with the $s+r$ form. Pass to the norm limit in eq. 7.xxx, then to spatial L^1 labels. Reflection with the even approximants and spatial translation invariance give, by the same dense-form calculation,

$$\Phi_s(h)^* = \Phi_s(\bar{h}), \qquad U_y \Phi_s(h) U_y^{-1} = \Phi_s(\tau_y h). \tag{7.xxxii}$$

If spatial rotations are supplied, their actual quotient unitaries similarly intertwine $\Phi_s(h)$ and $\Phi_s(r_R h)$.

For larger s, define Φ_s using the right side of eq. 7.xxxi with any smaller fixed heat parameter. The small-parameter identity proves independence of that choice and then eq. 7.xxxi for all $s, r > 0$. Its safe global estimate is $C\min(s,1/4)^{-N}\|h\|_1$. Only the small-s polynomial estimate is used below; no decay as $s \to \infty$ is required.

The ordered sector is preserved. To see the domain explicitly, compact tests supported inside $0 < t_1 < \cdots < t_n$ can be covered by finitely many product boxes with strictly ordered time intervals. A product-box Fourier approximation gives sums of ordered tensors. For a general ordered Schwartz test, first cut off infinity and then cut out the time boundary and adjacent equal-time hyperplanes. Flatness on those boundaries makes the cutoff errors tend to zero in every Schwartz seminorm by Taylor's remainder. Thus such compact ordered tensors are dense in the ordered quotient norm. For each of them, eq. 7.xxix prepends an insertion near time s and shifts all old entries by $2s$, giving another ordered vector. The bounded norm limit therefore preserves $\mathcal{K}_{\mathrm{ord}}$. The adjoint in eq. 7.xxxii does the same, so this subspace reduces every $\Phi_s(h)$.

Removing heat on finite bands. Let $P_m = \mathbf{1}_{[m,m+1)}(H)$, $m = 0, 1, \ldots$. Their orthogonal sum is identity. The notation

$$A_{mn}(h) = (e^{sH} P_m)\Phi_s(h)(P_n e^{sH}) : P_n\mathcal{K} \longrightarrow P_m\mathcal{K} \tag{7.xxxiii}$$

uses bounded outer operators, of norms at most $e^{s(m+1)}$ and $e^{s(n+1)}$. If a larger heat parameter is used, eq. 7.xxxi cancels the extra factors on these same finite bands. Hence eq. 7.xxxiii is independent of $s > 0$. Taking $s = [8(1+m+n)]^{-1}$ in eq. 7.xxviii gives

$$\|A_{mn}(h)\| \le C_A(1+m+n)^N \|h\|_1, \qquad A_{mn}(h)^* = A_{nm}(\bar{h}). \tag{7.xxxiv}$$

All spatial covariance identities restrict to these blocks because the spatial unitaries commute with H. The same construction can be made at a spatial point using $\Phi_s(x) = V_{4s}(0, x)$. Compatibility and the block bound hold pointwise in x, by continuity and eq. 7.xxxi tested against spatial labels, and $A_{mn}(h) = \int h(x) A_{mn}(x)\, dx$.

The unregularized block matrix in eq. 7.xxxiv need not define a Hilbert-space operator at a sharp time. Its polynomially growing columns have not been shown square summable. We next define the spacetime-smeared operator, for which the missing summability is supplied by time integration.

General spacetime tests and the block estimate. For $g \in \mathcal{S}(\mathbb{R} \times \mathbb{R}^3)$, write $g_t(x) = g(t, x)$. The bounded linear map $h \mapsto A_{mn}(h)$ on spatial L^1 makes $t \mapsto A_{mn}(g_t)$ differentiable in operator norm, with derivatives $A_{mn}(\partial_t^j g_t)$. Define directly

$$B_{mn}(g) = \int_{\mathbb{R}} e^{itH} A_{mn}(g_t) e^{-itH}\, dt, \qquad \mathfrak{t}_q(g) = \sum_{j=0}^{q} \|\partial_t^j g\|_{L^1(\mathbb{R}^4)}. \tag{7.xxxv}$$

This is a norm integral between the fixed bands. It is already a definition for arbitrary spacetime Schwartz tests, not just tensors.

Pull out the scalar phase $e^{it(m-n)}$. The remaining generators $(H-m)|_{P_m\mathcal{K}}$ and $(H-n)|_{P_n\mathcal{K}}$ have norm at most one. A derivative of their conjugation costs at most two. Leibniz's rule followed by q integrations by parts therefore gives, when $|m-n| \ge 1$, the bound with factor $3^q|m-n|^{-q}\mathfrak{t}_q(g)$. Boundary terms vanish by the Schwartz decay in temporal L^1. For $m = n$ use the original norm integral. Together these estimates give the explicit safe bound

$$\|B_{mn}(g)\| \le C_A 6^q (1+m+n)^N (1+|m-n|)^{-q} \mathfrak{t}_q(g). \tag{7.xxxvi}$$

The adjoint blocks satisfy $B_{mn}(g)^* = B_{nm}(\bar{g})$. The proof used actual derivatives of a bounded map into fixed energy bands and did not differentiate an unbounded sharp-time field.

Put $W = 1 + H$. On the m-th band, powers of W have norm at most $(m+2)^k$, while $\|W^{-l}P_n\| \le (n+1)^{-l}$. The elementary comparison

$$\frac{(m+2)^k (1+m+n)^N}{(n+1)^{N+k}} \le 2^{N+k}(1+|m-n|)^{N+k} \tag{7.xxxvii}$$

shows exactly how the energy weights are paid. Set $q = N+k+2$, and let $Z_2 = 2\sum_{d\ge 0}(1+d)^{-2} < \infty$. The scalar row and column sums of the weighted blocks are at most $C_A 2^{N+k} 6^{N+k+2} Z_2 \mathrm{t}_{N+k+2}(g)$. Block Schur consequently gives

$$\|W^k \phi(g) W^{-(N+k)}\| \le C_k \mathrm{t}_{N+k+2}(g) \le C'_k p_{N+k+7}(g). \tag{7.xxxviii}$$

For the last inequality use the ordinary four-dimensional Schwartz seminorm: its weight of order at least five is integrable, and it controls all the indicated temporal derivatives. These are actual seminorm estimates for non-tensor spacetime tests.

Here is the operator and domain construction behind eq. 7.xxxviii. For $k = 0$, the block matrix $B_{mn}(g)W^{-N}P_n$ defines a bounded operator by Schur. Multiply it on the right by W^N on $\operatorname{Dom} W^N$ to define $\phi(g)$. For finite-energy vectors its blocks are exactly eq. 7.xxxv. For $\xi \in \operatorname{Dom} W^{N+k}$, approximate by $Q_R\xi$, where $Q_R = \sum_{m=0}^{R} P_m$. The weighted Schur estimate makes both $\phi(g)Q_R\xi$ and $W^k\phi(g)Q_R\xi$ converge. Closedness of W^k proves the claimed domain inclusion and the operator identity in eq. 7.xxxviii.

It follows that

$$\mathcal{D}_\infty = \bigcap_{k\ge 0} \operatorname{Dom} H^k \quad \text{is dense and} \quad \phi(g)\mathcal{D}_\infty \subset \mathcal{D}_\infty. \tag{7.xxxix}$$

Finite-energy vectors make it dense. The adjoint-block identity, first on such vectors and then by their graph-norm approximation, gives

$$\langle \xi, \phi(g)\eta\rangle = \langle \phi(\bar g)\xi, \eta\rangle \quad (\xi,\eta \in \mathcal{D}_\infty). \tag{7.xl}$$

Thus each field restricted to this common invariant domain is closable, and it is symmetric for real tests. eq. 7.xxxviii also proves continuity into every graph seminorm for each fixed domain vector. Essential self-adjointness is not inferred.

All energy projections, sharp insertions and real translations reduce $\mathcal{K}_{\mathrm{ord}}$. The same block limits therefore preserve $\mathcal{D}_\infty \cap \mathcal{K}_{\mathrm{ord}}$. Spatial covariance and time smearing give exact domain identities

$$\begin{aligned} \mathscr{U}(t,y) = e^{itH}U_y, \qquad & \mathscr{U}(t,y)\mathcal{D}_\infty = \mathcal{D}_\infty, \\ \mathscr{U}(t,y)\phi(g)\mathscr{U}(t,y)^{-1} &= \phi(\tau_{(t,y)}g). \end{aligned} \tag{7.xli}$$

Spatial rotations have the analogous covariance when supplied. Our time convention is fixed by the positive sign in e^{itH}. With the standard Minkowski pairing $Et - p\cdot x$, its spatial momentum is $-P$; the round cone is unchanged by this sign.

Positive tempered moments with an explicit extension. The vacuum belongs to $\mathcal{D}_\infty$, and eq. 7.xxxviii can be iterated. Normalize $W_0 = \|\Omega\|^2 = 1$. For each fixed n,

$$\|\phi(g_1)\cdots\phi(g_n)\Omega\| \le D_n \prod_{j=1}^{n} p_{M_n}(g_j), \qquad M_n = nN + 7. \tag{7.xlii}$$

Indeed the energy exponent needed at the next factor increases by N at each step; the largest test order is $nN+7$. Define the vacuum moments on tensors by $W_n(g_1\otimes\cdots\otimes g_n) = \langle\Omega, \phi(g_1)\cdots\phi(g_n)\Omega\rangle$. Multilinearity factors through the algebraic tensor product. Its map into functions is injective on every finite collection: choose point evaluations distinguishing the finite-dimensional function span in each slot and invert those evaluation matrices. Tensor relations therefore introduce no ambiguity.

We prove a fixed-order tempered estimate explicitly. Take a smooth unit product-grid partition and expand each localized test on period-eight boxes in every four-dimensional slot. Multiply each Fourier wave by a fixed larger compact cutoff. Its one-slot p_M norm is at most $C_M(1+|z|)^M(1+|l|)^M$, where $z \in \mathbb{Z}^4$ is the box center and $l \in \mathbb{Z}^4$ its Fourier index. Choose $2r = 2\lceil (M_n+6)/2\rceil$, and integrate $(1-\Delta_i)^r$ in each slot when estimating the coefficients. This gives the factor $\prod_i (1+|l_i|^2)^{-r}$. Derivatives of the fixed cutoffs cost a finite constant depending on n, r. With

$$K_n = n(M_n + 8), \tag{7.xliii}$$

the seminorm $p_{K_n}(F)$ pays both their total derivative order $2rn \le n(M_n+7)$ and the per-slot location weight $(1+|z_i|)^{-(M_n+8)}$. The latter follows from $1+\sum_i |x_i|^2 \ge \prod_i (1+|x_i|^2)^{1/n}$, with fixed-box weight comparisons. After the tensor bound in eq. 7.xlii, the absolute series is controlled by the products of

$$\sum_{z\in\mathbb{Z}^4} (1+|z|)^{-8} < \infty, \qquad \sum_{l\in\mathbb{Z}^4} (1+|l|)^{M_n}(1+|l|^2)^{-r} < \infty. \tag{7.xliv}$$

The second sum converges since $2r - M_n \ge 6 > 4$. The Fourier series of the localized smooth tests converges in every required seminorm. For a tensor its coefficients factor, so the absolutely summed value agrees with its original multilinear value. This constructs the unique continuous extension, with

$$|W_n(F)| \le D'_n p_{K_n}(F) \quad (F \in \mathcal{S}(\mathbb{R}^{4n})). \tag{7.xlv}$$

The same absolute series, using the vector bound in eq. 7.xlii, constructs the Hilbert-valued vacuum-product distribution. Higher graph seminorms are treated by starting the iteration of eq. 7.xxxviii at the corresponding energy exponent.

Thus W_n is tempered at every fixed n. The displayed order $K_n = O(n^2)$ is sufficient for that assertion; no linear order bound or preserved factorial moment exponent is claimed here. For finite tensor sequences, eq. 7.xl gives

$$\sum_{r,s} W_{r+s}(F_r^* \otimes F_s) = \Big\| \sum_s \phi(F_s)\Omega \Big\|^2 \ge 0. \tag{7.xlvi}$$

Here F_r^* reverses and conjugates its arguments, and for a tensor $\phi(F_s)\Omega$ means its field product. The Hilbert-valued extension just constructed defines the same vector for a general Schwartz F_s. Ordinary tensor density and eq. 7.xlv then prove eq. 7.xlvi on all finite unrestricted Schwartz sequences. This proves the required positive Minkowski moment functional from the actual insertion input.

Exact Euclidean words and joint positive-gap analyticity. Let $z = (z_1, \dots, z_{n-1})$ have positive real components and take spatial labels $h_j \in L^1(\mathbb{R}^3)$. Choose small $a_j > 0$ with $a_j + a_{j+1} < \mathrm{Re}\, z_j$. Define

$$\begin{aligned} \mathcal{E}_n(z;h) &= \langle \Omega, \Phi_{a_1}(h_1)\mathcal{P}(z,a;h)\Omega\rangle, \\ \mathcal{P}(z,a;h) &= \prod_{j=1}^{n-1} \left[T_{z_j - a_j - a_{j+1}} \Phi_{a_{j+1}}(h_{j+1}) \right]. \end{aligned} \tag{7.xlvii}$$

The product is ordered by increasing j from left to right and is identity for $n = 1$. Here $T_z = e^{-zH}$ is the actual bounded analytic semigroup. Changing a_j to a smaller b_j inserts the two factors $T_{a_j - b_j}$ of eq. 7.xxxi; they join their adjacent heat factors and give precisely the formula with b_j. The endpoint heat factors fix Ω. Two arbitrary allowed choices are compared through a common smaller choice. Thus eq. 7.xlvii is independent of every auxiliary parameter.

On a neighbourhood of any positive-real-gap point, keep the a_j fixed. The formula is a finite product of bounded norm-holomorphic operators. The matching identities just proved glue these formulas on overlaps, giving joint analyticity on $\mathrm{Re}\, z_j > 0$ for every gap simultaneously. With

$$r = \min\{1/8, \tfrac{1}{4} \min_j \mathrm{Re}\, z_j\}, \qquad |\mathcal{E}_n(z;h)| \le C^n r^{-Nn} \prod_j \|h_j\|_1, \tag{7.xlviii}$$

the bound follows by taking every $a_j = r$. When $n = 1$, fix $a_1 = 1/8$; its vacuum value is independent of that choice.

We verify that this is the actual Euclidean continuation. For real ordered times $\tau_1 < \cdots < \tau_n$, replace every sharp label by $\chi_\epsilon(t) h_j(x)$ in the allowed core formula. Starting at the rightmost factor, repeated use of eq. 7.xxix puts the first insertion at a_1 and the later ones at $a_1 + (\tau_j - \tau_1)$, with the corresponding narrow profiles. A common translation by $\tau_1 - a_1$ identifies its vacuum expectation

with the original Euclidean moment. Operator-norm convergence in eq. 7.xxx therefore identifies the point-time limit with $\mathcal{E}_n(\tau_{j+1}-\tau_j;h)$.

For compact temporal profiles in disjoint ordered intervals there is a fixed positive gap. Choose the auxiliary heat parameters uniformly below that gap. Approximate the profiles by their convolutions with the narrow kernels. The original moments converge by local C^1 continuity, while eq. 7.xlviii permits Fubini and dominated convergence on the operator side. This recovers their exact original moment values. Product-box Fourier approximation gives the same identification for general compact ordered tests, not only time-space tensors. No diagonal Euclidean contact prescription is involved.

The corresponding vector formula, when all absolute times are positive, is

$$T_{\tau_1-a_1}\Phi_{a_1}(h_1)\mathcal{P}((\tau_{j+1}-\tau_j)_j,a;h)\Omega, \tag{7.xlix}$$

with $a_1<\tau_1$. The same core argument and norm limits identify its ordered-profile integrals with the actual ordered Euclidean vectors. It is a bounded formula throughout the retained positive gaps.

A joint tempered boundary, not separate limits. For positive gap regulators ϵ_j, define on tensor tests

$$W_n^\epsilon(g_1\otimes\cdots\otimes g_n)=\langle\Omega,\phi(g_1)T_{\epsilon_1}\phi(g_2)\cdots T_{\epsilon_{n-1}}\phi(g_n)\Omega\rangle. \tag{7.l}$$

Every heat contraction has norm at most one in every energy graph norm. The proof of eq. 7.xlii–eq. 7.xlv therefore gives, uniformly in all $\epsilon_j\ge 0$,

$$|W_n^\epsilon(F)|\le D_n' p_{K_n}(F),\qquad W_n^\epsilon(F)\longrightarrow W_n(F)\quad\text{as all }\epsilon_j\downarrow 0. \tag{7.li}$$

For tensors the convergence follows by replacing the finitely many heat factors one at a time. Strong convergence in every graph norm, combined with eq. 7.xxxviii, controls each term. For an arbitrary Schwartz test, first approximate it by finite tensors in p_{K_n}. The uniform bound controls the two approximation errors, and tensor convergence controls the fixed approximation. This proves joint, regulator-path-independent convergence in $\mathcal{S}'$.

To identify it as the boundary of eq. 7.xlvii, first insert the finite total-energy cutoff Q_R at every field. All generators and field blocks are then bounded, so time integration gives exactly

$$z_j=\epsilon_j-i(t_{j+1}-t_j) \tag{7.lii}$$

in that formula. For fixed positive regulators, its intermediate energy-band sums are absolutely convergent: eq. 7.xxxiv contributes only fixed polynomial factors, while every intermediate energy is damped by its positive gap. The convergence of the cutoff expressions is uniform in the real times and bounded by an integrable product of the spatial L^1 norms of the time slices of the tests. Fubini and dominated convergence therefore identify their integrals with eq. 7.l. On the field side, the cutoff products converge by the graph bounds and $Q_R\to I$ in every graph norm. eq. 7.li–eq. 7.lii consequently prove a jointly tempered boundary of the actual sewn Euclidean functions. Independent one-variable boundary statements have not been substituted for it.

The full spectral carrier and the cyclic sector. Assume now the supplied round cone. The finite-energy cutoff point field $A_R(x)=\sum_{m,n\le R}A_{mn}(x)$ is bounded, spatially covariant, and has bounded translation generators on its cutoff range. Its vacuum words have the usual difference-variable form with one joint translation between each adjacent pair of fields. If a test in one difference variable has Fourier transform vanishing on the forward carrier, integrating that translation gives zero by the joint spectral theorem. Other differences and spectator fields can be held fixed during this integration. On a compact Fourier set outside the product carrier, choose a finite cover by product boxes, in each of which one difference momentum is outside its carrier. A subordinate partition and product Fourier approximation reduce each localized test to the just-proved zero identities. This proves the full product support condition.

The cutoff vacuum distributions converge to W_n by eq. 7.xxxviii and the same uniform extension estimate as in eq. 7.li. Their difference-variable limits are legitimate distributions: fix a Schwartz test ρ of integral one in the common center coordinate, and pair the full distributions with $\rho(x_1)\psi(x_2 - x_1, \dots, x_n - x_{n-1})$. This is a continuous map from difference tests to full tests. The cutoff identities show that the limiting difference functional is independent of ρ and that its pairing with a full test uses the center integral of that test. Thus it is the actual difference-variable distribution of W_n. Support in a fixed closed set passes to this tempered limit. Hence

$$\operatorname{supp} \widehat{W_n^{\mathrm{diff}}} \subset (\overline{V}_+)^{n-1}, \qquad \overline{V}_+ = \{(E,p) : E \geq |p|_2\}, \tag{7.liii}$$

with the Fourier convention of eq. 7.xli and eq. 7.lii. In unreduced momenta this is the corresponding condition on all partial sums, not merely a bound on total translations of one fixed vector. Without the spatial rotation input the same proof retains the cube carrier provided by eq. 6.ccxliv.

Let $\mathcal{H}_\phi$ be the closed span of field-polynomial vacuum vectors. They lie in $\mathcal{K}_{\mathrm{ord}}$, and eq. 7.xli makes their span invariant under both signs of real translations. Thus $\mathcal{H}_\phi$ reduces H, its heat factors and its energy projections. The reverse inclusion, and hence cyclicity, follows as below.

First, polynomial vectors are graph-dense in $\mathcal{H}_\phi \cap \operatorname{Dom} W^l$ for every l. For a smooth compact spectral cutoff $c_R(H)$, its inverse Fourier transform is integrable. Therefore $c_R(H)$ is an integral of real time translations. Applied to a polynomial vector, that integral is approximated in the W^l graph norm by finite sums of translated polynomial vectors: the orbit is graph-norm continuous and its graph norm is constant. Given an arbitrary vector in the stated domain, first cut its spectrum off and then approximate the cutoff vector by these smoothed polynomial approximants. Finally let the cutoff tend to identity. This proves graph density. The energy estimate in eq. 7.xxxviii now shows that every $\phi(g)$ maps $\mathcal{H}_\phi \cap \mathcal{D}_\infty$ into $\mathcal{H}_\phi$.

For compact smooth h, the bounded operators $T_s\phi(\chi_\epsilon \otimes h)T_s$ converge in operator norm to $\Phi_s(h)$. On finitely many bands this follows from the temporal approximate identity and the bounded band generators. The tails converge uniformly: their block norms are bounded by

$$C(1+m+n)^N e^{-s(m+n)}\|h\|_1, \tag{7.liv}$$

independently of ϵ, since $\|\chi_\epsilon\|_1 = 1$. The row and column sums outside a growing finite square tend to zero. The limiting blocks are exactly those of $\Phi_s(h)$ by eq. 7.xxxiii. Each approximating operator preserves $\mathcal{H}_\phi$: the right heat factor sends its vectors into all energy domains, the preceding graph-density argument handles the field, and the left factor preserves the subspace. The norm limit does so as well. Spatial L^1 approximation extends this to all labels in eq. 7.xxviii.

Every vector in the exact Euclidean sewing formula in eq. 7.xlix therefore belongs to $\mathcal{H}_\phi$. Its ordered-profile integrals are the dense ordered Euclidean vectors established above. Consequently

$$\mathcal{H}_\phi = \mathcal{K}_{\mathrm{ord}}. \tag{7.lv}$$

This proves the actual cyclic realization and its inherited separability, evolution and phase vacuum conclusions. It makes no assertion that $\mathcal{K}_{\mathrm{ord}} = \mathcal{K}$.

The joint forward tube and its full cone boundary. The preceding argument also supplies the simultaneous complex spatial variables under the round-cone hypothesis; the following bounded formula proves joint continuation. Work on $\mathcal{K}_{\mathrm{ord}}$ and put

$$S(z,w) = e^{-zH + iw\cdot P}, \qquad \operatorname{Re} z > |\operatorname{Im} w|_2, \qquad \Phi_a^0 = V_{4a}(0,0). \tag{7.lvi}$$

The joint spectral proof in § 7.1 makes S a norm-holomorphic contraction on this tube. It also shows directly that derivatives of total order l on a smaller tube with margin δ have norm at most $l!\delta^{-l}$, because $|P|_2 \leq H$. The point operator Φ_a^0 is the norm limit of the spatial approximate identities in eq. 7.xxviii, by continuity of V_{4a}. It therefore preserves the ordered sector, has norm at most Ca^{-N}, and satisfies exactly the same heat consistency.

For $\delta_j = \operatorname{Re} z_j - |\operatorname{Im} w_j|_2 > 0$, choose $a_j + a_{j+1} < \delta_j$ and define

$$\mathscr{E}_n(z,w) = \left\langle \Omega, \Phi^0_{a_1} \prod_{j=1}^{n-1} \left[S(z_j - a_j - a_{j+1}, w_j) \Phi^0_{a_{j+1}} \right] \Omega \right\rangle, \qquad r = \min\{1/8, \tfrac{1}{4} \min_j \delta_j\}, \qquad |\mathscr{E}_n(z,w)| \le C^n r^{-Nn}. \tag{7.lvii}$$

The product has the same order as eq. 7.xlvii. Decreasing the auxiliary a_j and joining their extra heat factors to the adjacent joint semigroups proves independence, exactly as before: the heat factors commute with S, and every resulting joint semigroup remains inside its contraction tube. Fixed auxiliary parameters on a neighbourhood give joint norm holomorphy, and their independence glues the neighbourhoods. Taking every $a_j = r$ proves the bound. For $n = 1$ use the constant vacuum value with $a_1 = 1/8$.

For real spatial gaps, spatial covariance of the point operators identifies this formula with the spatial point version of eq. 7.xlvii. Spatial approximate identities converge in norm, so the exact Euclidean sewing already proved identifies it with the original ordered Euclidean density and with its spatially smeared values. Thus eq. 7.lvii is a jointly defined function of all $4(n-1)$ complex difference variables, not merely a family indexed by real spatial labels.

Let $\epsilon_j > |y_j|_2$, and insert $R_j = S(\epsilon_j, iy_j) = e^{-\epsilon_j H - y_j \cdot P}$ between the fields in eq. 7.l, obtaining $W_n^{\epsilon,y}$. The round cone gives $\|R_j\| \le 1$. These operators commute with W, are contractions in every graph norm, and converge strongly there to identity as $(\epsilon_j, y_j) \to 0$ within that cone. The last assertion is dominated convergence in the joint spectral measure: the multipliers are bounded by one and converge pointwise to one. The proof of eq. 7.li therefore gives

$$|W_n^{\epsilon,y}(F)| \le D'_n p_{K_n}(F), \qquad W_n^{\epsilon,y}(F) \longrightarrow W_n(F) \quad \text{for every } F \in \mathcal{S}(\mathbb{R}^{4n}). \tag{7.lviii}$$

This is a simultaneous limit along every cone-admissible approach.

Finite energy cutoffs identify the integrated function in eq. 7.lvii with $W_n^{\epsilon,y}$ at

$$z_j = \epsilon_j - i(t_{j+1} - t_j), \qquad w_j = x_{j+1} - x_j + iy_j. \tag{7.lix}$$

Indeed the inserted spectral multipliers are now bounded by $e^{-(\epsilon_j - |y_j|_2)H}$. Hence each intermediate energy sum has the same absolute polynomial-times-exponential bound as in eq. 7.lii, uniformly in all real coordinates. Finite-cutoff Fubini, then dominated convergence, proves the identity on tensor tests. The bound in eq. 7.lvii makes its fixed-regulator integral continuous on Schwartz tests, while eq. 7.lviii does the same on the field side; tensor density proves equality on every such test. eq. 7.lviii is therefore the actual joint tempered boundary of eq. 7.lvii, with all complex spatial and time regulators allowed by the round cone. In the convention of eq. 7.xli, these are difference points $(t + i\epsilon, x + iy)$ with imaginary part in the forward cone.

Lorentz covariance from the actual Euclidean rotations. For this step assume the full scalar Euclidean covariance G2 of the actual diagonal-flat moments. The finite hypercubic group alone does not supply this hypothesis. In particular G2 includes every real rotation in a time–space coordinate plane. No Lorentz covariance of the field has been used in constructing the tube.

Put $\zeta_j = (iz_j, w_j)$. The domain of eq. 7.lvii is precisely $\operatorname{Im} \zeta_j \in V_+$ for every gap. Denote the same holomorphic function by $\mathcal{F}_n(\zeta)$. Its Euclidean slice is $\zeta_j = (i\tau_j, r_j)$, with $\tau_j > 0$ and $r_j \in \mathbb{R}^3$. We first justify pointwise use of G2 on this slice. A compact neighbourhood of any such Euclidean configuration has strictly ordered time coordinates. The sewing formula represents its actual moment functional by the continuous point density in eq. 7.lvii. For a sufficiently small fixed Euclidean rotation, its rotated neighbourhood still has strictly ordered times. Apply G2 to arbitrary smooth tests supported in this neighbourhood. The scalar change-of-variables identity, whose Jacobian is one, makes the two continuous densities equal there. Their difference is zero against every compact smooth test and hence zero pointwise. Thus the local rotation identity is an identity for the actual sewn function, not an imposed extension across the diagonals. Common

Euclidean translations allow the first point to be set at zero, so rotations act linearly on all the difference variables.

Choose a time–space rotation with infinitesimal action $\dot\tau_j = r_j^k$, $\dot r_j^k = -\tau_j$, simultaneously for every gap. Differentiating the just-proved pointwise identity and using $\zeta_j^0 = i\tau_j$ gives

$$i\mathcal{B}_k\mathcal{F}_n = 0 \quad \text{on the Euclidean slice,} \qquad \mathcal{B}_k = \sum_{j=1}^{n-1}\left(\zeta_j^k\partial_{\zeta_j^0} + \zeta_j^0\partial_{\zeta_j^k}\right). \tag{7.lx}$$

The derivative exists because the point density is holomorphic on a complex neighbourhood of that slice. The slice is maximal totally real: the complex linear coordinate change $(\tau_j, r_j) \mapsto (i\tau_j, r_j)$ sends real open boxes to its open pieces. A holomorphic function vanishing on such a box vanishes on a complex neighbourhood, by applying the one-variable identity theorem successively in each coordinate. The product tube is connected, indeed convex. Apply this observation to the holomorphic function $\mathcal{B}_k\mathcal{F}_n$; it follows that it vanishes on the entire tube.

Every real proper orthochronous boost preserves V_+, so its whole real orbit stays inside the tube. Differentiating $s \mapsto \mathcal{F}_n(\Lambda_k(s)\zeta)$ now gives zero at every s. The function is constant along that orbit. Spatial rotations have the same invariance, either by G2 on the slice and the same uniqueness argument, or by their already implemented quotient unitaries. These transformations generate $\mathrm{SO}_+(1,3)$. Explicitly, for any Λ in this group write $\Lambda e_0 = (\gamma, \gamma v)$, where $|v| < 1$. The boost in direction v sends e_0 to this vector. Its inverse times Λ fixes e_0 and is a spatial proper rotation. A directional boost is a spatial rotation conjugate of a coordinate boost. Therefore

$$\mathcal{F}_n(\Lambda\zeta) = \mathcal{F}_n(\zeta) \quad (\Lambda \in \mathrm{SO}_+(1,3)). \tag{7.lxi}$$

The boundary passage uses the full cone limit proved above. If $\eta_j \in V_+$, then also $\Lambda^{-1}\eta_j \in V_+$. Changing real variables $\xi = \Lambda\chi$ in the integral of $\mathcal{F}_n(\xi + i\eta)$ against $f(\Lambda^{-1}\xi)$ changes its regulator to $\Lambda^{-1}\eta$, by eq. 7.lxi, and leaves the Jacobian one. Both regulator families have the same joint tempered limit by eq. 7.lviii. Consequently

$$W_n^{\mathrm{diff}}(f\circ\Lambda^{-1}) = W_n^{\mathrm{diff}}(f), \qquad W_n(\alpha_\Lambda F) = W_n(F), \tag{7.lxii}$$

where α_Λ pulls every argument back by Λ^{-1}. The second identity follows from the center integration defining the difference distribution, which commutes with a determinant-one simultaneous linear change of coordinates. The Schwartz pullback is continuous for every fixed Λ. This proves distributional Lorentz covariance without a separate boundary-exchange assertion.

The covariant field representation on the ordered sector. Let $X(F)$ denote a finite sum of the vacuum-product vectors constructed in eq. 7.xlii–eq. 7.xlvi. Their span is dense in $\mathcal{K}_{\mathrm{ord}}$ by eq. 7.lv. Define there

$$U(\Lambda)X(F) = X(\alpha_\Lambda F), \qquad U(\Lambda)\Omega = \Omega. \tag{7.lxiii}$$

eq. 7.xlvi and eq. 7.lxii, applied by polarization to two finite sequences, preserve their inner product. In particular a zero vector is sent to zero. The map is thus well-defined and isometric on the actual quotient, and its inverse is the same construction for Λ^{-1}. It extends to a unitary on the ordered sector. The pullback composition law gives a representation of $\mathrm{SO}_+(1,3)$ on this sector. On the spatial rotation subgroup it equals the quotient unitary already constructed: both maps have the same action on every field-polynomial vacuum vector, whose span is dense by eq. 7.lv.

If $\Lambda \to I$, its pullbacks converge in every Schwartz seminorm. This follows by the mean-value formula for the derivatives and polynomial weights on a bounded matrix neighbourhood of identity; one additional derivative and weight suffice for each fixed seminorm. The Hilbert-valued extension after eq. 7.xlv then makes $X(\alpha_\Lambda F) \to X(F)$. Unitarity and density extend this convergence to all vectors. Hence U is strongly continuous. The translation implementation already satisfies

$\mathscr{U}(a)X(F) = X(\tau_a F)$. The exact pullback identity therefore gives

$$\begin{aligned} U(\Lambda)\mathscr{U}(a)U(\Lambda)^{-1} &= \mathscr{U}(\Lambda a), \\ \mathscr{U}(a)U(\Lambda)\mathscr{U}(b)U(M) &= \mathscr{U}(a+\Lambda b)U(\Lambda M). \end{aligned} \tag{7.lxiv}$$

The second line exhibits the strongly continuous proper orthochronous Poincare representation, with the positive spectral cone already established. The notation M in this formula denotes another Lorentz matrix.

Covariance also holds on the energy domain. Stone's theorem applied to the first identity in eq. 7.lxiv gives the exact self-adjoint identity $U(\Lambda)HU(\Lambda)^{-1} = \gamma H + b \cdot P$, where $(\gamma, b) = \Lambda e_0$, $\gamma > |b|$. The right side is defined by the joint spectral calculus. The round cone gives

$$(\gamma - |b|)H \le \gamma H + b \cdot P \le (\gamma + |b|)H. \tag{7.lxv}$$

These are pointwise inequalities in that calculus. Their positive lower and upper constants show that the domains of every positive integer power of the two operators agree, with equivalent graph norms. Thus $U(\Lambda)\mathcal{D}_\infty = \mathcal{D}_\infty$ on the ordered sector. The polynomial intertwining identity follows directly from eq. 7.lxiii and multiplication of the field polynomials. Polynomial vectors are graph-dense in every ordered-sector energy domain by the proof preceding eq. 7.liv, now using eq. 7.lv. The graph bound in eq. 7.xxxviii, and the equivalent graph norms just proved, extend that identity to the common domain:

$$U(\Lambda)\phi(g)U(\Lambda)^{-1} = \phi(\alpha_\Lambda g) \quad \text{on } \mathcal{D}_\infty \cap \mathcal{K}_{\text{ord}}. \tag{7.lxvi}$$

This is a common-domain covariant scalar field construction on the actual cyclic space. No action of these Lorentz unitaries on $\mathcal{K} \ominus \mathcal{K}_{\text{ord}}$ is needed or asserted.

The construction has supplied common-domain Hermitian fields, positive tempered moments, the full translation spectral carrier, ordered Euclidean matching, a joint forward-tube tempered boundary, and Lorentz covariance under G2. Spacelike locality still requires the permutation and complex-continuation argument. It does not follow from the block estimate or the real boost identities alone and has not been asserted here. All underlying ordinary-source and ultraviolet gauge-theory hypotheses retain their declared conditional scope.

7.3. **Quantitative reconstruction and local commutativity.** The fields of § 7.2 were constructed before any local-commutativity conclusion was used. Their common domain, positive moments, ordered Euclidean values and joint tempered boundary are therefore available for a comparison with the corrected reconstruction theorem. We make that comparison explicitly. It supplies locality on the actual ordered Hilbert sector, together with the stronger distribution-order conclusion of the imported theorem. The proof does not infer locality from a spectral cone alone.

Throughout this section the ordinary-source, ultraviolet and symmetry hypotheses retain the scope declared in the preceding sections. In particular, full scalar Euclidean covariance means G2 on the actual diagonal-flat moments. It is a condition on the chosen state or component, not a conclusion drawn merely from the symmetry of a mixture. Clustering is used only for the conclusions that explicitly invoke a clustering component.

The distribution space and its numerical seminorms. For $d \ge 1$, use the global Euclidean seminorm

$$p_j^{(d)}(f) = \max_{|\alpha| \le j} \sup_{x \in \mathbb{R}^d} (1 + |x|^2)^{j/2} |\partial^\alpha f(x)|. \tag{7.lxvii}$$

The derivative order is the total multiindex order. The weight is one global weight in d variables. Neither a separate weight in every argument nor a derivative order separately bounded in every coordinate is being substituted for it. These choices matter when $d = 4n$ and j itself grows with n.

Let $\Delta_n = \bigcup_{i<j}\{x_i = x_j\}$, and let $\mathcal{S}_{\Delta,n}$ consist of the functions in $\mathcal{S}(\mathbb{R}^{4n})$ whose every partial derivative vanishes on Δ_n. It has the induced Schwartz topology. It is closed: evaluation of a fixed derivative at a fixed point of Δ_n is a continuous functional, and the space is the intersection of their

kernels. No quotient by contact distributions has been chosen in defining the test space. Rather, such distributions are invisible when a functional is restricted to this space.

For comparison with derivative-sum conventions, put

$$s_j^{(d)}(f) = \sum_{|\alpha|\le j} \sup_x (1+|x|^2)^{j/2} |\partial^\alpha f(x)|.$$

The exact count of multiindices is $\binom{d+j}{j}$. One proof appends a nonnegative slack coordinate so that $|\alpha| \le j$ becomes a composition of j into $d+1$ parts; the usual placement of separators then counts the compositions. Consequently

$$p_j^{(d)}(f) \le s_j^{(d)}(f) \le \binom{d+j}{j} p_j^{(d)}(f) \le 2^{d+j} p_j^{(d)}(f). \tag{7.lxviii}$$

At $d = 4n$, $j = 20n$, the cost is at most 2^{24n}. Thus a switch between a maximum and a sum costs one exponential in n, not an unspecified equivalence constant depending on the dimension. The total derivative order remains $20n$.

The global weight can also be compared with a coordinate maximum weight, but that comparison has a different numerical cost. Since $|x|_\infty \le |x|_2 \le \sqrt{d}\,|x|_\infty$, the reverse weight comparison costs $d^{j/2}$. For the displayed values this is $(4n)^{10n}$, which is still factorial growth. Indeed

$$\log(n!) = \sum_{r=1}^{n} \log r \ge \int_1^n \log t\, dt = n\log n - n + 1$$

implies $n^n \le e^n n!$, and hence

$$(4n)^{10n} \le (4e)^{10n} (n!)^{10}. \tag{7.lxix}$$

This estimate explains why a change of seminorm convention must record its dimension cost. We keep eq. 7.lxvii for the proved extension and give the following explicit comparison for the theorem interface.

Proposition 7.5 (The quantitative seminorm ledger)**.** For $f \in \mathcal{S}(\mathbb{R}^d)$ and an integer $r \ge 0$, put

$$\begin{aligned} q_{\mathrm{tot},r}(f) &= \max_{|\alpha|+|\beta|\le r} \sup_x |x^\alpha \partial^\beta f(x)|, \\ q_{\mathrm{sep},r}(f) &= \max_{|\alpha|\le r,\ |\beta|\le r} \sup_x |x^\alpha \partial^\beta f(x)|. \end{aligned} \tag{7.lxx}$$

Then

$$\begin{gathered} q_{\mathrm{tot},r} \le q_{\mathrm{sep},r} \le p_r, \qquad p_r \le (1+d)^r q_{\mathrm{sep},r}, \\ p_r \le (1+d)^r q_{\mathrm{tot},2r}. \end{gathered} \tag{7.lxxi}$$

In particular, in dimension $4n$,

$$p_{20n}(f) \le [(5e)^{20}]^n (n!)^{20} q_{\mathrm{tot},40n}(f). \tag{7.lxxii}$$

■

Proof. A monomial of degree at most r is bounded by $(1+|x|^2)^{r/2}$, which proves the first two comparisons. For the reverse comparison use $\sqrt{1+|x|^2} \le 1 + \sum_{i=1}^d |x_i|$, and expand its r-th power. All monomials have total degree at most r, and the sum of their nonnegative coefficients is exactly $(1+d)^r$. This proves the separate-order bound. The constraints $|\alpha|, |\beta| \le r$ imply $|\alpha|+|\beta| \le 2r$, giving the last line. Finally $1 + 4n \le 5n$, and the elementary factorial estimate preceding eq. 7.lxix gives $(5n)^{20n} \le [(5e)^{20}]^n (n!)^{20}$. □

The comparison distinguishes total combined order from separate monomial and derivative orders. It also proves a sufficient safe match with a doubled linear order, independently of which of these explicit seminorm conventions is used to state the standard theorem. No appeal to a dimension-dependent topological equivalence is needed.

The exact factorial input. For the actual scalar moments the quantitative extension has already proved, with one fixed finite k,

$$S_0 = 1, \qquad |S_n(f)| \le AB^n (n!)^{k+32} p_{20n}^{(4n)}(f), \quad f \in \mathcal{S}_{\Delta,n}. \tag{7.lxxiii}$$

The coefficient 20 controls every order at once. This is stronger information than continuity at each fixed n. The constant A can be replaced by $\max(1, A)$, and similarly put $B_+ = \max(1, B)$. For $n \ge 1$, the factors $2, 3, \dots, n$ give $n! \ge 2^{n-1}$. Therefore

$$B^n \le B_+ (n!)^{\log_2 B_+}, \qquad \sigma_n = AB_+ (n!)^{k+32+\lceil \log_2 B_+ \rceil} \tag{7.lxxiv}$$

is one factorial-growth majorant, and $|S_n(f)| \le \sigma_n p_{20n}(f)$. If the derivative-sum convention is used, its harmless exponential cost in eq. 7.lxviii is absorbed by replacing B by $2^{24}B$ before the same argument. Moreover the seminorm comparison gives

$$|S_n(f)| \le A\widetilde{B}^n (n!)^{k+52} q_{\mathrm{tot},40n}(f), \qquad \widetilde{B} = B(5e)^{20}. \tag{7.lxxv}$$

Absorbing $\widetilde{B}^n$ as in eq. 7.lxxiv gives a factorial majorant at the one fixed order $40n$. Since $q_{\mathrm{tot},40n} \le p_{40n}$, this also gives the weighted version at that order. Thus both the direct weighted route and the safe total-monomial route meet a fixed linear-order hypothesis. The increase by twenty in the factorial exponent is explicit, and no order proportional to n^2 has entered this Euclidean input.

The extension in eq. 7.lxxiii acts on precisely the coincidence-flat Schwartz space. A stronger assertion on unrestricted Euclidean tests is not needed for the corrected linear-growth hypothesis. In particular there is no step that assigns a distribution supported on Δ_n, then invokes the theorem as if that assignment had been fixed by the separated data.

It is useful to distinguish three estimates at this point. The formula in eq. 7.lxxiii is a proved implication of the declared source assumptions. The energy-band construction gives a possibly larger, quadratic in n, order for unrestricted Minkowski moments. The corrected reconstruction theorem below has its own stronger linear-order Minkowski conclusion. We will obtain that conclusion for the constructed moments only after identifying the two constructions. The identification does not use that stronger bound in advance.

The reflected products really belong to the flat domain. Let $\mathcal{S}_{\Delta,+,n}$ be the flat functions whose jets vanish whenever some time coordinate is nonpositive. Set $\theta(\mathbf{x}, t) = (\mathbf{x}, -t)$. For $F_m \in \mathcal{S}_{\Delta,+,m}$ and $G_n \in \mathcal{S}_{\Delta,+,n}$, consider

$$(\Theta\overline{F_m} \otimes G_n)(x_1, \dots, x_{m+n}) = \overline{F_m(\theta x_1, \dots, \theta x_m)} G_n(x_{m+1}, \dots, x_{m+n}). \tag{7.lxxvi}$$

Every derivative of this product vanishes on a coincidence within the first group, because the corresponding derivative of F_m does; the same applies within the second group. At a cross-group coincidence, simultaneous support of the two factors requires its time coordinate to be both nonpositive and nonnegative. It is therefore zero. At that time boundary every jet of at least one factor vanishes. Leibniz's rule proves vanishing of all derivatives of the product there as well. Thus eq. 7.lxxvi belongs to $\mathcal{S}_{\Delta,m+n}$, including the case in which one degree is zero.

Tensor products and reflection are continuous for the stated seminorms. For example, for each fixed j, m, n,

$$p_j^{(4(m+n))}(\Theta\overline{F} \otimes G) \le 2^{j/2} p_j^{(4m)}(F) p_j^{(4n)}(G). \tag{7.lxxvii}$$

The estimate follows by distributing a derivative between the two groups and using $1 + |x|^2 + |y|^2 \le 2(1 + |x|^2)(1 + |y|^2)$. Reflection changes no derivative magnitude or Euclidean length. This proves joint continuity on any fixed pair of degrees. Consequently the full finite-sequence reflected form

$$q(F, G) = \sum_{m,n} S_{m+n}(\Theta\overline{F_m} \otimes G_n) \tag{7.lxxviii}$$

is well-defined. Its positivity is the actual full-sequence positivity proved by the constrained density argument. The sum is finite; no completion in the number of arguments is being assumed.

The historical ordered space consists of the Schwartz functions whose jets vanish outside $0 < t_1 < \cdots < t_n$. It is a subspace of $\mathcal{S}_{\Delta,+,n}$: a coincidence forces equal times and hence lies outside the strict ordered region. The historical reflected product reverses the first argument group. Scalar permutation symmetry makes its value under S_{m+n} equal to eq. 7.lxxviii, by the permutation reversing just those m slots. This establishes the positivity convention required by the imported theorem on its actual test space.

The isometry between ordered quotients follows directly. Two ordered sequences with zero difference in eq. 7.lxxviii have the same image in the full quotient. Conversely a zero image has zero ordered norm because the two forms agree. Complete this isometry and denote its closed range by $\mathcal{K}_{\mathrm{ord}}$. The resulting Hilbert space is the same one on which the band fields were shown cyclic. An equality with the larger full positive-time space is not part of this argument.

Symmetry, reality and the clustering clause. Scalar permutation symmetry and reality are retained properties of the actual Euclidean functional. On separated tensors these are the identities for products of the same real scalar observable; the quantitative flat extension and constrained tensor density transfer them to the entire flat test space. G2 transfers in the same way. Thus the theorem is applied to the chosen functional itself. No invariance of a component is inferred solely from invariance of its barycenter.

For a clustering component, the compact-tuple cluster estimate gives on its ordered compact core

$$\langle [F], U_a[G]\rangle \longrightarrow \langle [F], \Omega\rangle\langle \Omega, [G]\rangle \quad (|a| \longrightarrow \infty), \tag{7.lxxix}$$

where a is spatial. To extend this to any two ordered Hilbert vectors ξ, η, choose compact-core approximants ξ_l, η_l. Unitarity bounds the matrix-element error, uniformly in a, by

$$\|\xi - \xi_l\|\,\|\eta\| + \|\xi_l\|\,\|\eta - \eta_l\|. \tag{7.lxxx}$$

The corresponding rank-one vacuum expression has the same bound, since $\|\Omega\| = 1$. First take the far-translation limit at fixed l, and then let l grow. This proves eq. 7.lxxix on the whole sector, hence in particular on the historical ordered Schwartz sequences. It proves the exact cluster clause without assuming translation-uniform Schwartz bounds for approximate tests.

Several components need not satisfy eq. 7.lxxix after mixing. The cluster-free part of reconstruction still applies to their positive mixture, whereas a unique-vacuum conclusion must retain the component or rank-one cluster assumption. A polynomial decay estimate on compact tuples does not become the same numerical rate on all Hilbert vectors by the preceding density proof.

One verified reconstruction import. We use the corrected scalar theorem $E' \to R'$ of [OS75, Section IV.1, pp. 287–289]. In the notation fixed above, with the exact input match in Prop. 7.5 and eq. 7.lxxv, its import is the following. Normalized coincidence-flat moments with a factorial majorant at one linear order, scalar Euclidean covariance, ordered reflection positivity, reality and permutation symmetry reconstruct positive local tempered scalar moments with the prescribed ordered Euclidean restrictions, the forward spectrum and relativistic covariance. They obey

$$|\widetilde{W}_n(F)| \le a b^{n^2} p_{wn}^{(4n)}(F) \quad (F \in \mathcal{S}(\mathbb{R}^{4n})) \tag{7.lxxxi}$$

for some fixed a, b, w. Adding the cluster clause gives the clustering conclusion. The axiom-subset form without clustering is the clause specified in [OS75, Introduction, Remark 6], with [OS73, Section 3, Remark 3(b)].

This is one standard theorem import. Its locality conclusion includes the permutation and complex-continuation step. That step is not an additional gauge-model estimate, nor is its proof asserted to follow from the band estimate. The previous sections have matched every model-facing input and its domain.

We specify the time convention before comparing moments. If the imported formulation uses a negative-imaginary-time tube, let $D(t,x) = (-t,x)$. Transport its moments by this real linear involution. The transported field has time action e^{+itH} when the original one uses e^{-itH}, and its Euclidean slice is $(i\tau, r)$. Positivity is unchanged, because pullback by D commutes with reversal and complex conjugation. Locality is unchanged, because D preserves the spacelike relation. Lorentz covariance is transported by $\Lambda \mapsto D\Lambda D$, which again belongs to $\mathrm{SO}_+(1,3)$. Finally $p_j(F \circ D) = p_j(F)$, so eq. 7.lxxxi is unchanged. Equivalently, if $\widetilde{E}_n(z;r)$ is the ordered-gap function, the two conventions have boundaries

$$\widetilde{W}_n^{(-)} : z_j = \epsilon_j + it_j, \qquad \widetilde{W}_n^{(+)} : z_j = \epsilon_j - it_j. \tag{7.lxxxii}$$

In the rest of this section $\widetilde{W}$ denotes the second, which is the convention of the constructed band fields. This is a coordinate convention, not a change of the Euclidean data.

Identifying the local moments without assuming locality. Let $E_n(z;r)$ be the point-insertion ordered-gap function from the band construction, with the first Euclidean point fixed at zero. Let $\widetilde{E}_n(z;r)$ be the ordered-gap function of the import. Both are jointly holomorphic for all $\operatorname{Re} z_j > 0$, and continuous in real spatial gaps r. Their Euclidean restrictions represent the same actual moment functional on compact strictly ordered configurations. The sewing proof gives that assertion for E_n; the prescribed Euclidean restriction is part of the reconstruction import for $\widetilde{E}_n$.

We verify equality of the densities. On any compact ordered neighbourhood the actual moment is represented by the continuous band density. The imported function represents the same functional there. Their difference integrates to zero against every compact smooth test. If it were nonzero at a point, continuity would give a smaller ball and a fixed complex phase on which its real part had a strict sign; a nonnegative test in that ball would contradict the zero integral. Thus the two continuous densities agree pointwise. After common center integration this gives

$$E_n(\tau;r) = \widetilde{E}_n(\tau;r) \quad \text{for every } \tau_j > 0 \text{ and real } r. \tag{7.lxxxiii}$$

Fix r. For fixed positive real values of every variable except z_1, the difference is a holomorphic function of z_1 in the right half-plane and vanishes on its positive real interval. The one-variable identity theorem makes it zero for every such z_1. Keep this first variable at an arbitrary complex value and apply the same argument to z_2. Continue through all the gap variables. It follows that

$$E_n(z;r) = \widetilde{E}_n(z;r) \quad \text{whenever every } \operatorname{Re} z_j > 0. \tag{7.lxxxiv}$$

This induction uses functions already jointly holomorphic on one product domain. It does not replace a joint boundary statement by separate tempered limits.

At every strictly positive regulator, eq. 7.lxxxiv identifies the two integrals against arbitrary spacetime Schwartz tests. The band integrals are well-defined and have their regulator-uniform seminorm bound; the import has its actual tempered boundary in the convention in eq. 7.lxxxii. Let all regulators tend to zero jointly. The independently proved band boundary therefore gives

$$W_n(F) = \widetilde{W}_n(F) \quad \text{for every } F \in \mathcal{S}(\mathbb{R}^{4n}). \tag{7.lxxxv}$$

For $n = 1$ this is the same equality of constant vacuum means; for $n = 0$ it is normalization. The argument has never used locality of W. Uniqueness among already local theories alone would not have justified eq. 7.lxxxv; equality of the actual analytic functions and of their unrestricted boundaries does justify it.

In particular eq. 7.lxxxi now holds for the constructed moments. This is an imported improvement of their growth bound, obtained after identification. Their original energy-band proof required only its own explicit fixed-order estimates and was not circularly based on this improvement.

Distributional locality and the full common domain. For adjacent slots $j, j+1$, let π_j swap those slots. The imported locality and eq. 7.lxxxv say exactly

$$(W_n - W_n \circ \pi_j)|_{\{(x_j - x_{j+1})^2 < 0\}} = 0. \tag{7.lxxxvi}$$

This is a distributional identity on that open subset of all $4n$ real coordinates; spectator arguments are unrestricted. It is not merely a commutation identity for a two-point function. It applies first to compact smooth tests in the open subset. Infinity cutoffs then extend it to a Schwartz test supported there: the cutoffs converge in every Schwartz seminorm, and each cutoff has compact support contained in the same open subset.

Take compact smooth g, h with spacelike separated supports. Let ξ, η be any two finite field-polynomial vacuum vectors. The adjoint identity on the common domain writes $\langle \xi, [\phi(g), \phi(h)]\eta \rangle$ as a finite sum of the expressions in eq. 7.lxxxvi, with the reversed conjugate bra labels before the adjacent g, h pair and arbitrary ket labels after it. Each is zero. The polynomial bra vectors are dense in $\mathcal{K}_{\mathrm{ord}}$, and the commutator ket is an actual Hilbert vector by invariance of the common domain. Hence the commutator is zero on every polynomial ket.

There is a further domain issue before asserting the same identity on $\mathcal{D}_\infty$. Let $W = 1 + H$ and retain the proved energy exponent $N = 9$. Applying the band bound first with $k = 0$, then with $k = N$, gives

$$\begin{aligned} \|\phi(g)\phi(h)\eta\| &\le C_0 C_N p_{2N+7}(g) p_{2N+7}(h) \|W^{2N}\eta\|, \\ \|[\phi(g), \phi(h)]\eta\| &\le 2C_0 C_N p_{2N+7}(g) p_{2N+7}(h) \|W^{2N}\eta\|. \end{aligned} \tag{7.lxxxvii}$$

Here $\eta \in \mathrm{Dom}\, W^{2N}$: the first field maps that domain into $\mathrm{Dom}\, W^N$, where the second is defined. Thus both products are actual continuous maps from this graph domain to the Hilbert space. Polynomial vectors are dense in that graph domain on the ordered sector, by the spectral-smoothing argument and cyclic identification already proved. Approximate η there and use eq. 7.lxxxvii. We obtain

$$[\phi(g), \phi(h)]\eta = 0 \quad \left(\eta \in \mathrm{Dom}\, W^{2N} \cap \mathcal{K}_{\mathrm{ord}}\right), \tag{7.lxxxviii}$$

in particular on the invariant common domain.

The same statement holds for Schwartz labels with spacelike separated supports. Multiply each label by smooth infinity cutoffs; their supports remain spacelike separated, and they converge in every seminorm appearing in eq. 7.lxxxvii. The two product maps therefore converge in the stated graph-to-Hilbert norm. This proves the extension without imposing a uniform spacelike distance at infinity.

eq. 7.lxxxviii is the local commutativity of the constructed unbounded Wightman field. It does not say that arbitrarily selected self-adjoint extensions have commuting spectral projections. Real test fields have been proved symmetric and closable, while essential self-adjointness and strong spectral commutation require their own operator criteria. No exponentials of such unspecified extensions are needed for eq. 7.lxxxviii.

The stronger vector and energy seminorm conclusions. The scalar bound in eq. 7.lxxxi also improves the vacuum-product test-space estimate. For a general $F \in \mathcal{S}(\mathbb{R}^{4n})$, let $X_n(F)$ be its actual Hilbert-valued vacuum product. On finite tensors positivity and the adjoint identity give $\|X_n(F)\|^2 = W_{2n}(F^* \otimes F)$. Both sides are continuous under the already proved unrestricted extensions, so this equality holds for every F. Tensor seminorm comparison then gives

$$\|X_n(F)\| \le A_n p^{(4n)}_{2wn}(F), \qquad A_n = \sqrt{a}\, b^{2n^2} 2^{wn/2}. \tag{7.lxxxix}$$

One may increase a, b, w to make them at least one. The harmless power of two comes from eq. 7.lxxvii; the specific larger constant displayed is sufficient. Reversal and conjugation do not change the seminorm. This estimate is compatible with the actual band-vector extension, because their values on the dense tensor space already agree.

There is an explicit energy version of eq. 7.lxxxix. Set $D_t = \sum_{j=1}^{n} \partial_{t_j}$. Translation covariance and continuity of the vector-valued test map imply

$$H^l X_n(F) = i^l X_n(D_t^l F), \qquad p_j(D_t^l F) \le n^l p_{j+l}(F). \tag{7.xc}$$

For the first identity, the simultaneous test translation is $F(t_1 - s, \dots, t_n - s)$; its derivative is $-D_t F$, while the vector translation is e^{isH}. Difference quotients converge in the Schwartz topology and therefore in the Hilbert space. Stone's closed generator criterion proves the domain identity for $l = 1$; induction proves every l. The second estimate is the multinomial expansion, whose absolute coefficients sum to n^l, followed by the monotonicity of the weights. Consequently

$$\|W^l X_n(F)\| \le A_n (1+n)^l p_{2wn+l}(F). \tag{7.xci}$$

This proves continuity of the vacuum-product distribution into every energy graph domain with a linear test order in n at fixed l. It does not give an essential-self-adjointness conclusion: such a conclusion would need control of repeated products of the same unbounded field on a suitable set of analytic vectors, which is a different estimate.

The exact conditional conclusion.

Proposition 7.6 (The scalar reconstruction on its actual cyclic sector)**.** Suppose the actual scalar moments satisfy eq. 7.lxxiii, the full positive form in eq. 7.lxxviii, reality, permutation symmetry, G2 and the UI/PD insertion hypotheses. The energy-band field on $\mathcal{D}_\infty \cap \mathcal{K}_{\mathrm{ord}}$ is Hermitian, tempered, Poincare covariant, local and cyclic, with the full forward spectrum. Its Euclidean correlations are exactly the original diagonal-flat moments in their declared sense. The conclusion uses one verified corrected reconstruction theorem import for the permutation and locality step and its stronger output-order bound. For a component satisfying eq. 7.lxxix, the corresponding cluster conclusion holds. No rank-one cluster assertion is required for the cluster-free local conclusion. ■

Proof. The field, domain, sewing, spectral and joint-boundary arguments were proved before the import. eq. 7.lxxxiii–eq. 7.lxxxv identify its moments; eq. 7.lxxxvi–eq. 7.lxxxviii prove locality on the actual energy domain. The remaining assertions are the already established covariance, positivity and cyclicity. □

The assertion concerns this scalar cyclic sector. Gauge-theory existence, full observable identification and a positive mass gap require separate arguments.

7.4. **Unrestricted test functions and joint boundary estimates.** This section proves the test-space statements used in constructing the band fields. Its estimates apply to general spacetime tests and to Hilbert-valued vacuum products. They also justify simultaneous regulator limits, the passage to difference variables and the spectral support in every cut. The arguments use explicit partitions and Fourier coefficients. No unrestricted Euclidean contact extension and no unquantified tensor-product assertion enter the proof.

Write $\mathcal{S}_d = \mathcal{S}(\mathbb{R}^d)$ and use $p_j^{(d)}$ from eq. 7.lxvii. Constants indexed by fixed integers n, j, r below are finite constants for those integers. A bound at every fixed field order is sufficient for the unrestricted temperedness constructed here. The stronger linear-order conclusion of the corrected reconstruction import has already been distinguished from these constructive estimates.

A product partition with controlled support. Choose $b \in C_c^\infty(\mathbb{R}^4)$, nonnegative, supported in $(-1,1)^4$ and positive on $[-3/4, 3/4]^4$. The function $d(x) = \sum_{z \in \mathbb{Z}^4} b(x - z)$ is positive, smooth and periodic. Only finitely many terms meet any point; the number is uniformly bounded. Positivity on one compact fundamental cell gives a strictly positive lower bound for d. Therefore

$$\chi_z(x) = \frac{b(x-z)}{d(x)}, \qquad \sum_z \chi_z(x) = 1, \qquad \sup_z \|\partial^\alpha \chi_z\|_\infty < \infty. \tag{7.xcii}$$

The derivative bound follows by repeatedly differentiating the reciprocal of the smooth periodic function with its positive lower bound. Every χ_z is supported in $z+[-1,1]^4$. For a fixed degree n, use the product partition $\chi_Z(X)=\prod_{i=1}^n \chi_{z_i}(x_i)$, where $Z=(z_1,\dots,z_n)$. It still sums to one and is locally finite. A derivative of prescribed total order has a bound depending only on that order and n, with no dependence on the locations.

Fix also $\eta\in C_c^\infty((-3,3)^4)$ equal to one on $[-1,1]^4$. Put $\kappa=2\pi/8$. On the period-eight box in each slot, expand $\chi_Z(X)F(X)$ in its ordinary smooth Fourier series. Its coefficients are

$$c_{Z,L}(F)=8^{-4n}\int_{[-4,4]^{4n}} \chi_Z(Z+Y)F(Z+Y)e^{-i\kappa\sum_i l_i\cdot y_i}\,dY, \tag{7.xciii}$$

where $L=(l_1,\dots,l_n)\in(\mathbb{Z}^4)^n$. The localized function vanishes in a neighbourhood of the periodic boundary. Its periodic extension is consequently smooth with all derivatives matching. There is no boundary term when derivatives are integrated off it.

Define one-slot waves

$$v_{z,l}(x)=\eta(x-z)e^{i\kappa l\cdot(x-z)}. \tag{7.xciv}$$

Multiplying the periodic Fourier series by the larger cutoffs gives the global identity $\chi_Z F=\sum_L c_{Z,L}\bigotimes_i v_{z_i,l_i}$. Indeed on the support of $\chi_Z F$ the cutoffs are one; off that support inside the periodic box the represented periodic function is zero; outside the larger cutoffs both sides are zero. The reason for using two nested cutoffs is precisely to obtain this global identity without leaving noncompact plane waves.

The coefficient estimate and the exact order budget. On the support of χ_Z, the distances between z_i and x_i are bounded by two in Euclidean norm. Thus their polynomial weights of any fixed order are comparable, uniformly in the centers. Also

$$\prod_{i=1}^n(1+|x_i|^2)^{1/n}\le 1+\sum_{i=1}^n|x_i|^2. \tag{7.xcv}$$

Each factor on the left is at most the common right-hand side before taking the product and the n-th root. Apply $\prod_i(1-\kappa^{-2}\Delta_{y_i})^r$ in eq. 7.xciii, where r is a positive integer. Its Fourier multiplier is $\prod_i(1+|l_i|^2)^r$. The derivative order used in all slots together is at most $2rn$. Leibniz's rule, eq. 7.xcii and eq. 7.xcv therefore give, whenever $J\ge 2rn$,

$$|c_{Z,L}(F)|\le C_{n,r,J}p_J^{(4n)}(F)\prod_{i=1}^n(1+|z_i|)^{-J/n}(1+|l_i|^2)^{-r}. \tag{7.xcvi}$$

The integration boxes have fixed volume, so no location-dependent volume factor is present. Derivatives of the fixed partition cost only $C_{n,r,J}$. The single global weight gives decay J/n in each slot.

For every nonnegative integer M, differentiating eq. 7.xciv gives

$$p_M^{(4)}(v_{z,l})\le C_M(1+|z|)^M(1+|l|)^M. \tag{7.xcvii}$$

Each derivative differentiates either the fixed cutoff or its exponential. The latter contributes a power of κl, and the former has a fixed derivative bound. On its support $1+|x|\le C(1+|z|)$, proving the weight factor. Since there are only finitely many derivative splittings up to order M, their sum is absorbed in C_M.

Choose

$$2r=2\left\lceil\frac{M+6}{2}\right\rceil,\qquad K=n(M+8). \tag{7.xcviii}$$

Then $M+6\le 2r\le M+7$, so $2rn\le K$. Combining eq. 7.xcvi–eq. 7.xcviii yields

$$\sum_{Z,L}|c_{Z,L}(F)|\prod_{i=1}^n p_M^{(4)}(v_{z_i,l_i})\le C_{n,M}p_K^{(4n)}(F). \tag{7.xcix}$$

Here the sums to be checked are exactly $\sum_z (1+|z|)^{-8}$ and $\sum_l (1+|l|)^M (1+|l|^2)^{-r}$, in four dimensions. For completeness, the shell $|z|_\infty = k$, $k \geq 1$, has $(2k+1)^4 - (2k-1)^4 \leq C(k+1)^3$ points. Euclidean and maximum norms in this fixed dimension differ by at most two. The first shell sum is dominated by $\sum (k+1)^{-5}$. The second is dominated by $\sum (k+1)^{3+M-2r}$, whose exponent is at most -3. Both converge. Taking their n-fold products proves eq. 7.xcix with a finite constant at the specified field order.

Actual Schwartz convergence of the tensor series. The identity used in eq. 7.xcix also converges in the full Schwartz topology, not merely in the one displayed seminorm. Fix an arbitrary target order j. A tensor in independent slots satisfies

$$p_j^{(4n)}\left(\bigotimes_i f_i\right) \leq \prod_i p_j^{(4)}(f_i), \tag{7.c}$$

because a total derivative splits between the slots and $1+\sum |x_i|^2 \leq \prod_i (1+|x_i|^2)$. Repeat eq. 7.xcvi with $2r \geq j+6$, and choose $J \geq \max\{2rn, n(j+8)\}$. eq. 7.xcvii and eq. 7.c now make the tensor series absolutely summable in $p_j^{(4n)}$. Since F is Schwartz, its p_J in this argument is finite for every such choice. This proves absolute summability in every target seminorm.

The Schwartz space is complete for this family: a Cauchy sequence converges with each derivative uniformly on compact sets; the limits are successive derivatives by the fundamental theorem of calculus, and the weighted Cauchy bounds put the resulting function in every seminorm. Therefore the tensor series has a Schwartz sum. Its pointwise sum is F, by the locally finite partition and the smooth periodic Fourier identities. Its Schwartz sum is hence also F. Finite sums of tensors are consequently dense in the ordinary unrestricted Schwartz space. Absolute convergence permits any enumeration of the indices, with no conditional rearrangement.

There is also no algebraic tensor ambiguity. For a finite-dimensional space E of functions, the evaluation functionals span E^*: otherwise a nonzero vector of their annihilator would be a function vanishing at every point. Select a basis of evaluations and invert its matrix on a basis of E. Applying these evaluation matrices in each slot shows that the natural map from a finite tensor product of such function spaces to functions on the product is injective. Every finite tensor relation lies in one such product. A multilinear functional therefore has a well-defined linear value on the actual finite tensor functions used above.

Scalar, vector and energy-graph extensions. Let $\mathcal{E}$ be a Banach space and suppose that an actual n-linear map satisfies

$$\|\mathcal{L}(f_1, \dots, f_n)\|_{\mathcal{E}} \leq D \prod_i p_M^{(4)}(f_i). \tag{7.ci}$$

Define its value on a general $F \in \mathcal{S}_{4n}$ by

$$\mathcal{L}(F) = \sum_{Z,L} c_{Z,L}(F)\, \mathcal{L}(v_{z_1,l_1}, \dots, v_{z_n,l_n}). \tag{7.cii}$$

The series is absolutely convergent in $\mathcal{E}$ by eq. 7.xcix, and $\|\mathcal{L}(F)\| \leq D C_{n,M} p_{n(M+8)}(F)$. Linearity follows from linearity of every coefficient and absolute summation. On a tensor $F = \bigotimes_i f_i$, the localized coefficients factor into their one-slot coefficients. The one-slot series converges in p_M; expand the finite product and pass to its absolutely convergent series using eq. 7.ci. This proves that eq. 7.cii agrees with the original multilinear value. Ordinary tensor density proves uniqueness of its continuous extension. In particular a different choice of cutoffs gives the same answer.

For the actual band fields put $\mathcal{L}(f_1,\dots,f_n)=\phi(f_1)\cdots\phi(f_n)\Omega$. Iteration of the weighted field bound gives, at every integer $l\ge 0$,

$$\begin{aligned}\|W^l\mathcal{L}(f_1,\dots,f_n)\| &\le D_{n,l}\prod_i p_{M_{n,l}}(f_i),\\ M_{n,l}=nN+l+7,\qquad & K_{n,l}=n(nN+l+15).\end{aligned}\tag{7.ciii}$$

At the first field the required right energy exponent is $l+N$; at the next it is $l+2N$, and so on. The largest temporal test order in the band estimate is exactly $nN+l+7$. Apply eq. 7.cii first in the Hilbert space, then in each energy graph space with its $\|W^l\cdot\|$ norm. The partial tensor sums are the same vectors. They converge both in the Hilbert space and after applying W^l. Closedness of W^l identifies the two limits. Hence the extension $X_n(F)$ satisfies

$$X_n(F)\in\mathcal{D}_\infty,\qquad \|W^lX_n(F)\|\le C_{n,l}p_{K_{n,l}}(F).\tag{7.civ}$$

This constructs the vector-valued distribution in all its graph seminorms. Coherence between graph orders is a consequence of closedness, not an assumed nuclear extension into an intersection of unbounded-operator domains.

If a fixed field $\phi(g)$ is applied to these vectors, the energy bound makes it continuous from the graph norm of W^{l+N} to that of W^l. Passing finite tensors to the limit proves

$$\phi(g)X_n(F)=X_{n+1}(g\otimes F)\quad\text{in every energy graph norm.}\tag{7.cv}$$

This is the precise multiplication identity needed for the unrestricted polynomial representation. It remains valid for non-tensor F; no product of two Euclidean separated-tuple symbols has been used to define it.

Uniform families and the topology of the boundary limit. Suppose $\mathcal{L}_\alpha$ obey eq. 7.ci with common D,M, and converge to $\mathcal{L}_0$ on every finite tensor function. Their extensions have a common p_K bound. For fixed F, choose a finite tensor approximation in that seminorm. The approximation error is bounded uniformly in α; convergence handles the one fixed finite approximation. This proves $\mathcal{L}_\alpha(F)\to\mathcal{L}_0(F)$ for every unrestricted test. It is valid for simultaneous parameters and therefore does not impose an order on their limits.

In fact the convergence is uniform on bounded Schwartz sets. Here is an elementary compactness argument for exactly the seminorm needed. For a bounded set $\mathcal{B}\subset\mathcal{S}_d$, smooth infinity cutoffs satisfy

$$\sup_{F\in\mathcal{B}}p_K((1-\chi_R)F)\le C_KR^{-1}\sup_{F\in\mathcal{B}}p_{K+1}(F)\longrightarrow 0.\tag{7.cvi}$$

The derivative bounds on χ_R and the extra power of decay prove this by Leibniz's rule. At fixed R, the cut-off set has common compact support and uniformly bounded derivatives through order $K+1$. The derivatives through order K are uniformly equicontinuous by the mean-value formula. Successive Arzela–Ascoli extraction for their finitely many derivatives proves precompactness in p_K. Combining this with eq. 7.cvi gives a finite p_K net for $\mathcal{B}$, with centers in the Schwartz space.

Apply the common bound to the distance from a net center. Convergence at its finitely many centers then gives

$$\sup_{F\in\mathcal{B}}\|\mathcal{L}_\alpha(F)-\mathcal{L}_0(F)\|_{\mathcal{E}}\longrightarrow 0.\tag{7.cvii}$$

Thus scalar convergence is in the strong tempered-distribution topology of uniform convergence on bounded Schwartz sets. The Banach-valued statement and the energy-graph version follow from the same finite-net proof. This strengthens the joint pointwise-in-test boundary passage and records exactly which uniform estimate makes the strengthening legitimate.

For the regulated field moments the intermediate operators are $e^{-\epsilon_jH-y_j\cdot P}$, with $\epsilon_j>|y_j|_2$. The cone makes them contractions in every energy graph norm, and the joint spectral theorem makes them converge strongly there to identity. The product field estimates therefore have the same constants as without regulators. Replacing the finitely many intermediate contractions one at a

time proves convergence on tensors in every needed graph norm. eq. 7.cvi–eq. 7.cvii then prove simultaneous strong distributional convergence on unrestricted tests. The construction does not rely on a separately tempered Laplace transform in each gap.

Center integration with an explicit continuous right inverse. For $n \geq 2$ let

$$C_n(a,\xi) = (a, a+\xi_1, \dots, a+\xi_1+\cdots+\xi_{n-1}), \qquad I_nF(\xi) = \int_{\mathbb{R}^4} F(C_n(a,\xi))\,da. \tag{7.cviii}$$

The linear coordinate change has determinant one. Its inverse is $a = x_1$, $\xi_j = x_{j+1} - x_j$, and

$$|a|^2 + \sum_j |\xi_j|^2 \leq 5 \sum_i |x_i|^2, \qquad |C_n(a,\xi)| \leq n|(a,\xi)|.$$

The first estimate follows from $|x_{j+1} - x_j|^2 \leq 2|x_{j+1}|^2 + 2|x_j|^2$. For the second, each cumulative sum is bounded by Cauchy–Schwarz and then the n slot bounds are added.

A derivative in a difference coordinate differentiates at most n original slots, with coefficients of magnitude one. Separate the center weight of order five from the remaining weight of order j. The first preceding comparison shows that

$$p_j^{(4(n-1))}(I_nF) \leq C_4\, 5^{(j+5)/2} n^j p_{j+5}^{(4n)}(F), \quad C_4 = \int_{\mathbb{R}^4} (1+|a|^2)^{-5/2}\,da < \infty. \tag{7.cix}$$

Derivatives may be taken under the integral by the same integrable bound. Thus center integration is an actual continuous map of Schwartz spaces.

Choose $\rho \in \mathcal{S}_4$ with integral one and put

$$J_\rho\psi(X) = \rho(x_1)\psi(x_2 - x_1, \dots, x_n - x_{n-1}). \tag{7.cx}$$

Then $I_nJ_\rho\psi = \psi$. The coordinate comparison above, the chain rule and the separate-variable weight inequality give

$$p_j^{(4n)}(J_\rho\psi) \leq (3n)^j p_j^{(4)}(\rho) p_j^{(4(n-1))}(\psi). \tag{7.cxi}$$

There are at most three summands when an original coordinate derivative hits the center factor or the adjacent difference factors; iterating gives 3^j. The factor n^j pays the global weight under C_n. These safe constants suffice without a dimension-independent assertion about the coordinate change. For $n = 1$, center integration is simply the integral of a Schwartz function and the right inverse is $c \mapsto c\rho$.

Factoring every translation-invariant distribution. We prove the factorization, including independence of ρ. In center coordinates simultaneous spacetime translation changes only a. A translation-invariant distribution annihilates each $\partial_{a_j}\Psi$, because translation difference quotients converge in the Schwartz topology to that derivative. It remains to identify the kernel of center integration.

Choose a one-dimensional Schwartz function ρ_1 of integral one. For a Schwartz function $f(a,\xi)$, define $P_jf = \rho_1(a_j)\int f\,da_j$. Each P_j is continuous on the full Schwartz space: an extra weight of order two gives an integrable majorant in its one integration variable, and the remaining weights are paid from the global weight. More explicitly $p_j(P_if) \leq C_{j,\rho_1} p_{j+2}(f)$. The P_j commute.

If a Schwartz function $g(t,z)$ has integral zero in t for every parameter z, set $Qg(t,z) = \int_{-\infty}^t g(s,z)\,ds$. For $t \geq 0$ it also equals $-\int_t^\infty g(s,z)\,ds$. In either tail $|s| \geq |t|$. The extra weight of order two therefore proves $p_j(Qg) \leq (1+\pi)p_{j+2}(g)$. Derivatives in z pass through the integral and still have zero integral; positive t derivatives are derivatives of g. Thus Q is a continuous Schwartz primitive and $\partial_t Qg = g$.

The telescoping identity

$$f - P_1P_2P_3P_4f = \sum_{j=1}^4 P_1\cdots P_{j-1}(1-P_j)f = \sum_{j=1}^4 \partial_{a_j}\Psi_j \tag{7.cxii}$$

uses this primitive in the j-th variable of each summand. The summand has zero integral in that variable, and all preceding P_i commute with its derivative. Every Ψ_j is Schwartz. If $\int f(a,\xi)\,da = 0$, the product $P_1P_2P_3P_4f$ vanishes; this proves that the kernel of center integration is exactly the sum of these derivative ranges.

It follows that every translation-invariant tempered distribution T has the unique difference distribution

$$t(\psi) = T(J_\rho\psi), \qquad T(F) = t(I_nF). \tag{7.cxiii}$$

Both maps are continuous by eq. 7.cix–eq. 7.cxi. Independence of ρ follows because two right inverses differ by an element of the just-identified kernel. Uniqueness follows from $I_nJ_\rho = 1$. This proof applies to the unrestricted Minkowski distributions. It does not require assigning a value to an arbitrary Euclidean contact distribution.

Finite spectral cutoffs and their actual graph limits. Let $Q_R = \sum_{m=0}^{R} P_m$ for the energy bands used earlier, and set $\phi_R(g) = Q_R\phi(g)Q_R$. These are bounded operators with finite energy range, even though the individual band subspaces can be infinite dimensional. Their weighted field bounds have the same constants as the original fields, since Q_R commutes with W and has norm one. For $\xi \in \mathcal{D}_\infty$,

$$\begin{aligned}\|W^l(\phi_R(g) - \phi(g))\xi\| \le{}& \|(Q_R - 1)W^l\phi(g)\xi\| \\ &+ C_l\mathbf{t}_{N+l+2}(g)\|W^{N+l}(Q_R - 1)\xi\| \longrightarrow 0.\end{aligned} \tag{7.cxiv}$$

Both terms tend to zero by the spectral theorem. Iterating the graph estimate for products and replacing one factor at a time proves convergence of every finite cutoff vacuum product. A uniform graph estimate is retained at each replacement, so the vectors on which the remaining field factors act are in the exact domains required. Applying the extension and uniform-family lemma gives convergence of the scalar and vector distributions on all unrestricted tests, including strong convergence on bounded Schwartz sets.

At a spatial point the bounded cutoff field is $A_R(x) = \sum_{m,n\le R} A_{mn}(x)$. The generators of its translations on $Q_R\mathcal{K}_{\mathrm{ord}}$ are bounded by the spectral cone and the bounded energy range. Its spacetime translate is therefore a norm-continuous bounded point field. Its vacuum products have an ordinary difference-variable expression, with one joint translation between every adjacent pair of fields. No finite-dimensionality of a band is needed for this assertion.

The carrier in every difference variable. Write a difference variable as $\xi = (t,x)$, and use physical momentum $p = -P$. The joint translation is $\mathscr{U}(\xi) = e^{i(Et - p\cdot x)}$ in joint spectral variables. If the test transform $f^+(E,p) = \int f(t,x)e^{i(Et-p\cdot x)}\,dt,dx$ vanishes on the forward cone, then

$$\int f(\xi)\mathscr{U}(\xi)\,d\xi = f^+(H,-P) = 0. \tag{7.cxv}$$

This follows by Fubini against scalar spectral measures; the integrable norm bound of f permits the operator weak integral. Insert this identity at any one of the intermediate translations of a cutoff vacuum word. The other difference tests and the bounded spectator operators can be held fixed during that integration. Thus its Fourier distribution has its carrier in the cone in each cut.

To obtain product support rigorously, take a compact Fourier set outside the product of the closed cones. Around each point choose a product box in which one designated momentum is outside its cone. A finite subcover and a smooth subordinate partition reduce an arbitrary test on that compact set to finitely many tests on such boxes. The product Fourier construction, with cutoffs inside each box, approximates each by finite tensors in the test topology. Every tensor gives zero by eq. 7.cxv. Hence the complete test gives zero. This proves the joint support statement in all momentum variables.

The difference distributions of the cutoffs converge to the actual difference distribution, because eq. 7.cxiii uses the continuous fixed right inverse J_ρ. Fourier transformation is continuous on

Schwartz space: differentiating its integral introduces powers of the original coordinates, while multiplication by a Fourier coordinate is integration by parts. An extra integrable weight gives, for instance, $p_j^{(d)}(\widehat{f}) \le C_{d,j} p_{2j+d+2}^{(d)}(f)$. Thus convergence passes through Fourier transformation. A test outside a fixed closed carrier was zero at every cutoff and remains zero in the limit. Consequently

$$\operatorname{supp} \widehat{W}_n^{\mathrm{diff}} \subset (\overline{V}_+)^{n-1}. \tag{7.cxvi}$$

The unreduced momentum statement follows by the determinant-one center-and-difference coordinate change. It is the corresponding condition on every partial sum. The center Fourier variable is zero by translation invariance. Nothing here replaces these multiple carrier conditions by the spectrum of a single vector.

An explicit absolute bound before removing the cutoffs. There is a useful stronger justification of Fubini at a strictly interior tube point. In a vacuum word set the endpoint band indices to zero, since the vacuum has energy zero. Every field block contributes at most $C(1+m_j+m_{j+1})^N$, and each intermediate cone regulator with margin $\delta_j > 0$ contributes at most $e^{-\delta_j m_j}$. Since $1+m+n \le (1+m)(1+n)$, the absolute sum is bounded by

$$C^n \prod_{j=1}^{n-1} \sum_{m\ge 0} (1+m)^{2N} e^{-\delta_j m} < \infty. \tag{7.cxvii}$$

There is no band-dimension factor: each path is estimated in operator norm before its band indices are summed. For fixed integer q, comparison with the integral of $(1+x)^q e^{-\delta x}$ gives $\sum_{m\ge 0}(1+m)^q e^{-\delta m} \le C_q(1+\delta^{-q-1})$. For $0<\delta\le 1$, expand $(1+x)^q$ and integrate its monomials; for $\delta \ge 1$, dominate by the fixed sum with $\delta = 1$. This proves the asserted bound in both ranges.

The series in eq. 7.cxvii is uniform in all real coordinate translations. Its tails outside a growing finite band cube tend to zero by absolute summability. Integrating against the absolute value of a Schwartz spacetime test is therefore legitimate, and dominated convergence removes the cutoffs. This proves the fixed-regulator identity with the actual holomorphic point function. The bound blows up at the boundary and is used only in the interior. The regulator-uniform Schwartz estimate, which is required for the joint boundary, comes separately from the field energy bound and graph contractions. The joint boundary therefore follows from the regulator-uniform estimate without interchanging the energy cutoff and a singular boundary limit.

Ordered cutoffs in every Schwartz seminorm. We give the constrained density proof also needed for exact sewing. Let $O_n = \{0 < t_1 < \cdots < t_n\}$, and suppose that every jet of F vanishes outside O_n. Put $\ell_0 = t_1$, $\ell_j = t_{j+1} - t_j$ for $1 \le j < n$. Choose a smooth one-variable cutoff c equal to zero on $(-\infty, 1]$ and one on $[2,\infty)$, and set $C_\delta(t) = \prod_{j=0}^{n-1} c(\ell_j/\delta)$. Derivatives of total order r cost at most $C_{n,r}\delta^{-r}$.

On the support of $(1-C_\delta)F$, a nonzero value of a derivative of F can occur only with all $\ell_j > 0$ and some $\ell_j \le 2\delta$. Move to that hyperplane along its normal. The distance is at most 2δ; all jets of F on the hyperplane are zero. Taylor's formula with integral remainder to order M, applied also to every derivative of F, gives an extra factor $C_M\delta^M$. The normal segment has bounded length for $\delta \le 1$, so the global weights are uniformly comparable along it. Leibniz's rule consequently proves, for $M > j$,

$$p_j((1-C_\delta)F) \le C_{n,j,M}\delta^{M-j} p_{j+M}(F). \tag{7.cxviii}$$

The same estimate covers points where a cutoff derivative is nonzero, because they lie in one of these boundary strips. A finite sum over the possible hyperplanes costs only a constant at fixed n, j, M. Thus $C_\delta F \to F$ in every Schwartz seminorm.

After cutting off infinity, these tests have compact support a positive distance from the ordered boundary. Choose a sufficiently fine product grid in the full configuration space. A product box meeting that compact support has its one-slot time intervals strictly ordered and strictly positive,

after slightly enlarging them while retaining their gaps. Only finitely many boxes occur. Localize and apply the product Fourier expansion with its larger cutoffs still inside those enlarged intervals. Every tensor term then has precisely the required support order. Its finite partial sums converge in every Schwartz seminorm. This proves density by compact ordered tensors, including the time boundary and all adjacent equal-time hyperplanes, rather than only a pointwise ordering of generic configurations.

Exact sewing beyond tensor profiles. For a compact ordered time configuration let $\rho = \min\{1, t_1, t_2 - t_1, \dots, t_n - t_{n-1}\}$. The point vector sewing formula, with all auxiliary heat parameters less than $\rho/4$, gives a vector $\mathcal{V}_n(X)$ and the scalar Euclidean density $\mathcal{E}_n(X)$, with

$$\|\mathcal{V}_n(X)\| + |\mathcal{E}_n(X)| \le C_n \rho^{-Nn}. \tag{7.cxix}$$

For the vector formula the first positive absolute time is needed to make its outer heat operator bounded. For the scalar formula it is harmless to include that additional minimum. The constants are uniform in the real spatial coordinates. On a compact set with a fixed positive ordered gap these are bounded continuous functions, by the actual bounded semigroup and insertion formulas.

For compact ordered tensors the narrow-time core insertion formula proves their exact original Euclidean scalar and vector values. The Fourier approximations just proved converge in the original test-space seminorms, and also in L^1 on this common compact set. The first convergence controls the original moments and quotient vectors; the second, with eq. 7.cxix, controls their sewn integrals. Passing the finite tensor identity to the limit proves exact sewing for every compact ordered test.

There is also an absolute-integral formulation for a general ordered Schwartz test. If $\rho < 1$, select its smallest boundary distance and use Taylor's flatness along that hyperplane to order $M = Nn+2$. If $\rho = 1$, the ordinary Schwartz bound already suffices. With $J = 4n + 2$, in either case

$$|F(X)| \le C_n \rho^{Nn+2} (1 + |X|^2)^{-J/2} p_{J+Nn+2}(F). \tag{7.cxx}$$

The finite normal displacement in the Taylor argument preserves the weight comparison. The indicated seminorm pays both its derivative order and its weight. Multiplying by eq. 7.cxix leaves $C_n \rho^2 (1 + |X|^2)^{-J/2}$, which is integrable on $\mathbb{R}^{4n}$. It follows that

$$\int_{O_n} (\|\mathcal{V}_n(X)\| + |\mathcal{E}_n(X)|) |F(X)| \, dX \le C_n p_{(N+4)n+4}(F). \tag{7.cxxi}$$

For $N = 9$, this is at most a p_{17n} bound for $n \ge 1$. In particular it is compatible with the available p_{20n} Euclidean continuity. No factorial-in-n assertion for the constants of this auxiliary ordered estimate is needed or inferred.

The integral in eq. 7.cxxi is a Bochner integral for the vector value: the vector sewing function is norm continuous on compact ordered sets, and the displayed majorant is integrable. The ordered cutoffs converge in Schwartz topology by eq. 7.cxviii. The formula in eq. 7.cxxi also controls the difference of their integrals. Thus the compact sewing identity extends to every ordered Schwartz test, both as a scalar identity and as the actual ordered quotient vector. This proves the precise unrestricted and constrained test-space bridges used in the field construction while leaving the ordinary Euclidean contact domain unassigned.

7.5. **The scalar polynomial representation and its domains.** The unrestricted moments now define a positive noncommutative polynomial state. We identify its quotient representation with the actual band fields, including their generators, graph cores and bounded heat-regularized insertions. The construction is on $\mathcal{K}_{\mathrm{ord}}$. The larger positive-time quotient need not be identified with it.

The algebra in this section is an algebra of Minkowski test sequences. Its concatenations are available on all Schwartz functions because the unrestricted joint boundary has been proved. The earlier separated Euclidean tuple domain, on which arbitrary concatenations need not be admissible, is not being declared an algebra by analogy.

The full test-sequence algebra. Let

$$\mathfrak{B} = \bigoplus_{n\ge 0}^{\text{finite}} \mathcal{S}(\mathbb{R}^{4n}), \qquad \mathcal{S}(\mathbb{R}^0) = \mathbb{C}. \tag{7.cxxii}$$

Every element has finitely many nonzero components. Define

$$\begin{aligned} (FG)_n &= \sum_{r+s=n} F_r \otimes G_s, \qquad 1 = (1, 0, \ldots), \\ F_n^*(x_1, \ldots, x_n) &= \overline{F_n(x_n, \ldots, x_1)}. \end{aligned} \tag{7.cxxiii}$$

Associativity follows by grouping the same finite triple sum over degrees; the unit is immediate. Reversal interchanges the two blocks of a tensor, so $(FG)^* = G^*F^*$, and a second reversal and conjugation gives $(F^*)^* = F$. These are identities of actual Schwartz functions, including components that are not finite tensor sums.

The topology is the locally convex direct-sum topology of the Schwartz spaces. A linear map from it to a locally convex space is continuous precisely when its restriction to each degree is continuous. On any prescribed finite set of degrees, multiplication is jointly continuous: the tensor seminorm estimate in eq. 7.c bounds each summand, and the degree sum is finite. No completion over infinitely many field degrees is needed for the state or the representation below.

Set

$$\omega(F) = \sum_n W_n(F_n), \qquad X(F) = \sum_n X_n(F_n). \tag{7.cxxiv}$$

The scalar and vector sums are finite. The proved unrestricted positivity and tensor-density passage give

$$\omega(F^*G) = \langle X(F), X(G)\rangle, \qquad \omega(1) = 1. \tag{7.cxxv}$$

Thus the polynomial state has been obtained from the actual moments, not imposed on an undefined Euclidean product. It is continuous on every degree. Its topology and positivity do not assert a C^*-norm bound for arbitrary polynomial multiplications.

Cauchy–Schwarz and the null left ideal. For completeness the quotient construction can be made directly from positivity. The form $q(F, G) = \omega(F^*G)$ is Hermitian and positive semidefinite. Hermiticity follows either from eq. 7.cxxv, or by expanding the nonnegative real number $\omega((F+zG)^*(F+zG))$ for real and imaginary values of z. For $q(G, G) > 0$, choose $z = -q(G, F)/q(G, G)$ in the quadratic form. If $q(G, G) = 0$, its linear coefficient must vanish for all complex z. These two cases prove

$$|q(F, G)|^2 \le q(F, F)q(G, G). \tag{7.cxxvi}$$

Consequently a null vector is orthogonal to every element.

Let $\mathfrak{N} = \{F : q(F, F) = 0\}$. It is a linear subspace by eq. 7.cxxvi. It is also a left ideal. If $F \in \mathfrak{N}$ and $A \in \mathfrak{B}$, put $B = A^*AF$, which is another finite algebra element. Orthogonality gives

$$\|AF\|_q^2 = \omega(F^*A^*AF) = q(F, A^*AF) = 0. \tag{7.cxxvii}$$

All terms are finite algebra products; no norm bound on left multiplication has been used. The ideal need not be a right ideal, and no tracial property has been assumed.

Complete $\mathfrak{B}/\mathfrak{N}$ to a Hilbert space $\mathcal{H}_\omega$, and let $\mathcal{D}_{\text{alg}} = \mathfrak{B}/\mathfrak{N}$ be its dense quotient domain. Define

$$\pi(A)[F] = [AF], \qquad \Omega_\omega = [1]. \tag{7.cxxviii}$$

The left ideal makes this well-defined. The domain is invariant under every $\pi(A)$, the algebra law is exact there, and $\langle [F], \pi(A)[G]\rangle = \langle \pi(A^*)[F], [G]\rangle$. The adjoint's domain therefore contains the dense subspace $\mathcal{D}_{\text{alg}}$, with $\pi(A^*) \subset \pi(A)^*$. Every $\pi(A)$ is closable. For $A = A^*$ it is symmetric on this domain; its closure is not thereby proved self-adjoint.

For a one-field label $g \in \mathcal{S}_4$, let $\iota(g) = (0, g, 0, \ldots)$. The corresponding GNS field is $\phi_\omega(g) = \pi(\iota(g))$. It depends linearly on g, and $\phi_\omega(g)^*$ contains $\phi_\omega(\bar{g})$ on the common quotient domain. All of these assertions are about defined Hilbert-space operators.

The exact unitary identification with the ordered sector. eq. 7.cxxv defines an isometry

$$J : \mathcal{D}_{\mathrm{alg}} \longrightarrow \mathcal{K}_{\mathrm{ord}}, \qquad J[F] = X(F). \tag{7.cxxix}$$

It is well-defined because $\mathfrak{N}$ is exactly the kernel of the actual vector map. Conversely every vector in that kernel is null, so no additional quotient has entered. The range contains every finite field-polynomial vacuum vector. Their span is dense in the ordered sector by the bounded sewing and cyclicity proof. Therefore the continuous extension of J is onto. It is a unitary from $\mathcal{H}_\omega$ to $\mathcal{K}_{\mathrm{ord}}$, sending Ω_ω to the actual vacuum Ω.

For a general non-tensor component the multiplication identity in eq. 7.cv says

$$J\phi_\omega(g)[F] = \phi(g)J[F]. \tag{7.cxxx}$$

The right side is defined because $X(F) \in \mathcal{D}_\infty$. For finite tensors it is the ordinary product identity. Passing to a general component in the energy graph norm of order N proves exactly the same equality; passing only in Hilbert norm would not have sufficed for the unbounded field on the right.

This identifies the field representation, not merely its numerical vacuum moments. In particular the cyclic Hilbert space in the reconstruction theorem is the actual closed ordered range. The unitary eq. 7.cxxix supplies no fields on $\mathcal{K} \ominus \mathcal{K}_{\mathrm{ord}}$, and it does not require that complement to vanish.

Translations, generators and spectral projections. Let τ_a shift every spacetime argument by the same real vector in the active test convention. Translation invariance of W preserves eq. 7.cxxv, so $U_\omega(a)[F] = [\tau_a F]$ extends to a unitary on the GNS space. The vector-valued Schwartz continuity makes it strongly continuous on the dense quotient domain; unitarity extends that continuity to all vectors. The actual band-field covariance gives

$$JU_\omega(t, y)J^{-1} = e^{itH}U_y \quad \text{on } \mathcal{K}_{\mathrm{ord}}. \tag{7.cxxxi}$$

This equality of bounded groups is first verified on the dense polynomial vectors and then extended. Stone's uniqueness theorem therefore identifies their self-adjoint generators with their exact domains. In particular

$$\begin{aligned} J\,\mathrm{Dom}\,H_\omega &= \mathrm{Dom}\,H \cap \mathcal{K}_{\mathrm{ord}}, \qquad & JH_\omega J^{-1} &= H_{\mathrm{ord}}, \\ Je^{-sH_\omega}J^{-1} &= T_s|_{\mathcal{K}_{\mathrm{ord}}}, \qquad & J\mathsf{E}_\omega(A)J^{-1} &= \mathsf{E}(A)|_{\mathcal{K}_{\mathrm{ord}}}. \end{aligned} \tag{7.cxxxii}$$

The last assertion holds for every Borel set of joint energy and momentum. Indeed the separate strongly commuting groups in eq. 7.cxxxi have the same joint spectral representation after conjugation. One can also obtain it first for their bounded Fourier transforms, then for the generated spectral projections by the uniqueness part of joint functional calculus. Thus there is no new choice of Hamiltonian or of momentum in the quotient representation.

For any integer l, the same functional calculus gives $J\,\mathrm{Dom}(1 + H_\omega)^l = \mathrm{Dom}\,W^l \cap \mathcal{K}_{\mathrm{ord}}$. The common energy domain is transported exactly. The signs in eq. 7.cxxxi are those of the band construction; physical spatial momentum in $Et - p \cdot x$ is $-P$. Its joint cone and all-cut moment spectrum are consequently the already proved ones.

Integrated polynomial operators on the energy domain. The vector extension can be strengthened to an operator extension. For a finite product of m fields and $l \geq 0$, iteration of the energy bound gives

$$\left\| W^l \phi(g_1) \cdots \phi(g_m) W^{-(mN+l)} \right\| \leq C_{m,l} \prod_i p_{mN+l+7}(g_i). \tag{7.cxxxiii}$$

The product is initially defined on the invariant energy domain. The bound gives its unique bounded extension between the indicated weighted spaces. Regard this as an m-linear map into the Banach space of bounded operators from $\operatorname{Dom} W^{mN+l}$, with norm $\|W^{mN+l}\xi\|$, to $\operatorname{Dom} W^{l}$, with norm $\|W^{l}\xi\|$. The constructive Fourier lemma applies in that actual Banach space. For $F \in \mathcal{S}(\mathbb{R}^{4m})$ it defines $\Phi_m(F)$ with

$$\|W^{l}\Phi_m(F)W^{-(mN+l)}\| \le C'_{m,l}p_{m(mN+l+15)}(F). \tag{7.cxxxiv}$$

The partial Fourier sums at different l are the same polynomial operators. On a vector in a higher energy domain their Hilbert limits agree; closedness of W^l identifies their graph limits. Hence these definitions give one coherent operator on $\mathcal{D}_\infty$, mapping it into itself.

For finite tensors, concatenation and reversal are the ordinary field-product rules. For general F, G, approximate each by finite tensors in every seminorm needed by eq. 7.cxxxiv. Before composing, use the estimate with the larger graph exponent required by the left factor. Both compositions then converge on the same domain. This proves

$$\begin{aligned} \Phi_m(F)\Phi_n(G) &= \Phi_{m+n}(F\otimes G) \quad \text{on } \mathcal{D}_\infty, \\ \langle \xi, \Phi_m(F)\eta\rangle &= \langle \Phi_m(F^*)\xi, \eta\rangle \quad (\xi,\eta\in\mathcal{D}_\infty). \end{aligned} \tag{7.cxxxv}$$

The tensor approximations converge in graph norms, so this passage does not apply a merely closable operator to an uncontrolled Hilbert-space limit. Each $\Phi_m(F)$ restricted to the common domain is closable, because its adjoint contains the densely defined conjugate operator in eq. 7.cxxxv.

The finite sum $\Phi(A) = \sum_m \Phi_m(A_m)$ is now an actual representation of $\mathfrak{B}$ on the invariant common domain. It extends its GNS polynomial realization: on $J\mathcal{D}_{\mathrm{alg}}$, eq. 7.cxxxv and vacuum cyclicity give $\Phi(A)J[F] = J[AF]$. Thus the unrestricted algebra product agrees with the field product on the energy domain.

Polynomial vectors form an energy graph core. Let $\mathcal{P}$ be the span of finite tensor field-polynomial vacuum vectors. It is dense in the ordered sector and is contained in every energy domain. It is invariant under real time translations by field covariance. We prove, for each fixed $l \ge 0$,

$$\overline{\mathcal{P}}^{\,\|W^l\cdot\|} = \operatorname{Dom} W^l \cap \mathcal{K}_{\mathrm{ord}}. \tag{7.cxxxvi}$$

Choose $c_R \in C_c^\infty(\mathbb{R})$, equal to one on $[0,R]$, with $0 \le c_R \le 1$ on the positive axis and support there below $2R+2$. The inverse Fourier transform is integrable, and the spectral theorem gives $c_R(H) = \int \check{c}_R(t)e^{itH}\,dt$ in the strong sense, with a consistent Fourier normalization.

For $\zeta \in \mathcal{P}$, this is also a Bochner integral in the W^l graph norm. The translated vector has constant graph norm $\|W^l\zeta\|$; its orbit is graph continuous, because e^{itH} commutes with W^l and is strongly continuous on the vector $W^l\zeta$. First truncate the integrable Fourier tail. On the remaining compact time interval, uniform continuity gives finite simple-function or Riemann-sum approximations in the graph norm. Every sample is a translated polynomial vector, hence remains in $\mathcal{P}$. Therefore $c_R(H)\zeta$ belongs to its graph closure.

Now let $\xi \in \operatorname{Dom} W^l \cap \mathcal{K}_{\mathrm{ord}}$. At fixed R, choose $\zeta_j \in \mathcal{P}$ converging to ξ in Hilbert norm. Boundedness of $W^l c_R(H)$ makes $c_R(H)\zeta_j \to c_R(H)\xi$ in graph norm. The previous paragraph puts all these approximants in the graph closure of $\mathcal{P}$. Finally $c_R(H)\xi \to \xi$ in that graph norm by dominated spectral convergence. This proves eq. 7.cxxxvi, including the order of the two approximations and the bounded operator which justifies the first.

The dense GNS domain $J\mathcal{D}_{\mathrm{alg}}$ contains $\mathcal{P}$, so it is also an energy graph core. Consequently the extension from the polynomial quotient to $\mathcal{D}_\infty$ does not create a different closure of a fixed field. For example,

$$\begin{aligned} \overline{\phi(g)|_{\mathcal{P}}} &= \overline{\phi(g)|_{J\mathcal{D}_{\mathrm{alg}}}} \\ &= \overline{\phi(g)|_{\mathcal{D}_\infty\cap\mathcal{K}_{\mathrm{ord}}}} \\ &= \overline{\phi(g)|_{\operatorname{Dom} W^N\cap\mathcal{K}_{\mathrm{ord}}}}. \end{aligned} \tag{7.cxxxvii}$$

To prove the last equality, approximate a vector in $\operatorname{Dom} W^N$ by polynomial vectors in that graph norm. Their field images converge by the $k = 0$ energy bound. Thus its graph lies in the closure of the polynomial graph. The reverse graph inclusions follow from the domain inclusions. All operators in eq. 7.cxxxvii are closable, by the conjugate-field adjoint identity. The same proof applies to a fixed integrated polynomial of degree at most m, using W^{mN}.

Poincare implementation on both natural domains. The reconstructed moments are Poincare covariant. Pullback of tests therefore gives a null-preserving isometry $[F] \mapsto [\alpha_{a,\Lambda} F]$ on the quotient. Its inverse is the inverse group transformation. It extends to a unitary, with exact group law. Schwartz continuity on every fixed degree makes it strongly continuous on the quotient domain, and unitarity extends this to the completion. On polynomial vectors it has exactly the band representation's action, so eq. 7.cxxix intertwines the two representations on the entire Hilbert spaces.

The quotient domain is invariant under this action. The energy domain is invariant as well, for a different reason. If $(\gamma, b) = \Lambda e_0$, the exact translation group law and Stone's theorem give $U(\Lambda) H U(\Lambda)^{-1} = \gamma H + b \cdot P$. The round cone yields the positive comparisons

$$(\gamma - |b|) H \le \gamma H + b \cdot P \le (\gamma + |b|) H. \tag{7.cxxxviii}$$

These are inequalities in one joint spectral representation. They imply equality of every integer-power domain and equivalence of its graph norms, since $\gamma > |b|$. For a fixed group element, the action is consequently continuous in each energy graph norm. The field intertwining law on the polynomial domain extends by eq. 7.cxxxvi and eq. 7.cxxxiv to the full common energy domain, for both single fields and integrated words.

This verifies two distinct useful domains: the algebraically invariant quotient domain and the complete intersection of energy domains. They need not be equal as sets. They give the same canonical field closures by eq. 7.cxxxvii, and the exact same Hilbert representation by eq. 7.cxxix. No choice of an unspecified larger extension is hidden in the comparison.

Local polynomial algebras and the locality ideal. For an open spacetime set O, let $\mathfrak{B}_{\mathrm{pol}}(O)$ be the unital algebra generated by the degree-one labels in $C_c^\infty(O)$, and use the actual representation Φ on $\mathcal{D}_\infty$. Isotony is immediate from inclusion of supports. Poincare transformations carry this algebra to that of the transformed region, by the already proved common-domain covariance.

If O_1 and O_2 are spacelike separated, every generator from the first commutes with every generator from the second on the invariant domain. Repeatedly move adjacent generators past one another, applying the proved field commutator at each step. Every intermediate vector remains in the common domain. Hence the represented polynomial algebras commute there:

$$\begin{gathered} [\Phi(A), \Phi(B)]\xi = 0, \\ A \in \mathfrak{B}_{\mathrm{pol}}(O_1), \quad B \in \mathfrak{B}_{\mathrm{pol}}(O_2), \quad \xi \in \mathcal{D}_\infty. \end{gathered} \tag{7.cxxxix}$$

One may also use compact jointly smeared words supported in O_i^m. Cover that compact support by product boxes whose larger cutoffs still lie in O_i, and apply the support-preserving Fourier approximation. The operator graph bound in eq. 7.cxxxiv then passes the same commutation identity to those general smearing functions. This is a topological extension of the local polynomial algebra, not an assertion that every such smearing is literally a finite tensor sum.

Let $\mathfrak{I}_{\mathrm{loc}}$ be the two-sided algebra ideal generated by $\iota(g)\iota(h) - \iota(h)\iota(g)$ with spacelike separated supports. Each generator acts as zero on the GNS domain by locality. Left and right multiplication preserve that domain, so every element of the ideal acts as zero. In particular

$$\mathfrak{I}_{\mathrm{loc}} \subset \mathfrak{N}, \qquad \pi(\mathfrak{I}_{\mathrm{loc}}) = 0. \tag{7.cxl}$$

The positive scalar state therefore factors through the local polynomial quotient. The ideal is invariant under the scalar Poincare pullbacks because those preserve spacelike separation. It is also invariant under star: the star of a generating commutator is the negative commutator of

the conjugate labels, with their supports unchanged. This provides an actual local polynomial observable structure. It does not assert strong commutation of spectral projections of closures of real fields, or select self-adjoint extensions of them. A bounded local operator net needs an additional operator criterion if it is to be built through such spectral calculi.

Recovering the actual bounded insertion operators. The preceding equivalence can be checked against the original bounded Euclidean insertions. On the ordered sector the energy-band proof established the operator-norm limit

$$T_s\phi(\chi_\epsilon \otimes h)T_s \longrightarrow \Phi_s(h) \quad (\epsilon \longrightarrow 0). \tag{7.cxli}$$

Here χ_ϵ is the fixed nonnegative scaled temporal approximate identity chosen in the band construction, with $\|\chi_\epsilon\|_1 = 1$, and h is a compact smooth spatial label. On finitely many bands the limit follows from the time approximate identity and bounded generators. The remaining block tails are bounded by $C(1+m+n)^N e^{-s(m+n)}\|h\|_1$, with vanishing absolute row and column tails uniformly in ϵ. Thus eq. 7.cxli is a bounded-operator limit, not a formal sharp-time substitution.

The same construction on the GNS representation is conjugated by J at every ϵ, by eq. 7.cxxx–eq. 7.cxxxii. The bounded limit is consequently the actual original Riesz operator $\Phi_s(h)$. Spatial approximate identities give the point operator $\Phi_s(x) = V_{4s}(0,x)$ in operator norm, because the analytic density is norm continuous in real space. This identifies more than the vacuum state of the insertion: it identifies the operator between every pair of Hilbert vectors.

There is an exact formula for its real Euclidean time translate. For $0 < s \le 1/4$ and $|t| < s$, choose $0 < a < s - |t|$. Then

$$V_{4s}(t,x) = T_{s+t-a}\Phi_a(x)T_{s-t-a}. \tag{7.cxlii}$$

To verify it, first replace the point label by a narrow compact spacetime approximation and test on ordered compact core vectors. The right heat factor shifts the old entries by $s-t-a$. The insertion at scale a puts the new entry at time a and shifts the old entries by another $2a$. The left heat factor finally puts the new entry at $s+t$ and all old entries at their original times plus $2s$. This is precisely the actual core formula with outside entries shifted by s and the central insertion at t. Both sides are bounded. Dense core equality and the norm point limits prove eq. 7.cxlii wherever the original density is defined. The displayed bounded formula also extends it to the larger interval $|t| < s$.

For the jointly complex translate, write $S(z,w) = e^{-zH+iw\cdot P}$. On the common domain where its two factors are contractions, the formula is

$$V_{4s}(z_4, z_{\mathrm{sp}}) = S(s+z_4-a, z_{\mathrm{sp}})\Phi_a(0)S(s-z_4-a, -z_{\mathrm{sp}}), \tag{7.cxliii}$$

with $|\operatorname{Re} z_4| + |\operatorname{Im} z_{\mathrm{sp}}|_2 < s-a$. At real arguments it agrees with eq. 7.cxlii and spatial covariance. Both sides are operator-norm holomorphic on the intersection with the original PD strip. Testing matrix elements and applying the several-variable identity theorem from a real open box proves their equality on connected common neighbourhoods. In this way the reconstructed generators and field identify the actual PD analytic density, with its branch fixed by the original insertion form. An arbitrary bounded coefficient function having the same vacuum expectation would not have sufficed for this conclusion.

7.6. **Conditional measures on compact metric spaces.** The conditional laws used in the phase construction take values in the Borel probability measures on a compact metric configuration space. The conditioning field may be completed and need not be countably generated as a literal collection of sets. It is the Borel field of the *target* space that is countably generated.

Proposition 7.7 (Compact-metric conditional law)**.** Let X be a nonempty compact metric space, let μ be a Borel probability measure on X, and let $\overline{\mathcal{B}}_\mu$ be the μ-completion of its Borel field $\mathcal{B}(X)$. Suppose

$$\mathcal{N}_\mu \subset \mathcal{H} \subset \overline{\mathcal{B}}_\mu, \tag{7.cxliv}$$

where $\mathcal{H}$ is a σ-field and $\mathcal{N}_\mu$ denotes all subsets of Borel μ-null sets. There exists a map $K : X \to \mathcal{P}(X)$, where $\mathcal{P}(X)$ carries its weak topology, with the following properties.

The map K is both Borel measurable and $\mathcal{H}$-measurable. For every bounded Borel $f : X \to \mathbb{C}$,

$$Kf(x) := \int_X f(y)\, K(x, dy)$$
$$\text{is a version of } E_\mu[f \mid \mathcal{H}]. \tag{7.cxlv}$$

In particular $x \mapsto K(x, B)$ is $\mathcal{H}$-measurable for every $B \in \mathcal{B}(X)$, and

$$\int_H K(x, B)\, \mu(dx) = \mu(H \cap B)$$
$$(H \in \mathcal{H}, B \in \mathcal{B}(X)). \tag{7.cxlvi}$$

The measure on the right is understood on the completion. If K' is another probability-valued kernel satisfying eq. 7.cxlv, then there is a single μ-null set N such that

$$K(x, \cdot) = K'(x, \cdot)$$
$$(x \notin N) \tag{7.cxlvii}$$

as Borel probability measures. One may take N to be a Borel null set. Consequently the law $K_*\mu$ on $\mathcal{P}(X)$ is independent of the choice of conditional kernel. ∎

Borel representatives and countably many tests. We first record why completion causes no obstacle to the Borel version in this statement. Every bounded $\overline{\mathcal{B}}_\mu$-measurable real function u has a Borel representative. Indeed, for each rational r replace $\{u > r\}$ by a Borel set differing from it inside a Borel null set. Outside the union of those countably many null sets, the rational level cuts reconstruct u. Their supremum, clipped to a bound for u, is a Borel function equal to u there. If u was $\mathcal{H}$-measurable, this representative remains $\mathcal{H}$-measurable: the change is confined to a Borel null set, all of whose subsets belong to $\mathcal{H}$ by eq. 7.cxliv. This observation will be applied only countably many times.

Choose a countable dense set $\{x_j\}$ in X. Let $D \subset C(X; \mathbb{R})$ be the collection generated by the constant 1 and the functions $y \mapsto d(y, x_j)$ under rational linear combinations, multiplication, pointwise minimum and pointwise maximum. It is countable, is a rational vector lattice and algebra, and separates points: if $x \neq y$, a dense point sufficiently near x gives different distances from x and y. Its uniform closure is a real algebra containing the constants and separating points, so the Stone–Weierstrass theorem makes D uniformly dense in $C(X; \mathbb{R})$.

For each $f \in D$ take a conditional expectation u_f of f given $\mathcal{H}$. These conditional expectations can be obtained as the orthogonal projections of f onto the closed subspace $L^2(\mathcal{H}, \mu)$ of $L^2(\mu)$. The projection identity against 1_H, $H \in \mathcal{H}$, gives

$$\int_H u_f\, d\mu = \int_H f\, d\mu. \tag{7.cxlviii}$$

Testing the sets on which $u_f < 0$, or u_f exceeds an upper bound for f, proves positivity and the usual L^∞ bound. Linearity and uniqueness follow from the same identity. Choose for each u_f a bounded representative that is both Borel and $\mathcal{H}$-measurable, using the preceding observation.

There are only countably many assertions

$$u_1 = 1,$$
$$u_{rf+sg} = ru_f + su_g$$
$$(f, g \in D, r, s \in \mathbb{Q}),$$
$$u_f \geq 0$$
$$(f \in D, f \geq 0 \text{ on } X). \tag{7.cxlix}$$

Each holds almost surely. Their exceptional sets therefore have a single Borel, $\mathcal{H}$-measurable null union N_0. This is the simultaneous exceptional set needed for the construction. No intersection over all continuous or all Borel functions is taken.

Pointwise Riesz representation. For $x \notin N_0$ define $L_x(f) = u_f(x)$ on D. It is rational linear, positive on nonnegative elements of D, and $L_x(1) = 1$. If rational $r > \|f\|_\infty$, then $r \pm f \in D$ are nonnegative, so

$$|L_x(f)| \leq r.$$

Letting rational r decrease to $\|f\|_\infty$ proves $|L_x(f)| \leq \|f\|_\infty$. Uniform density consequently gives a unique continuous extension to $C(X; \mathbb{R})$. The extension is real linear: approximate a real scalar by rationals and use the norm bound. It is positive: if $f \geq 0$ is continuous, choose $f_j \in D$ with $\|f_j - f\|_\infty < 1/j$; then $f_j + 1/j \geq 0$ and $L_x(f_j) \geq -1/j$. It still takes the value one at 1.

The Riesz representation theorem supplies a unique regular Borel probability measure $K(x, \cdot)$ representing L_x. For $x \in N_0$ set $K(x, \cdot) = \delta_{x_*}$ at one fixed $x_* \in X$. Thus $K(x, \cdot)$ is a probability measure at *every* point. Its values on the null set are a choice, with no conditional interpretation required.

We verify measurability of the probability-valued map. Enumerate D as $\{d_j\}$ and define

$$I : \mathcal{P}(X) \longrightarrow \mathbb{R}^{\mathbb{N}},$$
$$I(\rho) = (\rho(d_j))_j. \tag{7.cl}$$

The map is continuous and injective, by uniform density and uniqueness in Riesz representation. The weak probability space $\mathcal{P}(X)$ is metrized by $\sum_j 2^{-j}|\rho(d_j) - \rho'(d_j)|/(1 + 2\|d_j\|_\infty)$: uniform density identifies convergence in this metric with weak convergence. It is compact. Indeed, compactness follows by taking a diagonal subsequence of integrals on D, extending the resulting positive normalized functional as above, and applying Riesz again. Hence I is a homeomorphism onto its compact image in the Hausdorff space $\mathbb{R}^{\mathbb{N}}$.

Every coordinate of $I \circ K$ equals u_{d_j} outside N_0 and the constant $d_j(x_*)$ on N_0. It is both Borel and $\mathcal{H}$-measurable. The countable product map is therefore measurable for both fields; composing with the inverse of I proves the asserted measurability of K. This also supplies an explicit countable determining family for uniqueness.

All bounded Borel tests and uniqueness. For $f \in D$, the equality $Kf = u_f$ holds outside N_0; thus eq. 7.cxlviii holds with Kf in place of u_f. Uniform approximation extends it to every real continuous f, and Kf is measurable as a uniform limit of the corresponding measurable integrals.

Here are the remaining monotone-class details. The collection of bounded real Borel functions f for which Kf is measurable for both fields and

$$\int_H Kf\,d\mu = \int_H f\,d\mu$$
$$\text{for every } H \in \mathcal{H} \tag{7.cli}$$

is a vector space containing $C(X;\mathbb{R})$. It is closed under uniformly bounded increasing limits, by monotone convergence for each probability $K(x,\cdot)$ and for μ; subtracting a constant reduces to nonnegative functions. The bounded functional monotone-class theorem therefore makes it all bounded Borel functions, since the continuous algebra generates $\mathcal{B}(X)$. One can see the latter directly from a countable dense family of distance functions and the countable base of metric balls. Complex functions follow by their real and imaginary parts. This proves eq. 7.cxlv, and indicators give eq. 7.cxlvi. In particular it also verifies directly that K is a probability kernel, including measurability of every Borel-set evaluation.

For uniqueness, apply uniqueness of conditional expectation to Kd_j and $K'd_j$ for the countably many $d_j \in D$. Outside a single null set all these integrals agree. Uniform density then gives equality on every continuous function, and Riesz uniqueness gives eq. 7.cxlvii. The null set belongs to the completed Borel field and hence is contained in a Borel null set, as asserted. Changing a map on a null set does not change its probability-valued law. The law has barycenter μ, because eq. 7.cli with $H = X$ gives

$$\mu(f) = \int_{\mathcal{P}(X)} \rho(f)\,(K_*\mu)(d\rho)$$
$$(f \text{ bounded Borel}). \tag{7.clii}$$

The integrand is Borel on $\mathcal{P}(X)$: this is immediate for continuous f, and the same bounded monotone-class argument proves it for every bounded Borel f. □

The completed invariant field and the exact null-set scope. For a countable group of Borel, μ-preserving transformations, the field of events in $\overline{\mathcal{B}}_\mu$ invariant modulo μ under every group element is a σ-field containing $\mathcal{N}_\mu$. Thus it satisfies eq. 7.cxliv. In particular the theorem applies to the completed translation-invariant field of a compact metric lattice configuration space. The conditional measures are Borel probabilities on that configuration space; no countable generation of the completed invariant field is needed.

The uniqueness assertion is simultaneous for the resulting probability measures. The assertion that Kf is a conditional-expectation version holds separately for each bounded Borel f and, of course, for any preselected countable collection on one common conull set. It does not assert equality outside one universal exceptional set to an arbitrary previously selected version for *every* Borel function.

Nor does the theorem assert pointwise properness $K(x,H) = 1_H(x)$ simultaneously for all conditioning events. Even when those events are Borel, such a demand is false for completed fields. For example let μ be nonatomic and let $\mathcal{H} = \{H \in \overline{\mathcal{B}}_\mu : \mu(H) \in \{0,1\}\}$ be the null/co-null field. The conditional kernel is $K(x,\cdot) = \mu$ almost surely. If simultaneous properness held outside one null set, then at any point x of that conull set the conditioning event $\{x\} \in \mathcal{H}$ would require $K(x,\{x\}) = 1$, whereas $\mu(\{x\}) = 0$. This does not contradict eq. 7.cxlv: for a fixed Borel $H \in \mathcal{H}$, it gives $K(x,H) = 1_H(x)$ almost surely, with an exceptional set that may depend on H. eq. 7.cxlvi is the corresponding integral identity. The theorem concerns the countably generated Borel target $\mathcal{B}(X)$; no regular-conditional-law assertion for an arbitrary non-countably-generated target field is being made.

7.7. **Canonical phases from lattice estimates.** This section gives a conditional implication with completely specified probabilistic objects. The finite-spacing law G3 is proved in appendix A.7; it

is used before any continuum component is constructed. The all-state moment and one-point comparison estimate G4 is derived from the ordinary torus source hypothesis D1 in § 5.22. Conditional probability measures are constructed in § 7.6. The argument here deduces the canonical phase measure from those precise ingredients.

In this section a pure state means an extreme point of the translation-invariant DLR class $\mathcal{G}_j$, equivalently an ergodic state for lattice translations. Extremality in the larger class of all, possibly noninvariant, DLR states is not used and is not identified with this property without an additional argument.

Put $a_j = L^{-K_j} \downarrow 0$, with L an integer, and let $\Omega_j = \mathrm{SU}(2)^{\mathcal{B}_j}$ be the space of bond configurations on $a_j\mathbb{Z}^4$. The set $\mathcal{B}_j$ contains one orientation of each bond. Its countability makes Ω_j compact and metrizable: enumerate the bonds and use the sum of 2^{-m} times bounded metrics on the group factors. The Wilson specification γ_W integrates finitely many bonds W with density proportional to $\exp[-\beta_j \sum_{p:p\cap W\neq\varnothing} a_p]$. The denominator is positive, and compactness of the integration space shows that $\gamma_W F$ is continuous and local whenever F is. Define $\mathcal{G}_j$ to consist of the translation-invariant probability measures with $\rho(\gamma_W F) = \rho(F)$ for every finite W and continuous local F. The equations are weakly closed, so $\mathcal{G}_j$ is compact and convex. Its nonemptiness follows from the fixed-spacing torus-limit construction, and a centering state $\nu_j \in \mathcal{G}_j$ is fixed. G1 supplies the lattice symmetries and mirror positivity used in G3.

Let $\mathfrak{T}$ be the set of finite tuples of real C^1 compactly supported functions with pairwise disjoint supports, including the empty tuple. Concatenation is used only when its resulting supports are disjoint. For $X = (f_1, \dots, f_k)$ define the bounded continuous local function

$$X_j = \prod_{i=1}^{k} [\mathcal{O}_j(f_i) - \nu_j(\mathcal{O}_j(f_i))],$$

$$\varnothing_j = 1.$$

Assume $\nu_j(X_j) \to \sigma(X)$ on $\mathfrak{T}$. For support radii R and separation d, put $b_1 = C_1(R)$ and $b_n = C_n(d; R)$ for $n \geq 2$, and define

$$M_k(d; R) = \sum_{\pi \in \mathrm{Part}(\{1,\dots,k\})} \prod_{J\in\pi} b_{|J|},$$

$$M_0 = 1.$$

The ordinary moment–cumulant identity, applied under any $\rho \in \mathcal{G}_j$, gives

$$|\rho(X_j)| \leq M_k(d; R) \prod_i \|f_i\|_\sharp.$$

Indeed, a singleton block contributes the difference between the means in ρ and ν_j, and a larger block contributes the corresponding cumulant under ρ. This is why a bound on one-point differences is needed. Telescoping a difference of two products gives equicontinuity with the same constants whenever all supports remain in fixed separated containers.

7.7.1. *Decomposition at one spacing.* Let $\mathcal{I}$ denote the completed invariant σ-field for a fixed $\nu \in \mathcal{G}_j$. Prop. 7.7 gives a probability kernel $\omega \mapsto \nu^\omega$ satisfying $\nu^\omega(F) = E_\nu[F \mid \mathcal{I}](\omega)$ for bounded Borel F. We verify that the components are states of the required class.

First, a bounded invariant density preserves the DLR equations. To prove it, approximate such a density h in $L^1(\nu)$ by bounded continuous local functions h_n. This approximation is available because cylinder functions are uniformly dense in continuous functions on the compact product space, and continuous functions are dense in L^1 of a Borel probability measure. Translate h_n so

its support misses W. Invariance of h and ν leaves the approximation error unchanged, while $\gamma_W(h_nF) = h_n\gamma_W F$ for the translated function. Passing to the limit proves $\nu(h\gamma_W F) = \nu(hF)$.

Consequently $\nu^\omega(\gamma_W F) = \nu^\omega(F)$ almost surely. Likewise $\nu^\omega(\tau_v F) = \nu^\omega(F)$ almost surely for every lattice translation v. These statements can be imposed on one common full-measure set: finite bond sets and translations form countable families, and continuous functions on the compact configuration space have a countable dense family of continuous cylinder functions. Supremum-norm continuity then extends the equations to all continuous local functions. A monotone-class argument extends the integral identities to bounded Borel functions. Thus $\nu^\omega \in \mathcal{G}_j$ almost surely.

The law G3 proves that almost every such state is ergodic. Fix a continuous local A. Applied to ν^ω and then integrated, its far-translation limit gives

$$\int \mathrm{Pl}_{\nu^\omega}(A, A)\, d\nu(\omega) = \mathrm{Pl}_\nu(A, A) = \int |\nu^\omega(A)|^2\, d\nu(\omega).$$

The first passage to the limit uses the bound $\|A\|_\infty^2$ and dominated convergence. The difference of the integrands on the two sides is the nonnegative variance of the invariant conditional expectation of A in ν^ω. It is therefore zero almost surely. Impose this on a countable dense family of continuous local A. Density in $L^2(\nu^\omega)$ then says that every invariant L^2 function is constant, which is ergodicity.

Write $\mathcal{E}_j$ for these ergodic states. They are exactly the extreme points of $\mathcal{G}_j$. A nontrivial invariant event decomposes a state into two DLR states by the invariant-density argument. Conversely, the Radon–Nikodym density in a convex decomposition of an ergodic invariant state is invariant, and hence constant. Moreover $\mathcal{E}_j$ is closed. If $\rho_n \in \mathcal{E}_j$ tends weakly to ρ, G3 gives a decay estimate uniform in n. Passing first to this weak limit and then to far translations identifies $\mathrm{Pl}_\rho(A, A)$ with $|\rho(A)|^2$. The same dense-set argument proves that ρ is ergodic. Thus $\mathcal{E}_j$ is compact.

Let D_j be the law of ν_j^ω under ν_j. It is supported on $\mathcal{E}_j$, has barycenter ν_j, and does not depend on versions of the kernel. For this last assertion choose one countable determining family of continuous cylinder functions. Conditional expectations are unique almost surely for that entire family simultaneously; equality on the family implies equality of the probability measures. This also establishes measurability of the probability-valued map and of every evaluation used below.

Uniqueness among all decompositions supported on $\mathcal{E}_j$ requires one more observation. For any such law with barycenter ν_j, the uniform law G3 identifies the integral of a product of finitely many state evaluations with successive far-translation limits of ν_j. These moments are therefore the same as those of D_j. Evaluations of continuous local functions are continuous and separate measures in the compact space $\mathcal{E}_j$. Their polynomial algebra is dense by Stone–Weierstrass, so equal mixed moments imply equal laws.

7.7.2. *Continuum evaluation coordinates.* Choose countable dense test sets as follows. Let $\mathcal{Q}$ contain all finite unions of closed boxes with rational corners. The space of C^1 functions vanishing off $Q \in \mathcal{Q}$, with its C^1 norm, is separable: embed it by its value and four first derivatives in a finite product of separable continuous-function spaces. Choose a countable dense set in each space and enlarge their union by the countable group of L-adic translations and by W_4. Let $\mathfrak{T}^\circ$ consist of the separated tuples from this union. It is countable. Every separated tuple can be approximated by such tuples with supports in fixed separated containers: cover each original support by a finite union of sufficiently small rational boxes inside its chosen open container and use the dense set for that union.

For each $X \in \mathfrak{T}^\circ$ choose once and for all a moment bound M_X from the preceding estimate. Define the compact metrizable product

$$\mathsf{K} = \prod_{X \in \mathfrak{T}^\circ} [-M_X, M_X],$$

$$e_j(\rho) = (\rho(X_j))_{X\in\mathfrak{T}^\circ},$$
$$\lambda_j = (e_j)_* D_j.$$

The evaluation map is continuous for each fixed j. In particular λ_j is a well-defined probability measure on K.

Proposition 7.8 (Conditional canonical decomposition)**.** Under G1, the finite-spacing law G3, the estimates G4, and the stated convergence of $\nu_j(X_j)$, the measures λ_j converge weakly to one probability measure λ. Put $\mathsf{X} = \operatorname{supp}\lambda$. Every $\xi \in \mathsf{X}$ defines a unique functional σ_ξ on $\mathfrak{T}$, obtained as a limit along pure states $\rho_j \in \mathcal{E}_j$ centered at ν_j. The maps $\xi \mapsto \sigma_\xi(X)$ are continuous and separate points. Furthermore

$$\sigma(X) = \int_{\mathsf{X}} \sigma_\xi(X)\, d\lambda(\xi).$$

Their joint moments are the successive far-translation limits of σ. More precisely, for $q \geq 2$,

$$\int_{\mathsf{X}} \prod_{i=1}^{q} \sigma_\xi(X^i)\, d\lambda(\xi) = \lim_{|v_q|\to\infty} \cdots \lim_{|v_2|\to\infty} \sigma(X^1 \cdot \tau_{v_2} X^2 \cdots \tau_{v_q} X^q).$$

The innermost limit is taken first. At each stage the remaining groups must have disjoint supports; every sufficiently distant next translation is then admitted. Each of these intermediate limits exists. These properties determine the compact space, measure and functionals uniquely among compact metrizable full-support representations with continuous point-separating evaluations and the displayed mixed-moment property, up to the homeomorphism preserving all evaluations. Each component clusters with a bound $C(X,Y)|v|^{-2}$ for sufficiently distant separated products, where $C(X,Y)$ and the distance threshold are uniform in ξ. ∎

Proof. The crucial uniformity comes from reflection sizes rather than supremum norms of X_j. Choose an integer physical half-side ϖ so that all supports under consideration lie in $(-\varpi+1, \varpi-1)^4$. This also leaves room for the corners of plaquettes whose barycenters are in those supports. Then $r_j = \varpi/a_j$ is an integer. Each expression defining $\mathcal{N}_{\rho,r_j}(X_j)$ is the moment of two separated reflected copies of X. G4 bounds it uniformly in j and ρ by a constant determined by $M_{2|X|}$ and the test norms. For a displacement v common to the lattices,

$$\frac{r_j}{|v|_\infty/a_j - 2r_j} = \frac{\varpi}{|v|_\infty - 2\varpi}.$$

Thus G3 gives, in every pure state, factorization of the two separated products with error at most $C(X,Y)|v|^{-2}$, uniformly in the cutoff. The norms of the individual representatives, which can diverge, do not enter this bound.

For finitely many coordinates $X^1, \ldots, X^q$, integrate this factorization over D_j. Choose v_q first, then v_{q-1}, down to v_2, with each new vector sufficiently far from the already fixed union. In the factorization at that stage the enclosing support box and its constant may depend on the fixed outer translations, but not on j. Repeating the estimate and multiplying errors only by the uniform individual moment bounds makes the total error smaller than any prescribed ϵ, uniformly in j. At that one fixed finite configuration the remaining single moment converges by the hypothesis on ν_j. The mixed coordinate moments of λ_j are therefore Cauchy. Their precise iterated-limit representation will follow after the components and their uniform clustering have been constructed. Polynomials in finitely many coordinates separate points of K and contain constants. By Stone–Weierstrass they are uniformly dense in its continuous functions. Compactness therefore supplies a weak limit, and the convergent mixed moments make that limit unique along the full sequence.

If ξ belongs to its support, every neighborhood of ξ has positive λ measure. Portmanteau implies that its preimage has positive D_j measure for all sufficiently large j. Use a nested countable neighborhood base and a diagonal choice to obtain $\rho_j \in \mathcal{E}_j$ with $e_j(\rho_j) \to \xi$. The uniform telescoping estimate extends convergence from $\mathfrak{T}^\circ$ to every tuple, giving σ_ξ. It also proves independence from the choice of ρ_j and continuity in ξ, by uniformly approximating a given evaluation with dense-set evaluations. Multilinearity, symmetry and the moment bounds pass to this limit.

Barycenters and higher mixed moments pass to the limit first on the countable set and then on all tuples by the same uniform approximation. The evaluations separate points because their countable subfamily consists of the coordinates of K. If another compact full-support representation has the same mixed moments, embed both spaces by *all* their tuple evaluations into $\mathbb{R}^{\mathfrak{T}}$. Their images have compact union. Polynomials in finitely many of these coordinates are dense in the continuous functions on that union, again by Stone–Weierstrass. Equality of mixed moments therefore gives equality of the two image measures. Each compact image equals the support of its image measure. The images consequently coincide, and injectivity and compactness identify the two spaces by a homeomorphism preserving the measure and every evaluation. This argument does not presume that a countable subfamily separates an arbitrary competing representation.

Finally pass the pure-state factorization estimate to the limit for L-adic translations. Continuity of C^1 tests in the norm $\|\cdot\|_\sharp$ extends it to real translations, preserving the uniform constants after a fixed enlargement of the support margin. This proves the asserted clustering. Finally hold $v_3, \dots, v_q$ fixed and let $|v_2|$ tend to infinity in the barycenter identity. Uniform component clustering separates X^2 from the fixed union of all the other groups. The uniform moment bounds justify passing this limit through the integral. Then let $|v_3|$ tend to infinity, and continue in that order. This proves existence of every intermediate limit and the displayed mixed-moment formula, with the innermost limit taken first. □

7.7.2.1. Plaquette long-range order and the phase means. Let $\mathcal{I}_j$ be the invariant sigma-field of the lattice state ν_j. For a pure state ρ define its rescaled plaquette mean difference by

$$C_j(\rho) = 6a_j^{-4}\big[\rho(A_p) - \nu_j(A_p)\big].$$

Choose a real singleton f_* from the determining family with $\int f_* \neq 0$. By eq. 5.cdlxx, its coordinate in $e_j(\rho)$ is $R_j(f_*)C_j(\rho)$, with $R_j(f_*) \to \int f_*$. The coordinate is uniformly bounded. Weak convergence of λ_j therefore gives convergence of $\int C_j^2\, dD_j$ to $\int \mathfrak{c}_\xi^2\, d\lambda(\xi)$, where $\sigma_\xi((f)) = \mathfrak{c}_\xi \int f$. The barycenter has zero first moment, so $\int \mathfrak{c}_\xi\, d\lambda = 0$.

The finite-spacing conditional law in G3 gives $\rho(A_p) = E_{\nu_j}[A_p \mid \mathcal{I}_j]$ under the ergodic decomposition. Hence

$$\kappa_S := \int \mathfrak{c}_\xi^2\, d\lambda(\xi) = \lim_j 36a_j^{-8}\,\mathrm{Var}_{\nu_j}\big(E_{\nu_j}[A_p \mid \mathcal{I}_j]\big).$$

The lattice plateau estimate identifies the unscaled variance with the far-translation limit of $\nu_j(A_p\,\tau_v A_p) - \nu_j(A_p)^2$ at that fixed spacing. For separated f, h, take the barycenter of the two-point moment and subtract the product of the means within each phase. This gives

$$S_2(f,h) = \int S_2^\xi(f,h)\, d\lambda(\xi) + \kappa_S \int f \int h.$$

In the zero-energy representation, the projection of a singleton with nonzero integral has a nonconstant phase coordinate when $\kappa_S > 0$. Its variance tests the singleton sector of the vacuum criterion.

For separated C^1 tests in one ball of radius $5\mathsf{d}$ with $\mathrm{Lip}\, f_i \le \|f_i\|_\infty/(\vartheta\mathsf{d})$, take the realizing states of two phases at the same cutoffs and apply the short-distance state comparison. Higher cumulants are invariant under the centering shifts. At order one use the same centering state for both means.

On taking limits the oscillation across phases of the cumulant of a subtuple B is at most

$$C_{|B|,\vartheta}\mathsf{d}^{4-|B|}\prod_{i\in B}\|f_i\|_\infty.$$

The same comparison includes the mixture by using its defining states. Apply eq. 6.lxxvi with the phase law λ. In each outer cumulant with at least two blocks subtract a fixed reference phase value from every argument. The bounded-variable cumulant estimate gives $O(\mathsf{d}^{4|\pi|-4}\prod_i\|f_i\|_\infty)$ for a partition π. Hence

$$\left|S_4(f_1,\dots,f_4)-\int S_4^\xi(f_1,\dots,f_4)\,d\lambda(\xi)\right|\le C_\vartheta\mathsf{d}^4\prod_i\|f_i\|_\infty.$$

Where the interacting lower bound of order $\bar{x}_s^{-4}\prod_i\|f_i\|_\infty$ holds for the mixture, $\mathsf{d}^4\bar{x}_s^4\to 0$ makes the phase average positive for sufficiently small d. By continuity the phases with positive fourth cumulant on that tuple then form an open set of positive λ-measure.

7.7.2.2. Isometries of the decomposition. Let $r(x)=Rx+c$ be an isometry preserving σ. The family $\sigma_\xi\circ r^{-1}$ has the same mixed moments as the original family. Indeed, $r^{-1}\tau_v=\tau_{R^{-1}v}r^{-1}$ on tuples, and the far-translation limits above allow all directions of approach to infinity. Apply the mixed-moment formula to the tuples $r^{-1}X^i$ with translations $R^{-1}v_i$, then use the invariance of σ. For one evaluation use the barycenter formula. The transformed evaluations are continuous and separate points since r is a bijection of the test tuples. Uniqueness gives a homeomorphism h_r with $(h_r)_*\lambda=\lambda$ and $\sigma_{h_r(\xi)}=\sigma_\xi\circ r^{-1}$. Uniqueness of the point with those evaluations also gives $h_{rs}=h_rh_s$.

Suppose now that σ is O(4)-invariant. Each realized component is fixed by the coordinate reflection θ_1 by the lattice symmetry of its realizing states and the continuum passage in G1. The centering state has that symmetry as well. For $R\in\mathrm{O}(4)$, $\sigma_\xi\circ R=\sigma_{h_{R^{-1}}(\xi)}$ is another such component. It follows that

$$\sigma_\xi(R\theta_1R^{-1}X)=\sigma_{h_{R^{-1}}(\xi)}(\theta_1R^{-1}X)=\sigma_{h_{R^{-1}}(\xi)}(R^{-1}X)=\sigma_\xi(X).$$

These hyperplane reflections generate O(4). Thus every component is invariant under this group. Invariance under translations and rotations also transfers coordinate reflection positivity to each affine mirror by conjugation.

7.8. **The invariant Hilbert space of scalar phases.** The canonical decomposition is a statement about correlation forms. A density argument below identifies its zero-energy Hilbert space without assuming that the linear span of phase evaluations is an algebra.

Let X be a compact metrizable phase space, let λ be a Borel probability measure of full support on X, and let σ_ξ be its component correlation forms. They act on finite separated tuples of compactly supported test functions and their complex linear span, including the empty tuple 1. Assume that

$$f_F(\xi):=\sigma_\xi(F)\in C(X),$$
$$\sigma(F)=\int_X f_F\,d\lambda,$$
$$f_1=1. \tag{7.cliii}$$

Assume that the functions f_F separate points of X, and that the components preserve conjugation, time reflection, and translations. Concatenation is used only when all its supports are separated.

The quantitative phase construction supplies uniform clustering: for any fixed separated tuples F,G, once their translated supports are disjoint,

$$\sup_{\xi\in X}|\sigma_\xi(F\,\tau_{te_4}G)-\sigma_\xi(F)\sigma_\xi(G)|\longrightarrow 0$$
$$(t\longrightarrow\infty). \tag{7.cliv}$$

Finite linear combinations inherit this property by summation. Uniform separated moment estimates ensure that all functions displayed in eq. 7.cliii–eq. 7.cliv are bounded, for each fixed tuple. The phases need not have the same one-point mean.

Assume that the reflection-positive quotient has been constructed and completed to a Hilbert space $\mathcal{H}$, with dense classes $[F]$ of separated tuples whose compact supports lie strictly in $x_4>0$, and their linear combinations. Suppose positive time translations induce a strongly continuous contraction semigroup e^{-tH} with a nonnegative self-adjoint generator H and

$$\langle[F],e^{-tH}[G]\rangle=\sigma(\overline{\theta F}\,\tau_{te_4}G),$$
$$t>0. \tag{7.clv}$$

These are the explicit Hilbert-space hypotheses; this section does not derive them from qualitative convergence alone. Write $P_0=1_{\{0\}}(H)$ for the zero-energy projection.

Proposition 7.9 (The zero-energy representation)**.** Under eq. 7.cliii–eq. 7.clv, there is a unique unitary

$$U:\ker H\longrightarrow L^2(X,\lambda)$$
such that
$$UP_0[F]=f_F. \tag{7.clvi}$$

The vacuum vector [1] maps to the constant function 1. If X has exactly $m<\infty$ points, then $\dim\ker H=m$. If X is infinite, then $\ker H$ has countably infinite Hilbert dimension. ■

Proof. The spectral theorem and dominated convergence give $e^{-tH}\to P_0$ strongly as $t\to\infty$. For fixed F,G, use eq. 7.cliii, reflection invariance, conjugation, and eq. 7.cliv in eq. 7.clv to obtain

$$\begin{aligned}\langle P_0[F],P_0[G]\rangle&=\lim_{t\to\infty}\int_X\sigma_\xi(\overline{\theta F}\,\tau_{te_4}G)\,\lambda(d\xi)\\&=\int_X\overline{f_F(\xi)}f_G(\xi)\,\lambda(d\xi).\end{aligned} \tag{7.clvii}$$

The limit is justified by uniform clustering, applied to the finite linear combinations as well as to individual tuples. In particular, if $P_0[F]=0$, then $f_F=0$ in L^2. Thus the rule in eq. 7.clvi is well defined and isometric on the span of the displayed vectors. That span is dense in $\ker H$, since the classes $[F]$ are dense in $\mathcal{H}$ and P_0 is a bounded projection. Its extension is an isometry with closed range. It remains to prove surjectivity.

Let $\mathcal{V}$ be the complex linear span in $C(X)$ of all the phase evaluations f_F with F supported at positive times. Any separated tuple can be moved into this half-space by a positive time translation, which leaves its phase evaluations unchanged. Consequently $\mathcal{V}$ still separates points of X. It contains 1 and is closed under complex conjugation.

For positive-time tuples F,G, the concatenation $F\,\tau_{te_4}G$ is a positive-time separated tuple for all sufficiently large t. By eq. 7.cliv,

$$f_{F\,\tau_{te_4}G}\longrightarrow f_Ff_G$$

uniformly on X.

It follows first for generators, and then for their finite linear combinations, that products of elements of $\mathcal{V}$ belong to its uniform closure. The uniform closure is itself closed under products: approximate each of two factors uniformly by elements of $\mathcal{V}$ and use boundedness of the approximants. It is therefore a unital conjugation-closed subalgebra separating points. The complex Stone–Weierstrass theorem makes that closure equal to $C(X)$. Since continuous functions are dense in $L^2(X,\lambda)$, the image in eq. 7.clvi is dense and closed, hence is the whole space.

The stated vector correspondence determines the unitary on a dense set, proving uniqueness. It sends $[1] = P_0[1]$ to 1, since translation fixes the empty tuple.

For a finite phase space, full support gives positive mass to each of its m points, so L^2 has dimension m. For an infinite compact metric space, L^2 is separable. One way to see this is to take a countable uniformly dense subset of $C(X)$ and then its rational complex linear span, which is dense in L^2. Its dimension cannot be finite: for every integer m choose m distinct points and disjoint open neighbourhoods of them. Full support gives each neighbourhood positive measure, so their indicator functions are m nonzero mutually orthogonal vectors. The dimension is therefore countably infinite. This proves all assertions. □

In particular, a single phase gives a one-dimensional zero-energy space under these hypotheses. Several phases can produce several vacua, even when each component has a unique vacuum. An infinite phase set is recorded by the extended natural count ∞ in dimension statements; its set-theoretic cardinality is not equated with Hilbert dimension. Nothing in this identification gives a strictly positive lower spectral bound on $(\ker H)^{\perp}$.

7.9. **The Hilbert realization of scalar phases.** The canonical phase decomposition first specifies scalar correlation forms. We now identify its ordered Hilbert realization, including its common-domain fields and zero-energy subspace. The proof constructs the measurable Hilbert field and shows that the mixed cyclic space fills its direct integral by proving density of the polynomial sections.

The phase space used here is the canonical *scalar* phase space. Its evaluations are those of the specified scalar observable. They separate this space by its construction. This statement does not say that a single scalar observable distinguishes every state of a larger gauge-observable algebra.

The actual phase hypotheses and their uniform extension. Let X be compact metrizable, let λ be a Borel probability measure of full support, and write S^{ξ} for the component scalar moments. The canonical decomposition gives, on separated compact tuples F,

$$f_F(\xi) = S^{\xi}(F) \in C(X), \qquad S(F) = \int_X f_F(\xi)\, d\lambda(\xi), \qquad f_1 = 1. \tag{7.clviii}$$

These evaluations separate points. Their reality, translations and permutation identities hold componentwise. We use the actual component G2 covariance and the uniform component source bounds; they are not inferred from symmetry of the mixture. The scalar phase construction supplies uniform clustering of each fixed pair of separated compact tuples after sufficiently far translations.

The quantitative scalar route has constants uniform on this state class. In particular, on the coincidence-flat Schwartz domain,

$$\sup_{\xi\in X} |S^{\xi}_n(F)| \le AB^n (n!)^{k+32} p_{20n}(F). \tag{7.clix}$$

The UI/PD insertion constants and the energy exponent $N = 9$ are uniform as well. These are the state-uniform conclusions of the declared ordinary-source hypotheses. They retain those hypotheses; no new uniform bound is extracted from compactness alone.

Constrained tensor density extends eq. 7.clviii to every flat Schwartz test: approximate in p_{20n}, use eq. 7.clix to make the approximation error uniform in ξ, and take the same limit in the barycenter

identity. It also makes $\xi \mapsto S_n^{\xi}(F)$ continuous, as a uniform limit of the compact-tuple evaluations. In particular the reflected forms $q_\xi(F,G)$, for any fixed finite ordered Schwartz sequences, have continuous Gram entries and satisfy

$$q(F,G) = \int_X q_\xi(F,G)\, d\lambda(\xi). \tag{7.clx}$$

The products in these forms are in the flat domain by their proved time-boundary vanishing. Their degree sums are finite.

If the original determining family was defined with compact C^1 labels, smooth labels still suffice. Choose fixed disjoint open containers around the original supports and mollify inside them in the C^1 norm. Telescoping the product and using the uniform separated moment bound gives

$$\sup_{\xi} |f_{(h_1,\dots,h_n)}(\xi) - f_{(h_1',\dots,h_n')}(\xi)| \le C_{h,\mathcal{U}} \sum_i \|h_i - h_i'\|_{C^1}. \tag{7.clxi}$$

The approximating labels have a common norm bound and stay in the fixed separated containers, so the constant is uniform along the approximation. This proves that the continuous scalar coordinates remain determined by smooth compact labels.

Ordered evaluations still separate the phase space. Let $\mathcal{V}_{\mathrm{ord}}$ be the complex span of evaluations of compact smooth tuples with strictly ordered positive-time supports, including the empty tuple. We prove that its uniform closure contains every evaluation in eq. 7.clviii.

Take a compact configuration set away from all coincidence diagonals. At a fixed configuration $(x_1,\dots,x_n)$, choose a unit vector v for which the numbers $v\cdot x_i$ are all distinct. Such a vector exists: the finite product $\prod_{i<j} v\cdot(x_i-x_j)$ is a nonzero homogeneous polynomial. If it vanished on the whole sphere, homogeneity would make it zero everywhere, a contradiction. Select a proper Euclidean rotation whose new time projection is this v, permute the slots into increasing projected-time order, and translate all times to be strictly positive. These strict inequalities persist in an open neighbourhood of the configuration.

A finite subcover of the compact set and a smooth subordinate partition split any supported test into finitely many such pieces. Componentwise G2, permutation symmetry and translation invariance move each piece into a compact ordered positive-time test. The support remains off the coincidence diagonals under all these transformations. Ordered support-preserving Fourier approximation expresses that piece as a Schwartz limit of finite ordered tensors. The formula in eq. 7.clix makes their evaluation errors uniform on X. Applying this to a separated tensor, and then using eq. 7.clxi for the original C^1 family, proves

$$\{f_F : F \text{ in the determining separated family}\} \subset \overline{\mathcal{V}_{\mathrm{ord}}}^{\|\cdot\|_\infty}. \tag{7.clxii}$$

Thus ordered evaluations retain point separation. This is a statement about scalar phase evaluations and their uniform norm, not a rotation of the reflection-positive Hilbert plane or a claim that the full positive-time quotient equals its ordered sector.

Uniform time clustering gives the multiplicative part. For two ordered compact tuples F,G, the concatenation $F\cdot\tau_{te_4}G$ is again ordered for all sufficiently large t, and

$$f_{F\cdot\tau_{te_4}G} \longrightarrow f_F f_G \quad \text{uniformly on } X. \tag{7.clxiii}$$

Finite linear combinations obey the same assertion by summation. The uniform closure of $\mathcal{V}_{\mathrm{ord}}$ is therefore closed under products: first multiply finite linear combinations using eq. 7.clxiii, then approximate each of two general closure elements uniformly and use boundedness of the approximants. Reality gives closure under conjugation, and the empty tuple gives the unit. It separates points by eq. 7.clxii. The complex Stone–Weierstrass theorem consequently yields

$$\overline{\mathcal{V}_{\mathrm{ord}}}^{\|\cdot\|_\infty} = C(X). \tag{7.clxiv}$$

The proof supplies the algebra property; it has not assumed that the original linear span of phase evaluations was already an algebra.

One countable core for all component Hilbert spaces. Write $\mathcal{K}_\xi$ for the component ordered Hilbert sector. Choose a countable family $(F_j)_{j\ge1}$ of finite ordered compact tensor sequences, with $F_1 = 1$, whose images are dense in every $\mathcal{K}_\xi$. Here is an explicit way to make the choice common. Use rational boxes with strictly ordered positive-time intervals, fixed nested compact cutoffs, and the countable Fourier waves on rational grids. Finite sums with rational complex coefficients form a countable family. For any ordered compact test the support-preserving Fourier construction approximates it in every required Schwartz seminorm using such boxes and waves; rational coefficients approximate the finitely many retained coefficients. Infinity and ordered-boundary cutoffs handle general ordered Schwartz tests. The uniform bound in eq. 7.clix, applied to the reflected form, makes these approximations uniform in the component Hilbert norms.

Put

$$v_j(\xi) = [F_j]_\xi, \qquad g_{ij}(\xi) = \langle v_i(\xi), v_j(\xi)\rangle = q_\xi(F_i, F_j). \tag{7.clxv}$$

The Gram entries are continuous by eq. 7.clx. In particular $\|v_j(\xi)\|$ is uniformly bounded on the compact phase space for each fixed j. Zero vectors at some phases cause no difficulty; no constant rank is assumed.

Construct a measurable orthonormal family by Gram–Schmidt with zeros retained. Recursively set

$$u_j = v_j - \sum_{i<j} e_i\langle e_i, v_j\rangle, \qquad e_j = \begin{cases} u_j/\|u_j\|, & \|u_j\| > 0,\\ 0, & \|u_j\| = 0. \end{cases} \tag{7.clxvi}$$

Every coefficient is a Borel function of the finite Gram data already constructed. The set $E_j = \{\|u_j\| > 0\}$ is Borel. At each phase the nonzero e_j form an orthonormal basis, because their finite spans successively recover those of the total fundamental family v_j. This explicit procedure handles phase-dependent ranks and possible vanishing Gram determinants.

A concrete direct-integral construction. A section ψ is called measurable when its coordinates $\psi_j(\xi) = \langle e_j(\xi), \psi(\xi)\rangle$ are Borel after null modifications. Its fiber norm is $\sum_j |\psi_j(\xi)|^2$. Define

$$\begin{aligned} \mathcal{D} &= \int_X^{\oplus} \mathcal{K}_\xi \, d\lambda(\xi),\\ \|\psi\|_{\mathcal{D}}^2 &= \int_X \sum_j |\psi_j(\xi)|^2 d\lambda(\xi) < \infty. \end{aligned} \tag{7.clxvii}$$

Its elements are measurable sections with finite displayed norm, modulo equality almost everywhere. Coordinates vanish off E_j, where the corresponding basis vector is zero. This is the Hilbert direct sum $\bigoplus_j L^2(E_j, \lambda)$, so completeness is immediate. Its scalar product is the integral of the fiber scalar products. The construction is independent up to its natural fiberwise unitary of the Gram–Schmidt presentation: another common total measurable family has measurable transition coefficients, and finite orthogonal projections followed by their strong limits identify the same sections and norms.

The elementary sections $\mathbf{1}_A v_j$, with A Borel, span a dense subspace. If a section were orthogonal to all of them, then $\int_A \langle v_j(\xi), \psi(\xi)\rangle d\lambda = 0$ for every A, j. The integrands are integrable, since the fundamental section has bounded norm and ψ is square integrable. They vanish almost everywhere. Countability gives one full-measure set for all j, and totality of the fibers then makes the section zero.

Continuous coefficients already suffice:

$$\operatorname{span}\{c(\xi)v_j(\xi) : c \in C(X),\ j \ge 1\} \text{ is dense in } \mathcal{D}. \tag{7.clxviii}$$

Indeed a Borel probability on a compact metric space is regular. Approximate the indicator of a Borel set in $L^2(\lambda)$ by continuous functions bounded by one: choose a compact subset and an

open superset with arbitrarily small measure difference, then use a continuous function equal to one on the compact set and zero outside the open set. The uniform bound on $\|v_j\|$ transfers that approximation to the section norm. The preceding elementary-section density proves eq. 7.clxviii.

The mixed quotient embeds isometrically. Let $\mathcal{K}_{\mathrm{mix}}$ be the ordered sector of the barycenter functional S. On its common ordered core set

$$J_0[F](\xi) = [F]_\xi. \tag{7.clxix}$$

For finite linear combinations of the F_j the section is measurable by construction. Any other ordered test is approximated uniformly in the component Hilbert norms by the common family. The section obtained in this way is measurable and agrees with the actual quotient vector in every fiber. Its norm is integrable by the same uniform estimate. The formula in eq. 7.clx gives

$$\langle J_0[F], J_0[G]\rangle_{\mathcal{D}} = q(F, G). \tag{7.clxx}$$

Thus null vectors are sent to zero and the rule extends to an isometry $J : \mathcal{K}_{\mathrm{mix}} \to \mathcal{D}$. Denote its closed range by M. At this stage no onto statement has been used.

The section $\Omega(\xi) = \Omega_\xi = [1]_\xi$ is the image of the mixed vacuum and has norm one. Each component Hilbert space is the actual cyclic scalar space established earlier. Neither $\mathcal{K}_{\mathrm{mix}}$ nor a fiber has been replaced by the full positive-time quotient.

Measurable evolution and exact range invariance. For a fixed $s \geq 0$, the component heat operator sends $[F]_\xi$ to $[\tau_{se_4}F]_\xi$. Its images of the common core are measurable, by uniform test approximation. Its norm is at most one. It therefore defines a bounded decomposable operator $T_s^{\oplus}\psi(\xi) = T_s^{\xi}\psi(\xi)$ on $\mathcal{D}$. The same reasoning applies to both signs of spatial translations. Fiberwise strong continuity and the bound $2\|\psi(\xi)\|$ give strong continuity on $\mathcal{D}$ by dominated convergence. They obey their group and semigroup laws pointwise and hence on this space.

The exact common-core translation identity gives

$$JT_s^{\mathrm{mix}} = T_s^{\oplus}J, \qquad JU_y^{\mathrm{mix}} = U_y^{\oplus}J. \tag{7.clxxi}$$

Thus M is invariant under the heat operators and both spatial translation signs. Since each heat operator is self-adjoint, invariance also makes $M^\perp$ invariant. Thus M reduces them and their spectral projections, including the strong limit of the heat semigroup as $s \to \infty$.

The insertion family is measurable as well. For a narrow smooth label k, its actual core vector identity is

$$\Phi_s^{\xi}(k)[F]_\xi = [(\tau_{se_4}k)\cdot\tau_{2se_4}F]_\xi. \tag{7.clxxii}$$

The right side is a common ordered test when the central temporal support is sufficiently narrow. Its Gram entries are continuous in ξ. The operator-norm approximation to the sharp spatial insertion has error $Cs^{-N-1}\epsilon\|h\|_1$, uniformly in the phase. Hence the sharp operators $\Phi_s^{\xi}(h)$ form a measurable bounded family with common norm $Cs^{-N}\|h\|_1$ for small s, and the safe extended bound for larger s.

eq. 7.clxxii proves range invariance at the vector level. Before taking a sharp limit, its right-hand test is independent of the phase and is exactly the corresponding mixed test. Thus the decomposable insertion sends $J[F]$ to the image under J of the actual mixed inserted vector. Pass to the uniform norm sharp limit, and then extend from the dense core. We obtain

$$J\Phi_s^{\mathrm{mix}}(h) = (\Phi_s(h))^{\oplus}J. \tag{7.clxxiii}$$

The conjugate insertion has the same property, so M reduces these bounded operators. A calculation of matrix elements only between vectors in M would not by itself have proved this invariance; the actual common test in eq. 7.clxxii is the needed step. Spatial approximate identities give the same assertion for the point operator, with uniform norm convergence from the analytic PD derivative bound.

Component zero energy is exactly the vacuum line. Uniform compact-tuple component clustering first gives the rank-one spatial matrix-element limit on the ordered compact core. The unitarity approximation argument extends it to all vectors of $\mathcal{K}_\xi$ for each fixed phase. If $\psi \in \ker H_\xi$, the cube cone already implies that its spatial momentum is zero. Indeed the joint spectral carrier on $E = 0$ has $p = 0$, so $U_y^\xi \psi = \psi$ for every spatial y. Apply the rank-one cluster limit to its own matrix element. It gives $\|\psi\|^2 = |\langle \Omega_\xi, \psi\rangle|^2$, which forces ψ onto the vacuum line. Conversely that line has energy zero. Therefore

$$\ker H_\xi = \mathbb{C}\Omega_\xi, \qquad P_0^\xi [F]_\xi = f_F(\xi)\Omega_\xi. \tag{7.clxxiv}$$

This proof uses component clustering. It does not apply that rank-one assertion to a nontrivial mixture.

Strong spectral convergence gives $T_s^\xi \to P_0^\xi$ as $s \to \infty$. Dominated convergence of the squared section norms makes $T_s^\oplus \to (P_0)^\oplus$ strongly on $\mathcal{D}$. Since M reduces the heat family, it contains the projection of every one of its vectors. For an ordered compact F,

$$J P_0^{\mathrm{mix}}[F] = f_F(\xi)\Omega_\xi \in M. \tag{7.clxxv}$$

eq. 7.clxiv and $\|\Omega_\xi\| = 1$ now give $c(\xi)\Omega_\xi \in M$ for every $c \in C(X)$. This is the supply of phase coefficients needed for surjectivity.

Bounded sewn words make the range onto. Fix a compact ordered test. Its times and adjacent gaps have a strictly positive common margin. Choose the auxiliary heat parameters below a quarter of that margin. Write the configuration as $X = ((\mathbf{x}_i, t_i))_{i=1}^n$. At every point of its compact support its exact vector is a bounded sewn word

$$\begin{aligned} B_\xi(X)\Omega_\xi &= T^\xi_{t_1 - a_1} \Phi^\xi_{a_1}(\mathbf{x}_1)\, \mathcal{Q}_\xi(X)\Omega_\xi, \\ \mathcal{Q}_\xi(X) &= \prod_{j=1}^{n-1} \left[T^\xi_{t_{j+1} - t_j - a_j - a_{j+1}} \Phi^\xi_{a_{j+1}}(\mathbf{x}_{j+1}) \right]. \end{aligned} \tag{7.clxxvi}$$

The product is ordered from left to right with increasing j, and is identity when $n = 1$. The operator norms are bounded uniformly in the phase and in the support variables. The positive heat margins also give norm continuity of these words uniformly in the phase: for heat use the bound on $He^{-\delta H}$; for spatial insertions use the uniform PD Cauchy derivative. Thus their decomposable operators have a norm-continuous compactly parameterized family.

Every factor preserves M by eq. 7.clxxi–eq. 7.clxxiii. Applying a word to $c\Omega \in M$ consequently gives the section $c(\xi)B_\xi(X)\Omega_\xi \in M$. Integrate against the fixed compact test. The uniform norm bound permits a Bochner integral, approximated in norm by finite sums. The range is closed, so the result is in M. Exact ordered sewing in each fiber identifies that result with $c(\xi)[F]_\xi$. For the fundamental core this proves

$$c(\xi) v_j(\xi) \in M \quad (c \in C(X),\ j \geq 1). \tag{7.clxxvii}$$

One may use the ordered Schwartz Bochner estimate to make the same assertion for all ordered tests, but the compact fundamental family already suffices.

These sections are dense in $\mathcal{D}$ by eq. 7.clxviii. Since M is closed, we have proved the onto identification

$$J : \mathcal{K}_{\mathrm{mix}} \xrightarrow{\cong} \int_X^\oplus \mathcal{K}_\xi \, d\lambda(\xi). \tag{7.clxxviii}$$

No density of constant sections was assumed. The zero-energy projection first produced nonconstant phase coefficients; actual bounded insertions and sewing then propagated them to a fiberwise total family. This proves precisely why the complete direct integral is obtained for this scalar phase construction.

Exact generator domains in the direct integral. The heat family on $\mathcal{D}$ is a strongly continuous self-adjoint contraction semigroup, hence has a nonnegative self-adjoint generator $H^{\oplus}$. Its resolvent is

$$(1+H^{\oplus})^{-1}=\int_0^\infty e^{-s}T_s^{\oplus}\,ds,\qquad ((1+H^{\oplus})^{-1}\psi)(\xi)=(1+H_\xi)^{-1}\psi(\xi). \tag{7.clxxix}$$

The integral is strongly convergent, and fiberwise integration follows from the integrable bound $e^{-s}\|\psi(\xi)\|$. The resolvent identifies the generator domain as follows.

If ψ is in that domain, write it as the resolvent applied to $f\in\mathcal{D}$. In each fiber it then lies in $\operatorname{Dom} H_\xi$, and $H_\xi\psi(\xi)=f(\xi)-\psi(\xi)$, a square-integrable section. Conversely, if the fiber domain condition holds and that section is measurable and square integrable, put $f(\xi)=(1+H_\xi)\psi(\xi)$. The pointwise resolvent identity recovers ψ, placing it in the global generator domain. Iterating the same argument with resolvent powers gives

$$\begin{aligned}\operatorname{Dom}(1+H^{\oplus})^l=\{\psi:&\psi(\xi)\in\operatorname{Dom}(1+H_\xi)^l \text{ a.e.},\\ &\int_X\|(1+H_\xi)^l\psi(\xi)\|^2d\lambda<\infty\}.\end{aligned} \tag{7.clxxx}$$

The domain includes the measurability of the displayed section; equivalently it is the range of the measurable resolvent power. The mixed generator is unitarily identified with this operator by eq. 7.clxxi and eq. 7.clxxviii, including its exact domain.

The common global energy domain requires eq. 7.clxxx for *every* integer l. Membership in the fiberwise intersection alone does not ensure these integrability conditions. Since the intersection is countable, a vector in the global domain is in the fiber common domain on one common full-measure set. This distinction is retained in every field formula below.

Spatial unitary groups are also decomposable by eq. 7.clxxi. Stone's theorem identifies their generator domains in the same way. Their groups commute with the heat semigroup, so their joint spectral calculus is the componentwise one. One can see this first for products of bounded resolvents and Fourier–Laplace transforms, then extend to bounded Borel functions by bounded pointwise spectral approximation and strong limits. In particular all band projections and bounded inverse-heat factors on a band are measurable decomposable operators.

Measurable band fields and the global common domain. For fixed $m,n,s>0$, the component block

$$A^\xi_{mn}(h)=(e^{sH_\xi}P^\xi_m)\Phi^\xi_s(h)(P^\xi_n e^{sH_\xi}) \tag{7.clxxxi}$$

is a measurable bounded operator field: its outer factors are bounded Borel functions of the measurable energy generator and its middle factor was constructed above. Its norm has the uniform bound $C(1+m+n)^N\|h\|_1$, by the same small-heat optimization. Time smearing is a norm integral between the fixed bands. Approximation by simple temporal sums, or scalar dominated integration of its matrix entries, makes the resulting blocks measurable. The weighted block-Schur estimate has common constants over all phases.

It follows that

$$L^\xi_g=\phi_\xi(g)(1+H_\xi)^{-N}\quad\text{is measurable and}\quad\sup_\xi\|L^\xi_g\|\le Cp_{N+7}(g). \tag{7.clxxxii}$$

To justify measurability of the full matrix, first retain finitely many bands. Those operators are measurable by the preceding construction. Their strong limit is the weighted field matrix: the bounded Schur operator has those blocks, and the finite orthogonal projections tend strongly to identity. The uniform operator bound passes to the limit. This proves eq. 7.clxxxii without postulating a globally unsandwiched sharp-time field.

Every step defining the blocks commutes with the unitary eq. 7.clxxviii: the energy functional calculus, the actual bounded insertion, the fixed-band inverse heat, the temporal integral and finally

the uniformly bounded strong matrix limit. Therefore the actual mixed field has the identity

$$(J\phi_{\mathrm{mix}}(g)\psi)(\xi) = \phi_\xi(g)(J\psi)(\xi) \quad \left(\psi \in \mathcal{D}_\infty^{\mathrm{mix}}\right). \tag{7.clxxxiii}$$

For its construction on $\mathrm{Dom}(1+H^{\mathrm{mix}})^N$, apply the bounded decomposable field $(L_g)^\oplus$ to the global vector $(1+H^\oplus)^N J\psi$. The integrability condition in eq. 7.clxxx makes this defined. The stronger uniform weighted bounds show that it preserves the global common energy domain. Thus eq. 7.clxxxiii is an exact common-domain formula, not a claim about a maximal direct-integral domain for arbitrarily chosen self-adjoint field extensions.

The same operator-valued Fourier construction gives this identity for every integrated scalar polynomial. Its graph bounds are uniform because the input field energy estimates are uniform. Consequently the full actual scalar polynomial representation, with its common invariant domain, is decomposed by eq. 7.clxxviii.

Measurability of the reconstructed Poincare action. We prove measurability for each component directly. Fixed Minkowski polynomial vacuum vectors in a component form measurable sections. To verify it, start with the measurable vacuum section and use finite band approximations to each smeared field. All are measurable. Their products converge in every required energy graph norm by the uniform field bounds. Pointwise limits of their measurable coordinates are measurable. The general joint-smearing statement follows from the uniform vector Fourier extension.

Choose a countable dense family of Minkowski Schwartz labels and their finite polynomial words. These vectors are total in every component by its cyclic scalar reconstruction. Their Gram entries are measurable by the preceding paragraph. They can therefore be used as another measurable fundamental family, with a Gram–Schmidt construction exactly as in eq. 7.clxvi.

For a fixed Poincare element (a,Λ), the component unitary sends every member of this total family to the same word with transformed tests. The result is a measurable section, by the just-proved test continuity and field measurability. Finite orthogonal projections in that family then prove measurability on the original fundamental sections: expand each original section in its measurable orthonormal coordinates, apply the unitary to a finite expansion, and take the fiber norm limit. The operator norm is one throughout. This constructs the decomposable unitary

$$(U^\oplus(a,\Lambda)\psi)(\xi) = U_\xi(a,\Lambda)\psi(\xi). \tag{7.clxxxiv}$$

The component group laws give its group law. Fiberwise strong continuity and the bound by $2\|\psi(\xi)\|$ give strong continuity after integration. No continuous choice of a basis in the fibers is necessary.

On a mixed Minkowski polynomial vacuum vector the intertwining identity follows from eq. 7.clxxxiii, the invariant component vacua and the common transformed tests. Those vectors are dense in the mixed ordered sector, and both maps are bounded unitaries. Thus

$$JU_{\mathrm{mix}}(a,\Lambda)J^{-1} = U^\oplus(a,\Lambda). \tag{7.clxxxv}$$

All covariance statements here use actual component G2. A symmetry which only permuted components would instead require an accompanying action on the phase variable; that different case is not silently substituted for the componentwise invariance assumed in this scalar route.

Phase multipliers and zero-energy multiplicity. For $c \in L^\infty(X,\lambda)$, multiplication of sections defines a bounded operator M_c of norm at most $\|c\|_\infty$. It commutes with the decomposable Poincare operators and with energy functional calculus. It preserves every global graph domain by eq. 7.clxxx, and the pointwise field identity gives

$$M_c\phi(g)\psi = \phi(g)M_c\psi \quad (\psi \in \mathcal{D}_\infty). \tag{7.clxxxvi}$$

The same is true for integrated polynomial operators on that domain. This is a precise commuting multiplier structure for the scalar representation. It is not an assertion about the center of an unspecified bounded local gauge-observable net.

By eq. 7.clxxiv, the global zero-energy sections are exactly $c(\xi)\Omega_\xi$ with $c \in L^2(X,\lambda)$. The unitary identification therefore gives

$$\ker H^{\mathrm{mix}} \cong L^2(X,\lambda), \qquad P_0^{\mathrm{mix}}[F] \longmapsto f_F, \qquad \Omega^{\mathrm{mix}} \longmapsto 1. \tag{7.clxxxvii}$$

This recovers the phase evaluation rule on the actual ordered sector. Its onto property follows from eq. 7.clxiv, or directly from the full direct-integral identification, and does not assume equality with the larger positive-time Hilbert space. The same sections are invariant under the full reconstructed Poincare group, because every component vacuum is invariant. Conversely any Poincare-invariant vector has energy zero.

If X has exactly m points, full support gives positive mass at every one and $\dim\ker H^{\mathrm{mix}} = m$. If X is infinite, $L^2(X,\lambda)$ is separable: continuous functions have a countable uniformly dense family and are dense in L^2. Its dimension is not finite, because for any m one can choose m distinct points with disjoint open neighbourhoods; full support gives positive measure to each neighbourhood, whose normalized indicators are orthogonal. The Hilbert dimension is therefore countably infinite. It is not the set-theoretic cardinality of the phase space.

The precise uniform spectral-gap criterion. The direct integral also identifies exactly the uniform spectral statement that a further estimate would have to prove. Put $\Pi_m^\xi = \mathbf{1}_{(0,m)}(H_\xi)$ for $m > 0$. These projections are measurable and decompose under J. One explicit verification uses the bounded resolvent $R_\xi = (1 + H_\xi)^{-1}$. Continuous functions of R_ξ decompose by polynomial approximation and eq. 7.clxxix. Continuous functions on $[0,1]$, bounded by one and increasing to the indicator of $((1+m)^{-1}, 1)$, then converge strongly to Π_m^ξ. The same approximation holds for the global resolvent, and dominated section convergence identifies the two limits. Hence

$$\begin{aligned} J\mathbf{1}_{(0,m)}(H^{\mathrm{mix}})J^{-1} &= \int_X^\oplus \Pi_m^\xi \, d\lambda(\xi), \\ \mathbf{1}_{(0,m)}(H^{\mathrm{mix}}) = 0 \iff \Pi_m^\xi &= 0 \text{ a.e.} \end{aligned} \tag{7.clxxxviii}$$

For the reverse implication in the last equivalence integrate the squared norm of a projected section. For the forward implication apply the zero global projection to every fundamental section v_j. The integrals of their nonnegative squared projected norms vanish. Countability and fiber totality make the component projection zero almost everywhere.

Define the extended component gap by $g(\xi) = \sup\{q \in \mathbb{Q}_{>0} : \Pi_q^\xi = 0\}$, with supremum zero for the empty set and infinity when there are no positive energies. It is measurable, since each zero-projection event is the countable intersection of $\{\|\Pi_q^\xi v_j(\xi)\| = 0\}$. Using rational thresholds in eq. 7.clxxxviii gives

$$g_{\mathrm{mix}} = \operatorname*{ess\,inf}_{\xi\in X} g(\xi). \tag{7.clxxxix}$$

Thus positive component gaps almost everywhere are insufficient unless their essential lower bound is positive. No continuity or positive lower bound of this measurable function follows merely from the continuous finite Gram entries.

An elementary Hilbert-family example verifies that distinction. Take $X = [0,1]$ with Lebesgue measure, a vacuum vector in every fiber, and one extra orthogonal unit vector e for $x > 0$. There is no extra vector at $x = 0$. Use fundamental sections $v_1 = \Omega$ and $v_2(x) = \sqrt{x}\, e$, with $v_2(0) = 0$, and let $H_x e = xe$. Their nonconstant Gram entry is x; its heat-translated entry is xe^{-tx}. Both are continuous at zero. Every fiber has a one-dimensional zero-energy space. Its gap is x for $x > 0$, and infinity at zero, while the direct integral has gap zero. This example establishes the spectral point about Gram data; it is not asserted to be a gauge-theory phase model.

The equivalent heat estimate is

$$\begin{gathered}\mathbf{1}_{(0,m)}(H^{\mathrm{mix}}) = 0 \quad \Longleftrightarrow \\ \|e^{-tH^{\mathrm{mix}}} - P_0^{\mathrm{mix}}\| \le e^{-mt} \quad (t \ge 0).\end{gathered} \tag{7.cxc}$$

The forward implication is the spectral supremum on positive energies. Conversely a nonzero spectral projection in $(0, m)$ has a nonzero subprojection in some compact interval strictly below m. A unit vector in that subspace has a slower exponential lower bound, contradicting the displayed norm estimate. Here P_0^{mix} is the whole phase vacuum space in eq. 7.clxxxvii, not just the projection onto the one vector Ω^{mix}.

A dense-core version can be useful without an operator-norm estimate as input. Suppose one common $m > 0$ satisfies, for every vector ζ in a dense core, an estimate

$$\begin{gathered}0 \le \langle \zeta, (e^{-tH^{\mathrm{mix}}} - P_0^{\mathrm{mix}})\zeta \rangle \le C_\zeta e^{-mt}, \\ t \text{ sufficiently large.}\end{gathered} \tag{7.cxci}$$

Each C_ζ may depend on the vector. Its positive spectral measure cannot charge $(0, c]$ for any $c < m$: such a charge would give a lower bound proportional to e^{-ct}, contradicting eq. 7.cxci. Thus the projection onto $(0, m)$ kills the dense core and hence vanishes. Conversely eq. 7.cxc implies eq. 7.cxci with $C_\zeta = \|\zeta\|^2$. These are exact conditional criteria, not an estimate of a positive m. The available compact-tuple clustering does not itself supply eq. 7.cxci.

The identification concerns the scalar correlation phase space and its scalar fields. Extending it to a larger gauge-observable family requires the additional observable and state-consistency data specified separately.

7.10. **The gauge-invariant cutoff algebra.** The scalar field constructed above has a precise polynomial observable sector. To compare it with a gauge theory one first needs the larger gauge-invariant algebra whose observables would have to be transported and identified. We construct that algebra at a cutoff, prove concrete dense families, and state the exact measure-preservation consequence of testing them. These are algebraic statements about the actual bond variables. A continuum limit for the additional observable family is a further requirement.

Bonds, orientations and the full local gauge action. Let $\Gamma = (V, E)$ be a finite or countable locally finite graph, and select one orientation E_+ of its unoriented bonds. The hypercubic lattice and its admissible periodic quotients are the intended cases. Write

$$K = \mathrm{SU}(2), \qquad \Omega_\Gamma = K^{E_+}, \qquad U_{\bar{e}} = U_e^{-1}. \tag{7.cxcii}$$

For a finite composable oriented path $\gamma = e_1 \cdots e_r$, use the ordered product $U_\gamma = U_{e_1} \cdots U_{e_r}$; the empty path has holonomy identity. With $s(e), t(e)$ its endpoints, a site gauge $g = (g_v)_{v \in V}$ acts by

$$(g \cdot U)_e = g_{s(e)} U_e g_{t(e)}^{-1}, \qquad (g \cdot U)_\gamma = g_{s(\gamma)} U_\gamma g_{t(\gamma)}^{-1}. \tag{7.cxciii}$$

The path identity follows by cancelling every adjacent $g_v^{-1} g_v$. It is compatible with reversed paths and with insertion or deletion of immediate retracings.

For a closed path the normalized trace

$$w_\gamma(U) = \tfrac{1}{2} \operatorname{Tr} U_\gamma \tag{7.cxciv}$$

is real, lies in $[-1, 1]$, and is gauge invariant. Reality follows from the conjugate eigenvalues of an SU(2) matrix. Cyclic changes of a loop's basepoint and reversal do not change this trace. The matrix holonomy of an open path is instead gauge covariant at its two endpoints; it is not a scalar gauge-invariant observable by itself.

The gauge group $\mathcal{G} = K^V$ has its compact product topology. Its action on Ω_Γ is continuous: each output bond depends continuously on only that bond and its two site variables. For countable sets,

both product spaces are compact metrizable. An action of all site gauges is meant here. Invariance under gauges fixing selected centers is a different, generally weaker condition.

Continuous local functions and their uniform completion. For finite $F \subset E_+$, let $\mathcal{A}_F = C(K^F)$, embedded into $C(\Omega_\Gamma)$ by ignoring the remaining bonds. If $F \subset F'$, this is an injective unital star map and preserves the supremum norm. Any two local functions belong to the algebra for their finite union of bonds. The union is therefore a unital star algebra.

In the infinite case enumerate the bonds and choose the bounded bi-invariant matrix metric $d_K \le 1$. The product metric $d_\Omega(U,U') = \sum_j 2^{-j} d_K(U_{e_j}, U'_{e_j})$ is compatible with the topology. Fix a reference configuration. Replacing all coordinates after the first N by their reference values changes this metric by at most 2^{-N}. For $f \in C(\Omega_\Gamma)$, uniform continuity shows that the corresponding cylinder functions converge uniformly to f. Hence

$$\mathcal{A} = \overline{\bigcup_{F \Subset E_+} \mathcal{A}_F}^{\|\cdot\|_\infty} = C(\Omega_\Gamma). \tag{7.cxcv}$$

This argument gives the concrete meaning of the quasilocal completion in the compact bond model. It does not include an additional charged field at infinity or a choice of boundary frame for an open path.

Let $S(F)$ be the finite set of endpoints of the bonds in F. A local function is invariant under every full site gauge exactly when it is invariant under $K^{S(F)}$, since no other gauge coordinate enters its value. Define

$$\mathcal{A}_F^{\mathrm{inv}} = C(K^F)^{K^{S(F)}}, \qquad \mathcal{A}^{\mathrm{inv}} = \{f \in C(\Omega_\Gamma) : f(g \cdot U) = f(U)\}. \tag{7.cxcvi}$$

These are unital closed star subalgebras. The local embeddings preserve invariance. Finite products of Wilson traces belong to the appropriate local invariant algebra.

Finite Haar averaging and the actual projection. For $f \in \mathcal{A}_F$, set

$$(\mathcal{E} f)(U) = \int_{K^{S(F)}} f(g \cdot U)\, dg, \tag{7.cxcvii}$$

with normalized product Haar measure and gauges outside $S(F)$ equal to identity. The result is continuous and depends only on F. If a larger endpoint set is used the additional integrations do not change the integrand. If the same cylinder function is represented in a larger bond algebra, the answer is again the same function. Thus eq. 7.cxcvii is one well-defined linear map on the local union.

Haar invariance makes its range gauge invariant. It is positive, preserves the unit and star, and satisfies

$$\|\mathcal{E} f\|_\infty \le \|f\|_\infty, \qquad \mathcal{E}^2 = \mathcal{E}, \qquad \mathcal{E} b = b \quad (b \text{ invariant}). \tag{7.cxcviii}$$

For idempotence, average twice and combine the two site gauges; the normalized product Haar integral is unchanged. All the integrals are on finite compact groups at this stage. The norm bound extends $\mathcal{E}$ uniquely to $C(\Omega_\Gamma)$, still positive, unital and contractive.

The extended image is precisely $\mathcal{A}^{\mathrm{inv}}$. Images of local approximants are invariant, so their uniform limits are invariant. Conversely, if b is invariant and $f_N \to b$ are cylinder approximants, then $\|\mathcal{E} f_N - b\|_\infty \le \|f_N - b\|_\infty$: inside eq. 7.cxcvii, replace $f_N(g \cdot U)$ by $b(g \cdot U) = b(U)$. Thus $\mathcal{E} b = b$. In particular

$$\mathcal{A}^{\mathrm{inv}} = \overline{\bigcup_F \mathcal{A}_F^{\mathrm{inv}}}^{\|\cdot\|_\infty}. \tag{7.cxcix}$$

No assertion that arbitrary cylinder approximants are themselves invariant was needed; averaging makes them so without increasing their approximation error.

For invariant b, c, the finite integral also gives $\mathcal{E}(bfc) = b(\mathcal{E} f)c$, and uniform approximation extends this to the full algebra. The same pointwise argument proves complete positivity: an

average of positive matrices of continuous functions remains positive when tested against every constant coefficient vector. Thus $\mathcal{E}$ is an actual conditional expectation with the stated range and norm.

The compact orbit space and invariant states. The product metric can be chosen gauge invariant, since left and right multiplication preserve the matrix metric on each bond. On gauge orbits define

$$d_{\mathrm{orb}}([U],[V]) = \min_{g\in\mathcal{G}} d_\Omega(U, g\cdot V). \tag{7.cc}$$

The minimum exists by compactness of $\mathcal{G}$ and continuity. Symmetry follows by inversion of the gauge, and the triangle inequality follows by composing two gauges and using that they act by isometries. If the distance is zero, a minimizing gauge gives $U = g\cdot V$, so the orbits coincide. Thus it is a metric. The orbit map is continuous because $d_{\mathrm{orb}}([U],[V]) \le d_\Omega(U,V)$. The compact domain maps onto a Hausdorff metric space, so this is its quotient topology. In particular the orbit space is compact metrizable and all orbits are closed.

Invariant continuous functions descend and lift through this quotient. Hence

$$\mathcal{A}^{\mathrm{inv}} \cong C(\Omega_\Gamma/\mathcal{G}) \tag{7.cci}$$

isometrically as unital star algebras. States of the invariant algebra are therefore probability measures on this compact orbit space. There is no choice of a possibly discontinuous gauge-fixed representative in this assertion.

Every state ω of $\mathcal{A}^{\mathrm{inv}}$ has the gauge-invariant extension $\widehat{\omega}(f) = \omega(\mathcal{E}f)$ to $\mathcal{A}$. It is positive and normalized by eq. 7.cxcviii. Conversely a gauge-invariant state τ on $\mathcal{A}$ satisfies $\tau(\mathcal{E}f) = \tau(f)$. For a cylinder function this follows by integrating its state value over the finite gauge group; the map into continuous functions is norm continuous, so the bounded functional passes through the integral. Uniform approximation handles all f. Thus

$$\begin{aligned} \mathrm{St}(\mathcal{A}^{\mathrm{inv}}) &\longleftrightarrow \mathrm{St}_{\mathcal{G}}(\mathcal{A}), \\ \omega \longmapsto \omega\circ\mathcal{E}, &\qquad \tau \longmapsto \tau|_{\mathcal{A}^{\mathrm{inv}}}. \end{aligned} \tag{7.ccii}$$

is an affine bijection; St denotes normalized positive states and its subscript denotes gauge invariance. By the Riesz representation theorem these are also the corresponding gauge-invariant probability measures on bond configurations. In particular the *full* invariant state determines its unique gauge-invariant lift. A state on a proper scalar subalgebra has a different information content, addressed below.

Gauge invariance of the actual cutoff Gibbs states. For a plaquette p, let $A_p = 1 - \frac{1}{2}\operatorname{Re}\operatorname{Tr} U_p$. It is gauge invariant by eq. 7.cxciii. On a finite periodic lattice, the Wilson density with respect to product bond Haar measure is therefore gauge invariant, and the measure itself is invariant by the left and right invariance of every bond integral. Its positive normalization does not affect the identity.

The same fact holds for a Wilson DLR state on the infinite locally finite graph with its local plaquette specification. Let g be supported on finitely many sites and let W contain every bond incident to those sites. This is finite by local finiteness. All outside bonds are fixed under this gauge. In the conditional kernel γ_W, change the inside variables by that gauge. Product Haar measure is preserved, and each plaquette term meeting W has unchanged trace, including the plaquettes containing fixed outside bonds. Consequently

$$\gamma_W(f\circ g) = \gamma_W f, \qquad \mu(f\circ g) = \mu(\gamma_W(f\circ g)) = \mu(f). \tag{7.cciii}$$

The second identity is the DLR equation. It applies to a local continuous f; its additional outside variables are simply held fixed in the conditional integral.

For an arbitrary site gauge and a local f, only the endpoint values of the finitely many bonds in its support matter. Copy those values to a finitely supported gauge and set the rest to identity.

It has exactly the same action on f, so eq. 7.cciii proves invariance under the arbitrary gauge on all local tests. eq. 7.cxcv then gives invariance on the whole continuous algebra. Thus the cutoff Gibbs and DLR states supply actual states of $\mathcal{A}^{\mathrm{inv}}$, not merely states of its $\mathrm{tr}(F^2)$ part.

This proof is at a fixed cutoff and does not establish joint continuum limits for all these observables. Gauge invariance of a cutoff state and existence of a particular scalar scaling limit have distinct analytical contents.

A concrete dense family of invariant polynomials. On a finite bond set, let $\mathcal{P}_F$ be the unital star algebra generated by the matrix entries of each U_e and their complex conjugates. It separates points of K^F because the defining matrix representation is faithful. It is closed under conjugation. Stone–Weierstrass gives uniform density in $C(K^F)$. Apply the contractive expectation:

$$\overline{\mathcal{E}\mathcal{P}_F}^{\|\cdot\|_\infty} = \mathcal{A}_F^{\mathrm{inv}}. \tag{7.cciv}$$

The averaged polynomial is still a matrix-entry polynomial. Indeed substitute eq. 7.cxciii in each monomial, expand its finitely many indices, and integrate the gauge-dependent coefficients. Only constant coefficients change. It follows that $\mathcal{E}\mathcal{P}_F = \mathcal{P}_F \cap \mathcal{A}_F^{\mathrm{inv}}$, which is itself a unital star algebra. Its density is therefore an algebraic density statement with a concrete averaging map, not a formal span assumption.

The invariant tensors in this family can also be read directly. At each site collect the fundamental, dual and conjugate representation factors carried by the incident matrix entries of a monomial. They form one finite-dimensional unitary representation $R_v(g)$. Haar averaging at that site is

$$P_v = \int_K R_v(g)\, dg. \tag{7.ccv}$$

It is an orthogonal projection onto the invariant tensors: inversion of g proves $P_v^* = P_v$, two Haar integrals prove $P_v^2 = P_v$, and left invariance gives $R_v(h)P_v = P_v$. Conversely it fixes every invariant vector. Choosing an orthonormal basis of that finite invariant space writes P_v as a finite sum of rank-one tensor contractions. Taking the product over vertices shows exactly how an averaged matrix monomial becomes a finite sum of gauge-invariant tensor networks.

This argument uses tensor powers of the defining representation and their invariant projections. No classification of all irreducible representations is required for the density proof. In the SU(2) case the next section gives a second complete family using only closed Wilson trace words and an explicit orbit-separation argument.

Based gauges and physical invariance. The gauge group fixing one root in a connected graph is a proper subgroup of the full site gauge group. A rooted holonomy can be invariant under the former and still transform by conjugation under the remaining root value. Likewise a coordinate chart which fixes block centers may retain coarse bond matrices with their endpoint covariance.

For example, under a gauge fixing all internal path vertices but changing the two endpoints, an open holonomy still obeys the two factors in eq. 7.cxciii. Its individual matrix entries therefore do not belong to $\mathcal{A}^{\mathrm{inv}}$. A gauge-fixed background or a free coordinate in a constrained chart is useful geometric data, but its covariance must be included when an observable is read out. Full gauge-invariant traces or invariant index contractions remove the remaining endpoint action. The distinction prevents a uniqueness theorem modulo center-fixing gauges from being mistaken for a complete specification of physical gauge observables.

Boundary frames can be kept deliberately, in which case the relevant algebra is covariant under the boundary group rather than fixed by it. Its endpoints, transformation law and any later invariant contraction must then be part of the observable type. The invariant algebra in eq. 7.cxcvi uses no unspecified boundary frame.

What a dense insertion test really proves. Suppose a finite-cutoff operation gives a bounded linear readout T from the invariant continuous algebra to another continuous algebra, and probability states μ, ν on the two sides. If $\mu(P) = \nu(TP)$ for every member of a uniformly dense invariant polynomial family, then for any invariant continuous f, choose $P_l \to f$ uniformly and estimate

$$|\mu(f) - \nu(Tf)| \le (1 + \|T\|)\|f - P_l\|_\infty + |\mu(P_l) - \nu(TP_l)| \longrightarrow 0. \tag{7.ccvi}$$

For a positive unital Markov readout, $\|T\| = 1$; if a different bounded norm is used it is the displayed norm which must be checked. Thus exactness on a concrete complete invariant family can establish exactness on the entire continuous gauge-observable algebra.

If the induced full measures are gauge invariant, equality of their invariant states identifies their gauge-invariant lifts by eq. 7.ccii, hence identifies their Borel probability measures. Their integrals then agree on all bounded Borel insertions. For a change of variables or a probability kernel this is an actual measure identity once its induced measure and gauge covariance have been specified. Without that covariance, eq. 7.ccvi still states exactly the invariant continuous identity that was proved and does not silently add a stronger lift.

Preserving only the normalization tests the single element 1, not the dense family in eq. 7.cciv. Preserving scalar tr(F^2) moments tests another subalgebra whose size must be determined. The next two sections make the finite SU(2) complete family and the scalar restriction explicit, so that a proposed larger gauge-theory identification can be checked against defined observables rather than inferred from one sector's existence.

7.11. **Complete Wilson coordinates for a finite** SU(2) **graph.** We prove a concrete completeness result for the cutoff observable algebra. On each finite graph, finitely many Wilson traces of words of length at most three in a fundamental loop family separate every gauge orbit. Their polynomials are uniformly dense in all continuous gauge-invariant functions. We also describe their exact compact coordinate image. The result is kinematic; it does not assume a Gibbs measure or a continuum limit of these coordinates.

Tree frames with a specified root. First take a connected finite graph with vertex set V and one orientation for each bond in E_+. Choose a root o and a spanning tree T. For $v \in V$, let p_v be the tree path from o to v, using inverse matrices whenever a stored orientation is traversed backwards. Set

$$H_v(U) = U_{p_v}, \qquad H_o = I, \qquad (\mathcal{T}U)_e = H_{s(e)} U_e H_{t(e)}^{-1}. \tag{7.ccvii}$$

This is the actual site gauge with values $g_v = H_v$. Every tree bond becomes identity. For a tree edge traversed from parent v to child w, the path identity is $H_w = H_v U_{vw}$, so the transformed bond is $H_v U_{vw} H_w^{-1} = I$. The reversed stored orientation gives the inverse identity and hence also identity.

Enumerate the non-tree bonds as $e_1, \dots, e_r$, where $r = |E_+| - |V| + 1$, and put

$$h_i(U) = H_{s(e_i)} U_{e_i} H_{t(e_i)}^{-1} = U_{p_{s(e_i)} e_i p_{t(e_i)}^{-1}}. \tag{7.ccviii}$$

Thus h_i is the holonomy of a specified closed path based at the root. All these functions are continuous finite products and inverses of actual bond variables. Every tuple in K^r is obtained: set every tree bond to identity and assign the desired tuple to the non-tree bonds.

For an arbitrary site gauge k, the path transformation law gives

$$H_v(k \cdot U) = k_o H_v(U) k_v^{-1}, \qquad h_i(k \cdot U) = k_o h_i(U) k_o^{-1}. \tag{7.ccix}$$

In particular the tuple is invariant under gauges fixing the root. If two configurations have the same tuple, their tree gauges send them to the same tree-identity configuration. The composition of the inverse of one tree gauge and the other is a gauge fixing the root and mapping one configuration to the other. This proves that based gauge orbits are exactly the fibers of the tuple map.

Under the full site group the only residual action on this tuple is simultaneous conjugation. A constant site gauge keeps all tree bonds identity and conjugates every non-tree bond, so every such conjugation is realized. Conversely eq. 7.ccix shows that a full gauge transformation can do no more. We have therefore proved a continuous bijection of compact orbit spaces

$$K^{E_+}/K^V \;\cong\; K^r/\operatorname{Ad} K. \tag{7.ccx}$$

Both quotient spaces are Hausdorff by the compact orbit metric construction. The continuous bijection is consequently a homeomorphism. A tree gauge is not a discarded formal coordinate choice; its exact root covariance is what produces the remaining conjugation quotient.

Several components and changing the tree. For a graph with finitely many connected components choose a root and spanning tree in each. Its orbit space is the product of the corresponding $K^{r_c}/\operatorname{Ad} K$, with an independent root conjugation in every component. In particular a component that is a tree has one orbit and contributes only constant invariant functions. Products of invariant functions from the different components separate this product space. No closed path joining distinct components is introduced.

The construction is independent of the chosen forest at the level of observables. In tree-identity gauge, any closed path is a word in the non-tree bond matrices and their inverses; tree traversals contribute identity. New fundamental loops from another tree are therefore continuous word functions of the old tuple. The converse is true by interchanging the trees. After quotienting by root conjugation these are the same intrinsic orbit coordinates related by homeomorphisms. We will prove completeness using one convenient forest, without attributing physical meaning to its choice.

If a larger finite graph is used, the old closed paths still define exactly the old functions on its bond configurations. The embedding of local invariant algebras is the isometric one proved earlier, not a prescription to identify two different root frames. This will make the final dense Wilson family compatible with nested local windows.

Real quaternion coordinates and the product signs. Let $\sigma_1,\sigma_2,\sigma_3$ be the Pauli matrices, with $\sigma_i\sigma_j = \delta_{ij}I + i\varepsilon_{ijk}\sigma_k$. Every $H \in \mathrm{SU}(2)$ has the unique form

$$H = aI + i\,b\cdot\sigma, \qquad a\in\mathbb{R}, \quad b\in\mathbb{R}^3, \qquad a^2+|b|^2 = 1. \tag{7.ccxi}$$

For example the usual matrix form $\left(\begin{smallmatrix}\alpha & \beta\\ -\bar\beta & \bar\alpha\end{smallmatrix}\right)$, $|\alpha|^2+|\beta|^2=1$, gives $a=\operatorname{Re}\alpha$, $b_3=\operatorname{Im}\alpha$, $b_1=\operatorname{Im}\beta$, $b_2=\operatorname{Re}\beta$. Conversely eq. 7.ccxi is unitary with determinant one. Its inverse is $aI - ib\cdot\sigma$.

In these conventions direct multiplication gives

$$\begin{aligned}(aI+ib\cdot\sigma)(cI+id\cdot\sigma) = {}& (ac - b\cdot d)I\\ &+ i\,(ad+cb-b\times d)\cdot\sigma.\end{aligned} \tag{7.ccxii}$$

The minus sign in the cross product is fixed by the two factors of i. It is useful to retain that sign explicitly when extracting the triple trace.

Write $H_i = a_iI + ib_i\cdot\sigma$. The normalized traces of one, two and three matrices are

$$\begin{aligned} a_i &= \tfrac12\operatorname{Tr}H_i,\\ c_{ij} &= \tfrac12\operatorname{Tr}(H_iH_j) = a_ia_j - b_i\cdot b_j,\\ c_{ijk} &= \tfrac12\operatorname{Tr}(H_iH_jH_k)\\ &= a_ia_ja_k - a_kb_i\cdot b_j - a_ib_j\cdot b_k - a_jb_i\cdot b_k + (b_i\times b_j)\cdot b_k. \end{aligned} \tag{7.ccxiii}$$

This follows by taking the scalar part of eq. 7.ccxii, then multiplying by the third factor. All the displayed traces are real. Thus the selected Wilson traces recover

$$\begin{gathered} G_{ii} = 1-a_i^2, \qquad G_{ij} = a_ia_j - c_{ij} = b_i\cdot b_j,\\ D_{ijk} = c_{ijk} - a_ia_ja_k + a_kG_{ij} + a_iG_{jk} + a_jG_{ik} = \det(b_i,b_j,b_k). \end{gathered} \tag{7.ccxiv}$$

Pairs with $i < j$ and triples with $i < j < k$ suffice; the diagonal Gram entries are already fixed by eq. 7.ccxi.

Conjugation is exactly proper spatial rotation. Conjugation of the traceless Hermitian matrices $b\cdot\sigma$ by an SU(2) matrix is a real orthogonal map of $\mathbb{R}^3$. Indeed it preserves that real three-dimensional space and its inner product $\frac{1}{2}\operatorname{Tr}((b\cdot\sigma)(d\cdot\sigma)) = b\cdot d$. It has determinant one: the map depends continuously on the connected group SU(2), while its determinant takes only the values ±1 and is one at identity.

Every proper rotation occurs. For a unit axis n and angle θ, choose $q = \cos(\theta/2)I - i\sin(\theta/2)n\cdot\sigma$. Using the Pauli identity twice gives

$$\begin{aligned} q(b\cdot\sigma)q^{-1} = \big[&\cos\theta\, b + \sin\theta\,(n\times b) \\ &+ (1-\cos\theta)(n\cdot b)n\big]\cdot\sigma. \end{aligned} \tag{7.ccxv}$$

This is the rotation about n. Any proper real orthogonal matrix in dimension three fixes some axis and acts as a two-dimensional rotation on its orthogonal plane. To see the fixed axis, use its real eigenvalue and determinant one: the remaining eigenvalues are either a conjugate unit pair or real signs, which forces at least one eigenvalue one. Its plane action has determinant one and hence is a rotation. Thus eq. 7.ccxv realizes every element of SO(3).

It follows that simultaneous conjugation of the H_i leaves the a_i fixed and rotates all the b_i by one common proper rotation. The completeness problem is now a finite real linear-algebra problem, including degenerate spans.

Gram data and orientation separate every orbit. Suppose two tuples have equal selected data in eq. 7.ccxiii. Their scalar parts agree, and eq. 7.ccxiv gives the same Gram matrix and the same oriented triple determinants. Define on the span of the first family $T(\sum_i t_i b_i) = \sum_i t_i b'_i$. If the first sum is zero, its squared norm is $t^T G t = 0$; the same Gram matrix makes the second sum zero. Thus the map is well-defined. It preserves inner products and is an isometry onto the second span. Extend it by orthonormal bases of the complements to an element of O(3).

If the span has rank three, some triple determinant is nonzero. Its equality in the two families forces the determinant of this isometry to be $+1$. If the rank is at most two, the complement has a nonzero dimension. Reverse one vector in the chosen complementary image basis if necessary; this changes the full determinant while leaving all the prescribed images $b_i \mapsto b'_i$ untouched. In every rank there is therefore a proper rotation taking the first family to the second. Lift it by eq. 7.ccxv. We have proved

$$\begin{aligned} &(a_i, c_{ij}, c_{ijk}) = (a'_i, c'_{ij}, c'_{ijk}) \\ \iff\quad &H'_i = qH_iq^{-1} \text{ for one } q\in \mathrm{SU}(2). \end{aligned} \tag{7.ccxvi}$$

The reverse implication is trace invariance. The proof includes central matrices, collinear families and coplanar families; it has not divided by a possibly vanishing triple determinant in these cases.

For rank three the orientation data cannot simply be omitted. For example $i\sigma_1, i\sigma_2, i\sigma_3$ and $i\sigma_1, i\sigma_2, -i\sigma_3$ have the same scalar parts and pair Gram entries, but their triple traces have opposite sign. No common proper rotation maps the two triples. The triple coordinate is the part of the trace family which records this distinction.

The exact compact coordinate image. Let Z_r be the image in $\mathbb{R}^{M_r}$, $M_r = r + \binom{r}{2} + \binom{r}{3}$, of the selected data. It is compact as the continuous image of K^r. The data map factors through the simultaneous-conjugation quotient and is injective there by eq. 7.ccxvi. Hence

$$K^r/\operatorname{Ad} K \;\cong\; Z_r. \tag{7.ccxvii}$$

This is a homeomorphism of compact spaces, not just a one-to-one generic-coordinate parametrization.

There is also an explicit test for membership in the image. Given real a_i, c_{ij}, c_{ijk}, form the symmetric matrix G and numbers D_I from eq. 7.ccxiv, with increasing triples I. They are realizable precisely when

$$\begin{gathered} G \geq 0, \qquad \operatorname{rank} G \leq 3, \qquad G_{ii} = 1 - a_i^2, \\ D_I D_J = \det G_{I,J} \quad \text{for all increasing triples } I, J. \end{gathered} \tag{7.ccxviii}$$

Here $G_{I,J}$ is the indicated three-by-three cross Gram matrix. When there are fewer than three indices the second line has no conditions.

Necessity is immediate from a family of real vectors: $G = B^T B$ is positive with rank at most three, and $\det(B_I^T B_J) = \det B_I \det B_J$. For sufficiency, the real spectral theorem supplies vectors $b_i \in \mathbb{R}^3$ with the given positive Gram matrix. Their lengths and the diagonal condition make $a_i I + i b_i \cdot \sigma$ elements of K. If the rank is below three, every three-by-three principal Gram determinant is zero, so the conditions $D_I^2 = 0$ force all the desired triple determinants to vanish, as they do for the reconstructed vectors.

If the rank is three, choose a triple I_0 with positive principal Gram determinant. Its desired D_{I_0} has the same nonzero absolute value as the determinant of those three reconstructed vectors. Apply one common orthogonal reflection if necessary to arrange equality of their signs. For every other triple J, the cross-determinant condition gives $D_{I_0} D_J = \det G_{I_0,J}$. The reconstructed vectors obey the same equality with their actual determinants. Division by this one nonzero D_{I_0} forces all remaining triple determinants to agree. The formula in eq. 7.ccxiii now gives every desired trace. This proves sufficiency, including all degenerate cases.

These are finite polynomial equalities and inequalities: positive semidefiniteness is expressed by principal minors, and rank at most three by the vanishing higher minors. For a positive matrix, vanishing of all four-by-four principal minors already suffices for that rank bound, because four independent Gram vectors would have a positive principal determinant. The cross-determinant conditions link the orientations of different triples. Requiring only their squared determinants would not impose one common orientation across all indices.

Finite Wilson trace words are a complete family. Return to the fundamental based loops γ_i in eq. 7.ccviii. The coordinates in eq. 7.ccxiii are exactly the Wilson traces of

$$\gamma_i, \qquad \gamma_i \gamma_j \ (i < j), \qquad \gamma_i \gamma_j \gamma_k \ (i < j < k). \tag{7.ccxix}$$

These are closed paths based at the same root; repetitions, intersections and retracings are allowed. Each is contained in the original finite graph. The coordinate family for separate connected components is used componentwise and then multiplied as scalar functions.

The unital complex polynomial algebra in these real-valued coordinates is closed under conjugation and separates the compact orbit space. Stone–Weierstrass and eq. 7.ccx, eq. 7.ccxvii therefore give

$$\overline{\mathbb{C}[w_{\gamma_i}, w_{\gamma_i\gamma_j}, w_{\gamma_i\gamma_j\gamma_k}]}^{\|\cdot\|_\infty} = C(K^{E_+})^{K^V}. \tag{7.ccxx}$$

This proves uniform completeness of an actual finite gauge-invariant observable family. It requires neither a generic full-rank assumption nor a separate trace-word invariant-theory assumption. The real linear algebra and compactness above supplied separation in every rank.

The number of coordinates is finite, with $M_r \leq (r+1)^3$. Each fundamental loop has length at most $2(|V| - 1) + 1$; the longest selected word has at most three times that length. Thus the construction supplies explicit finite paths within the original support window. This is a statement about a complete test family, not a uniform low-degree approximation rate for every continuous observable.

Exact trace relations at the cutoff. Some consistency relations can be written without the tree coordinates. For $B \in \mathrm{SU}(2)$, its characteristic equation gives $B + B^{-1} = (\operatorname{Tr} B)I$. Multiply by A and take the trace to obtain

$$\begin{aligned} \operatorname{Tr} A \operatorname{Tr} B &= \operatorname{Tr}(AB) + \operatorname{Tr}(AB^{-1}), \\ w_A w_B &= \tfrac{1}{2}(w_{AB} + w_{AB^{-1}}). \end{aligned} \tag{7.ccxxi}$$

For based closed paths this is an exact identity of continuous bond functions. Empty paths have trace one, retracings can be deleted, reversal leaves the trace fixed, and conjugating a loop by a connecting path leaves its trace fixed. These relations, together with the coordinate-image conditions in eq. 7.ccxviii, give concrete finite compatibility tests for a proposed bare loop readout.

They are identities of the bounded cutoff variables. If a different renormalized observable is defined by cutoff-dependent normalizations or mixing, its transformed relations must be derived from that definition. The unchanged bare identities are not automatically identities between unspecified renormalized composite fields at coincident points.

From a finite complete family to the quasilocal algebra. Every finite local gauge-invariant function is uniformly approximated by the Wilson polynomials just constructed on its own finite graph. Combining this with eq. 7.cxcix gives

$$\mathcal{A}^{\mathrm{inv}} = \overline{\mathbb{C}[w_\gamma : \gamma \text{ a finite closed edge path}]}^{\|\cdot\|_\infty}. \tag{7.ccxxii}$$

A polynomial in finitely many traces is still local; its support is contained in the finite union of the paths' bonds. Conversely no enlargement of a local graph was needed to approximate its invariant functions. The statement is therefore compatible with local support and with the isometric inclusions of finite windows.

On a countable graph the finite closed paths form a countable family. Polynomials with rational complex coefficients in them are a countable uniformly dense family of the invariant algebra. A proposed bounded observable transport can consequently be tested on an explicit determining family, subject to the boundedness and gauge-covariance conditions of eq. 7.ccvi.

At one finite cutoff a state of the invariant algebra is determined by all joint polynomial moments of the selected coordinates. Indeed these moments give its values on the dense polynomial algebra in eq. 7.ccxx, and a state is norm continuous. Equivalently they determine a probability measure on the compact image Z_r. It is the joint moments which are required; separate one-variable laws alone do not specify the correlations of the coordinates.

No continuum path limit has been taken in this argument. The countability of lattice paths, exact finite graph relations and compact bounded moment problem are the cutoff kinematics. Geometric rounding independence, renormalized loop limits, their joint correlations with the scalar field and their physical reconstruction remain separate observable readout questions.

7.12. **The scalar observable and its information.** The complete cutoff invariant algebra has now been described without reference to a continuum limit. We compare it with the actual scalar observable used in the construction. This comparison has two different outcomes. At a fixed cutoff the scalar algebra is a proper subalgebra, and we exhibit the missing information explicitly. In the continuum, the scalar distributions do determine their own cyclic representation and canonical field closures. Neither statement supplies the joint continuum law of other gauge observables.

The actual cutoff normalization. Write $a > 0$ for a fixed lattice spacing. Count each elementary positive coordinate-plane plaquette once, write x_p for its barycenter in physical coordinates, and let U_p be its oriented holonomy. The observable is

$$\begin{aligned} A_p(U) &= 1 - \tfrac{1}{2}\operatorname{ReTr} U_p \in [0,2], \\ O_a(f) &= \sum_p f(x_p) A_p, \qquad X_a(f) = O_a(f) - \rho_a(O_a(f)). \end{aligned} \tag{7.ccxxiii}$$

There is no power of a multiplying this displayed sum. Any proposed different normalization or mixing is a different readout and requires its own estimates. For $f \in C_c^\infty(\mathbb{R}^4)$ the sum is finite; for Schwartz f it converges uniformly as a function of U, since the plaquette barycenters form a finite union of translates of $a\mathbb{Z}^4$. In particular it is a bounded continuous invariant function at this fixed a.

Let $\mathfrak{A}_a^{\mathrm{inv}}$ be the invariant algebra constructed above, with the finite periodic version used on a torus. Define

$$\mathfrak{A}_{a,d} = C^*(1, A_p : \ p \text{ an elementary plaquette}) = C^*(1, O_a(f) : f \in C_c^\infty(\mathbb{R}^4)) \ \subset \ \mathfrak{A}_a^{\mathrm{inv}}. \quad \text{(7.ccxxiv)}$$

For the second equality, the inclusion from right to left follows from the finite sum in eq. 7.ccxxiii. Conversely the barycenters of distinct positive coordinate-plane plaquettes are distinct: their fractional coordinate pattern records the plane, and their integer parts record the translate. Around any one barycenter choose a smooth bump which is one there and zero at every other barycenter. The corresponding $O_a(f)$ is exactly A_p. The same argument uses smooth periodic functions on a finite torus. Adding or subtracting the constants $\rho_a(O_a(f))$ leaves the unital algebra unchanged.

This is an equality of algebras at a fixed cutoff. The bump isolating a single plaquette may depend on a. For example $f_{a,p}(x) = \chi((x - x_p)/(ca))$, with a fixed sufficiently small c, has derivatives of order r of size $O(a^{-r})$. Consequently the algebraic equality does not give a uniform estimate for the isolation of a plaquette as $a \downarrow 0$. It cannot be substituted for the fixed-test estimates used in a continuum limit.

The compact scalar quotient and its moments. Put $Z_a = \Omega_a/\mathcal{G}_a$ and let Y_a be the image of the continuous map

$$\pi_a : Z_a \longrightarrow [0,2]^{\mathcal{P}_a}, \qquad [U] \longmapsto (A_p(U))_p. \quad \text{(7.ccxxv)}$$

The countable product on the right is compact metrizable. Its image Y_a is compact, and π_a is a surjection onto that image. The unital polynomial algebra in the coordinate functions on Y_a is conjugation closed and separates its points. Stone–Weierstrass and the isometric pullback therefore identify

$$\mathfrak{A}_{a,d} = \pi_a^* C(Y_a), \qquad \mathfrak{A}_a^{\mathrm{inv}} = C(Z_a). \quad \text{(7.ccxxvi)}$$

For an infinite graph this includes uniform limits of local scalar functions. It does not require that a scalar function have finite support after taking that limit.

All joint polynomial moments of the A_p determine a state on $\mathfrak{A}_{a,d}$. Indeed they determine its values on the coordinate polynomials, and for any continuous b and polynomial P the difference between two states is bounded by $2\|b - P\|_\infty$. Taking a uniformly approximating sequence proves uniqueness on $C(Y_a)$. The same statement applies to all joint moments of the $O_a(f)$ or the centered variables, provided the centering constants are specified. It is a statement about complete bounded cutoff moment data. A sequence of continuum separated-point limits is not, by itself, this complete fixed-cutoff data set.

What is lost by π_a can be seen without a dimension count or an invariant-theory assumption.

An explicit small-curvature loss of relative color data. Use the unit lattice $\mathbb{Z}^4$ and the Pauli matrices of eq. 7.ccxi. Let $0 < \alpha < \pi/2$ and set

$$A = e^{i\alpha\sigma_3}, \qquad B_\parallel = e^{i\alpha\sigma_3}, \qquad B_\perp = e^{i\alpha\sigma_1}. \quad \text{(7.ccxxvii)}$$

Consider two configurations. In both, all positively oriented bonds are identity except the bond $c_1 = (0, e_1)$, which is A, and the bond $c_2 = (4e_4, 4e_4 + e_1)$. The latter is $B_\parallel$ in the first configuration and $B_\perp$ in the second. Reversed bonds have inverse values as always.

No elementary plaquette contains both special bonds. Each elementary plaquette holonomy is consequently identity, $A^{\pm 1}$, or $B^{\pm 1}$. The plaquettes meeting a special bond are the same in the two configurations, and

$$\tfrac{1}{2}\,\mathrm{Tr}\, A^{\pm 1} = \tfrac{1}{2}\,\mathrm{Tr}\, B_\parallel^{\pm 1} = \tfrac{1}{2}\,\mathrm{Tr}\, B_\perp^{\pm 1} = \cos\alpha. \quad \text{(7.ccxxviii)}$$

Every plaquette action is therefore equal in the two configurations. Each nonidentity plaquette is within $O(\alpha)$ of identity in matrix norm. Thus the example has arbitrarily small plaquette curvature and requires no large-field exceptional set.

Let γ_1 be the positive 12-plaquette based at zero with first edge c_1, and let γ_2 be its translate by $4e_4$, based at $4e_4$. Their holonomies are A and B, respectively. Let P be the straight path from zero to $4e_4$ along coordinate four. All its bonds are identity. The closed path $\gamma = \gamma_1 P \gamma_2 P^{-1}$ has holonomy AB, so that

$$\begin{gathered} w_\gamma(U_\parallel) = \cos(2\alpha), \qquad w_\gamma(U_\perp) = \cos^2\alpha, \\ w_\gamma(U_\parallel) - w_\gamma(U_\perp) = -\sin^2\alpha \neq 0. \end{gathered} \tag{7.ccxxix}$$

The first equality uses the same axis twice. For the second, the scalar part of the product in eq. 7.ccxii is $\cos^2\alpha - \sin^2\alpha\, e_3 \cdot e_1 = \cos^2\alpha$. These configurations are not gauge equivalent, because the normalized trace of every closed path is invariant under the full site gauge group.

Let $\mathbb{E}_a$ be the Haar expectation of eq. 7.cxcvii. Evaluation at either configuration followed by $\mathbb{E}_a$ is a normalized positive, fully gauge-invariant state on $C(\Omega_a)$. Its restriction to $C(Z_a)$ is simply evaluation at that orbit. The two states agree on $\mathfrak{A}_{a,d}$, hence on every product of all the scalar observables in eq. 7.ccxxiii, but disagree on w_γ. This proves that $\mathfrak{A}_{a,d}$ is a proper subalgebra, including in an arbitrarily small-plaquette region.

These two states are algebraic cutoff examples. No assertion that they are Wilson Gibbs states, DLR states, reflection-positive states, or scaling limits is involved. Their role is exact: positivity, gauge invariance, and the complete scalar marginal do not logically determine the full invariant state. Additional dynamical hypotheses could select a unique extension within a smaller class; such a selection would be a further theorem.

A separate loss of periodic holonomy data. On a periodic four-dimensional lattice with side length $N \geq 3$, put $h_\theta = e^{i\theta\sigma_3/N}$ on every positive coordinate-one bond and identity on every other positive bond. All elementary plaquettes are identity, whereas the closed path winding once around coordinate one has

$$A_p = 0 \quad \text{for every } p, \qquad w_{\text{wind}} = \tfrac{1}{2}\operatorname{Tr} h_\theta^N = \cos\theta. \tag{7.ccxxx}$$

For different $\theta \in [0, \pi]$ these are different full gauge orbits with exactly the same scalar plaquette data. A periodic gauge transformation changes the winding holonomy only by conjugation. A nonperiodic change of frame which removes h_θ on the covering lattice is not a periodic gauge transformation and cannot identify these torus orbits.

The complete graph coordinates of eq. 7.ccxix retain such winding loops. Discarding them would change the observable algebra. This example concerns different holonomy data; it does not contradict uniqueness on a fixed nonlinear coarse fibre in the first-step background theorem. Together, eq. 7.ccxxix and eq. 7.ccxxx distinguish a local loss of relative nonabelian orientation from a global loss of periodic holonomy.

Exactly what abstract state extension gives. For any state ν on $C(Y_a)$ consider the set

$$\mathcal{E}_a(\nu) = \{\mu \in \operatorname{Prob}(Z_a) : (\pi_a)_*\mu = \nu\}. \tag{7.ccxxxi}$$

We use the Riesz correspondence between states and probability measures on compact spaces. The set in eq. 7.ccxxxi is convex and weakly closed in the compact state space of $C(Z_a)$. It is nonempty for every ν. Here is a proof which does not choose conditional measures on individual fibres.

Regard ν as a norm-one unital functional on the closed subalgebra $\pi_a^* C(Y_a)$. The complex Hahn–Banach theorem extends it to a functional ℓ on $C(Z_a)$ with

$$\ell|_{\pi_a^* C(Y_a)} = \nu, \qquad \ell(1) = 1, \qquad \|\ell\| = 1. \tag{7.ccxxxii}$$

Such a functional is positive. To check this directly, let b be real-valued with $\|b\|_\infty \le 1$, and write $\ell(b) = u + iv$. For every real t,

$$|1 + it\ell(b)|^2 \le \|1 + itb\|_\infty^2 \le 1 + t^2. \tag{7.ccxxxiii}$$

After expanding the left side and taking $t \to 0$ with both signs we obtain $v = 0$. Thus ℓ is real on real functions. If $0 \le b \le 1$, then $|\ell(b)| \le 1$ and $|1 - \ell(b)| \le 1$, since also $\|1 - b\|_\infty \le 1$. These two real inequalities give $0 \le \ell(b) \le 1$. Scaling proves positivity for every nonnegative b. Riesz now supplies the measure μ, and equality of the restrictions is precisely the pushforward condition in eq. 7.ccxxxi.

Composing this extension with $\mathbb{E}_a$ gives a full gauge-invariant probability law on the bond configuration space. This last lift is unique once μ on the *full* orbit space has been specified, by eq. 7.ccii. The Hahn–Banach step generally has no such uniqueness. Its conclusion concerns a positive bounded cutoff state; it supplies no action, DLR specification, ultraviolet estimates, reflection positivity, or continuum observable normalization.

The nonuniqueness can be located exactly for a point scalar state. For $y \in Y_a$,

$$\mathcal{E}_a(\delta_y) = \mathrm{Prob}(\pi_a^{-1}\{y\}), \qquad \mathcal{E}_a(\delta_y) \text{ is a singleton } \iff \pi_a^{-1}\{y\} \text{ is a singleton.} \tag{7.ccxxxiv}$$

Indeed a measure with pushforward δ_y gives mass one to the closed fibre, and conversely any measure on that fibre has that pushforward. Distinct points of the fibre give distinct Dirac measures. The two orbit points in eq. 7.ccxxix lie in one such nonsingleton fibre. We do not infer that every possible scalar state has multiple extensions.

More globally, equality $\mathfrak{A}_{a,d} = C(Z_a)$ is equivalent to injectivity of π_a. If it is injective, compactness makes it a homeomorphism onto Y_a, so its pullback is onto $C(Z_a)$. Conversely, if the pullback is all of $C(Z_a)$, equal images would force all continuous functions to agree at two points; continuous functions on a compact metric space separate points. This criterion isolates the precise algebraic reason that the scalar marginal does not determine the full cutoff law.

Ordinary positivity does not give reflection positivity. The distinction is already visible on a two-site classical system. Let $s_-, s_+ \in \{-1, 1\}$ and give mass $1/2$ to each of $(s_-, s_+) = (-1, 1), (1, -1)$. This is a positive normalized probability measure invariant under the reflection exchanging the sites. Take the positive-time function $F = s_+$ and let Θ act by exchange and complex conjugation. Then

$$\mu((\Theta F)F) = \mu(s_- s_+) = -1. \tag{7.ccxxxv}$$

Thus even reflection symmetry and ordinary probability positivity do not imply OS positivity. The latter is a distinct family of Gram inequalities pairing reflected positive-time words. An abstract extension from eq. 7.ccxxxii is not an extension satisfying those inequalities unless they too are proved. This example is a logical distinction between two positivity requirements, not a purported counterexample to the Wilson construction.

The scalar continuum distributions determine a cyclic theory. There is also a positive uniqueness statement, now for the actual continuum scalar output. Let two vacuum representations have the same full Minkowski distributions W_n on every $\mathcal{S}((\mathbb{R}^4)^n)$, with their common invariant polynomial domains generated from their vacua. For finite scalar words define

$$U(\varphi_1(f_1) \cdots \varphi_1(f_n)\Omega_1) = \varphi_2(f_1) \cdots \varphi_2(f_n)\Omega_2. \tag{7.ccxxxvi}$$

The formula is extended linearly over finite sums, including the empty word. The squared norm of any such sum is a finite sum of values of W_{m+n} on the reversed, complex-conjugate first word and the second word. Equality of all distributions proves equality of these Gram forms. In particular a null sum on one side is null on the other, and eq. 7.ccxxxvi is well defined and isometric. Its range is the other polynomial core, so it extends to a unitary between the two scalar cyclic Hilbert spaces.

Concatenating one further test function proves the field intertwining on these polynomial cores. Taking closures of the graphs proves equality of the corresponding canonical closed operators whenever these closures exist. Vacuum covariance gives intertwining of translations and proper orthochronous Lorentz transformations first on the core and then on the Hilbert spaces. For translations this also intertwines their joint spectral measures, the energy operator, all its powers and their domains. The common energy domains and canonical closures constructed in RD are therefore part of this determined scalar representation. This argument does not add essential self-adjointness or a bounded local observable net to the established conclusions.

Under their stated hypotheses, EB and QRM supply the full W_n and identify their cyclic space with $\mathcal{K}_{\mathrm{ord}}$. The formula in eq. 7.ccxxxvi thus gives uniqueness in the precise cyclic sense just proved. It makes no assertion that $\mathcal{K}_{\mathrm{ord}}$ exhausts the entire Euclidean OS space, or that adding an independent gauge observable leaves this cyclic space unchanged. A larger joint observable theory contains this scalar representation as the closure of its scalar vacuum words; surjectivity onto the larger space is an additional condition.

Bounded cutoff moments and unbounded continuum fields. At a fixed cutoff one has the elementary bound

$$\|O_a(f)\|_\infty \le 2\sum_p |f(x_p)|, \qquad \|X_a(f)\|_\infty \le 4\sum_p |f(x_p)|. \tag{7.ccxxxvii}$$

For a fixed nonzero physical test function the right side can grow as $a \downarrow 0$. Thus the compact moment argument for a fixed a does not pass to a common compact spectral interval in the continuum. Under those hypotheses, the continuum field has the graph bound, with $W = 1 + H$,

$$\|W^k \varphi(g) W^{-(N+k)}\| \le C_k\, \mathfrak{t}_{N+k+2}(g), \qquad N = 9. \tag{7.ccxxxviii}$$

Here $\mathfrak{t}_q$ is the finite spacetime test seminorm defined in EB. This gives a common invariant energy-smooth domain, products, closability, and the canonical graph identifications of RD. Repeated use increases the energy order and the required test seminorm. It does not give a bound of the form $\|\varphi(g)^n\Omega\| \le C^n n!$ for every Schwartz g with a fixed constant. Such an analytic-vector assertion has not been used to assign a spectral calculus to the field.

A concrete scalar moment calculation shows why positivity and a bound exponential in n^2 alone cannot replace compact moment determinacy. On $(0,\infty)$ let

$$d\mu_\epsilon(x) = \frac{e^{-(\log x)^2/2}}{x\sqrt{2\pi}}\big(1 + \epsilon \sin(2\pi \log x)\big)\, dx, \qquad -1 \le \epsilon \le 1. \tag{7.ccxxxix}$$

These are nonnegative measures. With $z = \log x$, their sine contribution to every nonnegative integer moment is

$$\begin{aligned} &\frac{1}{\sqrt{2\pi}} \int_{\mathbb{R}} e^{-z^2/2 + nz} \sin(2\pi z)\, dz \\ &\qquad = e^{(n^2 - 4\pi^2)/2} \sin(2\pi n) = 0, \qquad n = 0, 1, 2, \dots . \end{aligned} \tag{7.ccxl}$$

For completeness the complex Gaussian identity used here follows first for real u by completing the square in $\int e^{-z^2/2+uz}\, dz = \sqrt{2\pi} e^{u^2/2}$. Both sides are entire in u by dominated convergence on compact complex sets, so the one-variable identity theorem permits $u = n + 2\pi i$ and taking imaginary parts. The formula in eq. 7.ccxl at $n = 0$ proves normalization. For every ϵ the moments are

$$\int x^n\, d\mu_\epsilon(x) = e^{n^2/2}, \qquad n \ge 0, \tag{7.ccxli}$$

while the measures differ when ϵ differs, since their densities differ on an interval. There are therefore bounded continuous functions whose integrals differ, although all these polynomial moments agree.

This calculation is not an alternative continuum model satisfying the other hypotheses. It proves the narrower implication needed here: polynomial positivity and $e^{O(n^2)}$ moment growth alone

do not determine all bounded functions of an unbounded variable. The imported OS output has an ab^{n^2} type distribution bound; no compact moment or analytic-vector conclusion has been inferred from that form of bound. The actual scalar Wightman functional and its canonical cyclic graph representation remain determined by eq. 7.ccxxxvi. The distinction concerns further spectral completions or additional observables, not an ambiguity in those already constructed distributions.

Scalar phase labels and full gauge-state labels. The compact phase space used in SPH is separated by scalar evaluation functions $f_F(\xi)$ of ordered Euclidean words. Its points distinguish those scalar functionals. They are not, by this definition, points of Z_a, nor are they automatically all extremal states of a continuum gauge-observable algebra. If two proposed joint observable states have the same scalar restriction, all f_F agree for those restrictions even when a mixed or nonscalar correlation differs.

Conversely a theorem specifying a physical class of extensions could prove that its restriction map to scalar states is injective. The finite-cutoff examples show that this would require the additional class restrictions, not just gauge invariance and positivity. In a continuum construction the required conditions include actual joint readouts, their compatible limits, their positivity and covariance, and their relation to the scalar normalization in eq. 7.ccxxiii. The next section formulates these conditions as observable statements and proves the algebraic and representation consequences once they hold.

7.13. **Joint gauge-observable extension and identification.** We give precise conditions under which further observables extend the constructed scalar theory. They concern joint moments, not separate one-observable laws. We prove the resulting positivity, consistency, domain and identification statements, and distinguish them from the model estimates needed for a continuum readout. The scalar reconstruction already established in EB and QRM is retained throughout; none of its locality conclusions is inferred from an unconstructed larger observable family.

Typed words and the scalar restriction. Let I be a set of observable types with a distinguished scalar type 0. Each type has a complex test space E_α, an antilinear involution $f \mapsto f^*$ into E_{α^*}, and a specified localization region for each local test. For point fields take $E_\alpha = \mathcal{S}(\mathbb{R}^4)$, with the appropriate finite tensor components if necessary. A loop type instead needs an explicit space of geometric labels or smearing tests and a support convention; it is not silently a point field. Types are required to have compatible involutions, so $(\alpha^*)^* = \alpha$ and $(f^*)^* = f$.

First form the unital free algebra of finite typed words, with complex linearity in each test. The star is

$$(q_{\alpha_1}(f_1)\cdots q_{\alpha_n}(f_n))^* = q_{\alpha_n^*}(f_n^*)\cdots q_{\alpha_1^*}(f_1^*). \tag{7.ccxlii}$$

Let $\mathcal{I}$ be a declared two-sided star ideal of further relations and let $\mathcal{A}$ be the quotient. The relations may encode exact trace identities, conjugate observables, or other proved identifications. A normalization-dependent continuum identity is not included merely because the corresponding bare cutoff variables satisfy it. This distinction applies in particular to eq. 7.ccxxi.

There is a specified unital star map ι from the scalar word algebra into $\mathcal{A}$, sending its field generator to q_0. If an algebraic embedding is required, its injectivity is an additional algebraic property to check. For the Hilbert-space restriction below the necessary condition is equality of the scalar functional:

$$\omega(\iota(F)) = \omega_d(F) \quad \text{for every scalar word sum } F, \tag{7.ccxliii}$$

where ω_d is the full scalar Minkowski functional already constructed. Any scalar relation killed by ι must consequently be null for that functional. The readout identifying q_0 is the actual centered normalization in eq. 7.ccxxiii, not an independently chosen scalar spectator.

The exact mixed positivity and relation tests. A candidate joint moment family gives a complex linear functional ω on finite word sums. Its elementary requirements are normalization, hermiticity and all finite Gram inequalities:

$$\begin{aligned} &\omega(1) = 1, \qquad \omega(F^*) = \overline{\omega(F)}, \\ &\sum_{i,j=1}^{r} \overline{c_i} c_j \, \omega(F_i^* F_j) \geq 0 \quad (r < \infty, c_i \in \mathbb{C}). \end{aligned} \tag{7.ccxliv}$$

Here the F_i may involve different types and different word lengths. Separate positivity for each type is insufficient. The inequality for all finite sums is equivalent to $\omega(F^*F) \geq 0$ for every element F of the free algebra.

The ideal must also be annihilated. For a star-closed set of generators R of $\mathcal{I}$, an exact equivalent test, under eq. 7.ccxliv, is

$$\begin{aligned} &\omega(ARB) = 0 \quad \text{for every } A, B \text{ and every } R; \\ &\iff \quad \omega((RB)^* RB) = 0 \quad \text{for every } B \text{ and every } R. \end{aligned} \tag{7.ccxlv}$$

To prove the reverse implication, apply Cauchy–Schwarz to the positive form $\langle C, D\rangle = \omega(C^*D)$ with $C = A^*$ and $D = RB$. Its second diagonal entry is zero, so $\omega(ARB) = 0$. The forward implication uses $A = B^*R^*$. Linearity then annihilates the entire generated ideal. Both R and R^* are included in the declared generating set. Merely requiring $\omega(R) = 0$ would not suffice: a centered real variable can have zero mean and positive variance.

Even pairwise consistency of positive laws misses a genuine mixed constraint. Consider three proposed signs $A, B, C \in \{-1, 1\}$ with uniform individual marginals. Give (A, B) and (B, C) the law of two identical uniform signs, and (A, C) the law of two opposite uniform signs. Every pair law is positive and all their one-sign restrictions agree. A common joint positive state would nevertheless have

$$\omega((A - B + C)^2) = 3 - 2\omega(AB) + 2\omega(AC) - 2\omega(BC) = -3. \tag{7.ccxlvi}$$

This contradicts eq. 7.ccxliv. Thus a family of compatible two-observable laws is not a substitute for positive matrices of all finite words.

Test continuity has a concrete meaning. For a fixed word of point-field types, require a bound

$$|\omega(q_{\alpha_1}(f_1) \cdots q_{\alpha_n}(f_n))| \leq C_{\boldsymbol{\alpha}} \prod_{j=1}^{n} p_M(f_j) \tag{7.ccxlvii}$$

for some finite M, which may depend on the word. Different orders in the factors can be replaced by their maximum. This is equivalent to continuity of that multilinear form on the product of the Schwartz spaces: continuity at zero gives a product neighborhood where its absolute value is at most one, and rescaling each nonzero factor gives eq. 7.ccxlvii. The seminorms contain the supremum norm, so a zero factor seminorm means the test is zero.

The explicit tensor expansion of RTE, applied with this M, gives a unique full Schwartz distribution for the word, with

$$|W_{\boldsymbol{\alpha}}(F)| \leq C'_{\boldsymbol{\alpha}} p_{n(M+8)}(F), \qquad F \in \mathcal{S}((\mathbb{R}^4)^n). \tag{7.ccxlviii}$$

This does not postulate a tensor theorem without a norm: the absolutely summable grid/Fourier expansion proved in RTE bounds $\sum |c_\nu| \prod_j p_M(f_{\nu,j})$ by that full-test seminorm. The same construction works for vector-valued forms whenever the right side of eq. 7.ccxlvii bounds a norm in the stated complete target. Conversely a full distribution bound implies a simple-tensor bound, since $p_r(f_1 \otimes \cdots \otimes f_n) \leq \prod_j p_r(f_j)$.

Thus one may complete each fixed typed-word space to its full Schwartz space. Star reversal and concatenation are continuous. Positivity on this completed finite-degree algebra follows by approximating each of the finitely many full tests by tensor sums: every entry of its Gram matrix

converges, and finite positive matrices are closed under entrywise limits. The ideal test is imposed on this completed algebra as well, or extended there by a proved continuity bound for the specified relations. Other test types need their own explicitly stated continuity/completion criterion; eq. 7.ccxlviii does not assign them point-field test spaces.

These degreewise bounds do not by themselves verify the linear growth hypothesis of a Euclidean reconstruction theorem. Such a theorem has a further quantitative hypothesis across all word lengths. QRM checked that hypothesis for the scalar family; it has not checked it for arbitrary additional types.

The joint GNS construction and the scalar subspace. Assume eq. 7.ccxliii–eq. 7.ccxlv and the specified test continuity. On $\mathcal{A}$ use the positive form $\langle A, B\rangle = \omega(A^*B)$. Its Cauchy–Schwarz inequality follows by applying positivity to $A + zB$ for every complex z. The null space $\mathcal{N}$ is a left ideal. Indeed if $\omega(B^*B) = 0$, then

$$\omega((AB)^*AB) = \langle B, A^*AB\rangle = 0 \tag{7.ccxlix}$$

by Cauchy–Schwarz. All the words in the second argument are elements of the algebra, so their norms are finite. There is no implicit bounded-operator estimate in this proof.

Complete $\mathcal{D} = \mathcal{A}/\mathcal{N}$ to $\mathcal{H}$, put $\Omega = [1]$, and act by left multiplication. It is well defined by eq. 7.ccxlix and gives an invariant dense polynomial domain. On that domain the star identity gives

$$\langle \pi(A^*)v, w\rangle = \langle v, \pi(A)w\rangle, \qquad v, w \in \mathcal{D}. \tag{7.ccl}$$

In particular each field is closable, because its adjoint contains its declared star partner on a dense domain. Positivity alone gives neither boundedness nor essential self-adjointness of these fields.

The equality in eq. 7.ccxliii gives an isometry from the scalar polynomial space to $\mathcal{H}$, with

$$J[F]_d = [\iota(F)], \qquad \mathcal{H}_d = \overline{\pi(\iota(\mathcal{A}_d))\Omega}, \qquad J : \mathcal{K}_{\mathrm{ord}} \longrightarrow \mathcal{H}_d \text{ unitary.} \tag{7.ccli}$$

The norm identity is exactly the scalar restriction applied to F^*G; it proves that null vectors are respected. Surjectivity is onto the displayed closed subspace by its definition. It is onto the entire joint Hilbert space precisely when the scalar vacuum words are dense there. That density is an additional condition, not a consequence of matching the scalar moments.

Already for bounded commutative algebras one can see the distinction. The state $\nu \otimes \frac{1}{2}(\delta_{-1} + \delta_1)$ on $C(Y \times \{-1, 1\})$ restricts to ν on $C(Y)$. Its GNS scalar subspace is $L^2(\nu) \otimes \mathbb{C}1$, whereas the sign observable supplies the orthogonal nonzero vector $1 \otimes s$. This is an algebraic example of additional degrees of freedom with exactly the same scalar state; it makes no claim about a continuum gauge extension of the constructed model.

There is a useful exact compression criterion in this bounded case. For a representation of a unital star algebra by bounded operators, let P project onto a closed scalar subspace. Compression is multiplicative on the full algebra if and only if that subspace is reducing. One direction is immediate. For the other, a multiplicative compression would give

$$P\pi(A^*)(1 - P)\pi(A)P = P\pi(A^*A)P - P\pi(A^*)P\pi(A)P = 0. \tag{7.cclii}$$

The left side is the square of the norm of $(1 - P)\pi(A)P$ in quadratic-form language. Hence this operator vanishes for every A, and also for A^*, proving reduction. If Ω is in the subspace and is cyclic for the full algebra, reduction then forces the subspace to be all of $\mathcal{H}$. For unbounded fields an arbitrary projection need not even preserve their domains, so no unqualified compression representation is asserted.

Consistency across finite observable families. Suppose a directed system of unital star algebras $\mathcal{A}_J$ has compatible injective star maps for $J \subset K$. Suppose normalized positive functionals ω_J satisfy

$$\omega_K|_{\mathcal{A}_J} = \omega_J. \tag{7.ccliii}$$

There is then a unique normalized positive functional on their algebraic inductive limit. Define it on an element by using any stage containing that element. A common larger stage and eq. 7.ccliii make the value independent of the choice. Any finite word sum belongs to a common stage, so its square has a nonnegative expectation there; this proves positivity on the union. The same argument proves uniqueness. For a system of isometric unital C^* embeddings the state has norm one on the union and extends to its norm completion. An unbounded field algebra has no such automatic C^* completion; its degreewise test continuity is checked as in eq. 7.ccxlvii–eq. 7.ccxlviii.

If global relations are first specified in one free quotient, the maps from smaller quotients need not be injective automatically. One can instead prescribe all finite mixed moments in that global quotient and apply eq. 7.ccxliv–eq. 7.ccxlv directly. Adding a new type must not silently impose a previously untested relation on an old type.

A practical sufficient route to eq. 7.ccliii is uniqueness of a matched finite-family reconstruction. Suppose the same Euclidean joint data on every overlap have reconstructions unique in the exact analytic/boundary class being used. Restrict a larger reconstruction to the smaller family. It has the smaller Euclidean data and the same required class properties. Uniqueness makes it the smaller reconstruction. Thus the extensions at successive stages are consistent. Both the class membership and the uniqueness theorem must be checked for the actual new types; scalar uniqueness alone is not that theorem.

Covariance and its continuity on the joint space. Assume a declared spacetime symmetry group acts by star automorphisms α_g of $\mathcal{A}$, respecting the relations, and that $\omega \circ \alpha_g = \omega$. Then

$$U_g[A] = [\alpha_g A] \tag{7.ccliv}$$

is well defined and isometric; $\alpha_{g^{-1}}$ gives its inverse. It implements the action on the common polynomial domain, fixes Ω, and satisfies the group law there and hence everywhere. Strong continuity follows if, for every polynomial A, $g \mapsto \omega(A^*\alpha_g A)$ is continuous at the identity, because

$$\|U_g[A] - [A]\|^2 = 2\omega(A^*A) - 2\,\mathrm{Re}\,\omega(A^*\alpha_g A). \tag{7.cclv}$$

Density and the unitary norm then extend continuity to all vectors. For point-field types this condition follows from the actual continuous test action and the joint moment bounds. For geometric loop labels it is a condition on that declared label topology and their joint moments, not a consequence of a name assigned to a loop.

When the scalar inclusion intertwines these actions, its closed cyclic subspace is invariant under U_g and $U_{g^{-1}}$, hence reducing. The unitary in eq. 7.ccli intertwines the established scalar symmetries with their restrictions. It still says nothing about additional joint states orthogonal to that subspace.

Use the physical translation convention $U(a) = \exp(i(a^0 H - \mathbf{a}\cdot\mathbf{P}))$; in the notation of RHI the physical spatial momentum here is minus its spatial generator. Let E be the joint spectral measure of the strongly continuous translation group. Positivity of energy-momentum has the following exact dense test:

$$E(\mathbb{R}^4 \setminus \overline{V}_+) = 0 \quad\Longleftrightarrow\quad \operatorname{supp}\mu_A \subset \overline{V}_+ \ \text{ for every } A \in \mathcal{A}, \qquad \mu_A(B) = \|E(B)[A]\|^2. \tag{7.cclvi}$$

Indeed the forward implication is immediate. Conversely the spectral projection of the open complement kills every vector of the dense polynomial domain, and hence is zero. The measures μ_A are the positive Fourier spectral measures of $\omega(A^*\alpha_a A)$. Checking only the vacuum coefficient checks just the atom at zero, and checking only single-field vectors checks only their span. The criterion is for all words, unless an independent density theorem reduces that test family.

Locality as an all-spectator moment identity. For spacelike separated declared localization regions, put $R = [q_\alpha(f), q_\beta(g)]$. The exact joint locality criterion is

$$\omega(ARB) = 0 \quad \text{for every polynomial } A, B. \tag{7.cclvii}$$

It is equivalent to $\pi(R) = 0$ on the common polynomial domain. For if eq. 7.cclvii holds, the vector $\pi(R)[B]$ has zero inner product with every polynomial vector $[C]$, by taking $A = C^*$. Density forces the vector to vanish. Conversely vanishing of those vectors gives eq. 7.cclvii. Equivalently the norm-square test in eq. 7.ccxlv can be used for these commutator relations.

Equality of only the two-point functions with exchanged entries does not test eq. 7.cclvii, since it leaves out the spectators. Once the elementary commutators vanish on an invariant common domain, the Leibniz rule for commutators proves locality of their localized polynomial algebras on that domain. For extended geometric observables the regions are their actual supports, not nominal base points. No spacelike commutativity is inferred from two disjoint curves unless their complete declared localization regions satisfy the required condition.

This is a criterion for the larger moment family. For the scalar family the necessary identity is already a conclusion of QRM's matched corrected OS theorem. For a new family it must follow from that family's actual joint analytic/permutation argument or a reconstruction theorem whose hypotheses have been checked for it. It is not used here as an assumption purporting to prove that same joint continuation.

A precise common-domain criterion for added point fields. We next prove how verified energy bounds upgrade the polynomial construction. Restrict this paragraph to point-field Schwartz types, or to other test types with the same smooth translation action and moment continuity. Let the joint representation above contain only types meeting that assumption in this domain argument; otherwise the conclusion applies to the cyclic subspace of the qualified subfamily, without a graph-core assertion for the larger space. Let that representation have the forward spectral property. Its polynomial test domain $\mathcal{D}$ lies in $\bigcap_k \mathrm{Dom}\, H^k$. For a full word test F translation in time translates all its arguments; continuity of the two-word norm form permits every Schwartz difference quotient in Hilbert norm. Stone's generator identity gives

$$H^k[F] = i^k[D_0^k F], \qquad D_0 = \sum_j \partial_{x_j^0}. \tag{7.cclviii}$$

Iterating proves the assertion for all k. The sign agrees with $f_a(x) = f(x-a)$ and $U(t) = e^{itH}$.

The same domain is a graph core for every $(1+H)^k$. To see this, choose a smooth compactly supported scalar cutoff c_R equal to one on $[0,R]$ and tending pointwise to one on $[0,\infty)$, with $|c_R| \le 1$. For fixed R, $(1+H)^k c_R(H)$ is bounded, so dense polynomial vectors approximate $c_R(H)\psi$ in graph norm after applying $c_R(H)$. For a polynomial vector v, Fourier inversion expresses $c_R(H)v$ as an integral of $U(t)v$ with a Schwartz coefficient. This integral is approximated by finite Riemann sums in graph norm: on compact time intervals the translated full test is graph continuous by eq. 7.cclviii, and the tail is bounded by the L^1 tail times $\|(1+H)^k v\|$. The Riemann sums are polynomial vectors. Finally $c_R(H)\psi \to \psi$ in graph norm for $\psi \in \mathrm{Dom}(1+H)^k$ by spectral dominated convergence. This proves the core claim with both approximations in their required order.

Set $\mathsf{E} = 1 + H$. Suppose for each added type there is a nonnegative integer N_α such that, for every integer $k \ge 0$, the *actual* polynomial operator satisfies

$$\|\mathsf{E}^k \pi(q_\alpha(f))v\| \le C_{\alpha,k}\, p_{M_{\alpha,k}}(f)\, \|\mathsf{E}^{k+N_\alpha} v\|, \qquad v \in \mathcal{D}. \tag{7.cclix}$$

These are bounds to prove on the stated joint space. The scalar case with $N_0 = 9$ is already available on its own scalar cyclic space. In a larger representation even the action of the scalar field on vectors created by new observables requires the corresponding mixed bound. The scalar result proves neither that larger-space bound nor eq. 7.cclix for a Wilson-loop or composite type.

The core claim and closedness of E^k extend the operator coherently to $\mathcal{D}_\infty = \bigcap_k \mathrm{Dom}\, H^k$, mapping it into itself. More explicitly choose polynomial v_j approaching $v \in \mathcal{D}_\infty$ in graph norms through order j. For each fixed k, eq. 7.cclix makes the field images Cauchy in the E^k graph norm. Their Hilbert limits coincide for all k, and closedness identifies the higher energy powers of that

same limit. The extension is independent of the approximating sequence. The star identity extends by the same graph approximations for both vectors, so the extended operators remain closable.

For $k = 0$ the operator also extends from $\mathrm{Dom}\,\mathsf{E}^{N_\alpha}$ to the Hilbert space with its stated graph bound. Approximating in that graph norm shows that this extension lies in the closure of the original polynomial operator. Conversely all three operators, on $\mathcal{D}$, on $\mathcal{D}_\infty$, and on $\mathrm{Dom}\,\mathsf{E}^{N_\alpha}$, have the same closure: their graphs are nested, and every graph point of the largest restriction is approximated by the smallest. This is a canonical closure statement, not essential self-adjointness.

For a word let $S_j = \sum_{i<j} N_{\alpha_i}$ and $S = \sum_i N_{\alpha_i}$. Inserting the appropriate energy powers between factors gives, first on $\mathcal{D}_\infty$ and then as a bounded weighted map,

$$\|\mathsf{E}^l \pi(q_{\alpha_1}(f_1)) \cdots \pi(q_{\alpha_n}(f_n)) \mathsf{E}^{-(l+S)}\| \le \prod_{j=1}^{n} C_{\alpha_j, l+S_j} p_{M_{\alpha_j, l+S_j}}(f_j). \tag{7.cclx}$$

Indeed the jth weighted factor is $\mathsf{E}^{l+S_j} \pi(q_{\alpha_j}(f_j)) \mathsf{E}^{-(l+S_j+N_{\alpha_j})}$, and the adjacent powers cancel on the energy-smooth domain. Their bounded extensions give the asserted norm inequality. Applying the vector-valued RTE expansion with the maximum of the displayed test orders then gives a full non-tensor word operator with an explicit finite Schwartz seminorm bound. The vacuum vector has $\mathsf{E}^r \Omega = \Omega$, so this also bounds every fixed mixed vacuum distribution.

If eq. 7.cclvii holds, the product estimate with energy order $N_\alpha + N_\beta$ extends its commutator identity from the polynomial domain to $\mathrm{Dom}\,\mathsf{E}^{N_\alpha + N_\beta}$, using the graph core just proved. In particular it holds on $\mathcal{D}_\infty$. This extension is operator locality on a declared common domain; strong commutation of self-adjoint spectral calculi would require further hypotheses.

If the full joint Poincare representation is also established, its forward cone implies $c_\Lambda H \le U_\Lambda H U_\Lambda^{-1} \le C_\Lambda H$ for each fixed proper orthochronous Lorentz transformation, in the joint spectral sense. The time component of a transformed forward momentum is bounded above and below by positive constants times its energy. It follows that $U_\Lambda \mathcal{D}_\infty = \mathcal{D}_\infty$, with equivalent energy graph norms. Covariance on the polynomial domain then extends by eq. 7.cclix to this common domain, with the specified finite-component test transformations. No unrestricted inverse heat operator or all-energy band sum is needed for this domain argument.

Actual cutoff readouts and renormalization. A continuum label requires a concrete cutoff function on the same bond configuration space and the same real measure as the scalar construction. Denote it by $Q_{a,\alpha}(f)$. It must be fully site-gauge invariant. For compactly localized tests it also has a declared finite support, including every connecting path, smearing region and auxiliary loop. A typical linear mixing prescription is

$$Q_{a,\alpha}(f) = \sum_{\beta \in J_\alpha} Z_{a,\alpha\beta} B_{a,\beta}(D_{a,\alpha\beta} f) + c_{a,\alpha}(f) 1, \tag{7.cclxi}$$

where J_α is finite for this prescription, the bare functions $B_{a,\beta}$ and lattice smearing maps $D_{a,\alpha\beta}$ are specified, and the subtraction $c_{a,\alpha}$ is specified and linear. The formula in eq. 7.cclxi is a template for a definition, not an assertion that suitable coefficients or bounds exist. A proposed readout has to supply its actual coefficients, their normalization, and the moment bounds after mixing. Diverging Z factors cannot be ignored because each bare Wilson trace is bounded.

The star and Euclidean reflection operations must be matched by that definition. In particular the real cutoff identities are

$$Q_{a,\alpha^*}(f^*) = \overline{Q_{a,\alpha}(f)}, \qquad \Theta_a Q_{a,\alpha}(f) = Q_{a,\vartheta\alpha}(\vartheta f), \tag{7.cclxii}$$

with the antilinear test/reflection action on the right specified for the type. For a tensor observable the reflection can act on its components. For a loop it acts on its entire oriented path. The complex coefficients and counterterms in eq. 7.cclxi must respect these identities or their explicitly proved limiting versions. The constant counterterm has empty localization support; the nonconstant part has its actual support.

For a point-field readout a useful localization requirement is

$$\operatorname{supp} Q_{a,\alpha}(f) \subset (\operatorname{supp} f)^{\epsilon_a}, \qquad \epsilon_a \downarrow 0, \tag{7.cclxiii}$$

where the left side denotes the physical locations of all bonds on which the function depends. For an extended type replace supp f by its declared geometric region. It is this condition, not the name of the observable, that allows a fixed positive-time gap to survive at small cutoff. It does not by itself give a moment bound or independence of the lattice rounding of a curve.

The Euclidean readout map takes products into the commutative algebra of bond functions. It is not a homomorphism from the noncommutative Minkowski field algebra. A Euclidean family must first be reconstructed, with its ordered analytic continuation and boundary conventions, before it can supply the joint Minkowski functional used in eq. 7.ccxliii–eq. 7.cclx. Ordinary positive probability expectations of the commuting cutoff functions do not alone prove Minkowski positivity and spectrum.

Passing the actual reflected Gram matrices to a limit. Let ρ_a be real probability measures with a proved lattice OS reflection inequality. Write Θ_a for its antilinear reflection, including complex conjugation. For positive-time cutoff functions $F_{a,1}, \dots, F_{a,r}$ the actual inequality is

$$\sum_{i,j} \overline{c_i} c_j \, \rho_a((\Theta_a F_{a,i}) F_{a,j}) \geq 0. \tag{7.cclxiv}$$

Suppose the word tests defining these functions have a fixed positive-time gap $\delta > 0$ and their readouts satisfy eq. 7.cclxiii. If the discrete reflection plane is displaced by $b_a \to 0$ from the continuum plane, then for all sufficiently small a, $\epsilon_a + |b_a| < \delta$. Every bond support is on the required positive side. Thus eq. 7.cclxiv applies to the actual readouts rather than a formally localized replacement.

Suppose also that each entry in eq. 7.cclxiv has a joint limit given by the proposed Euclidean data. Passing a finite sum to the limit gives a positive continuum reflected Gram matrix. This is a complete proof of that implication: for each fixed vector of coefficients the quadratic form is a limit of nonnegative real numbers. One must nevertheless verify that the reflected word test for each entry belongs to the space on which the limit is known. A separated or diagonal-flat distribution cannot be evaluated on an arbitrary coincident-point test without this check.

For the scalar family QRM performs the reflected-product diagonal-flat check and the enlargement of the positive-time quotient. For a proposed new family one can start with compact strictly ordered positive-time words away from all internal diagonals, verify that their reflected products are in the declared joint limit space, and then prove the density/insertion estimate needed to enlarge that space. This explicitly identifies the further test-space task. It does not invent Euclidean contact terms to make an undefined Gram entry exist.

Likewise lattice symmetries pass to any joint limit when their actual readouts intertwine the corresponding test actions and the limiting distributions are continuous in the needed topology. Discrete lattice rotations alone do not prove continuous Euclidean rotational covariance. The scalar G2 argument supplies it for its own family. An extension needs the matching assertion for its mixed data if that assertion enters its reconstruction theorem.

Real OS inequalities are used at real physical measures. An analytic continuation of coarse backgrounds or of external currents is a separate analytic operation. A complex source functional is not a probability state merely because its restriction at zero real source is positive.

A useful bounded loop compactness statement. There is a limited joint compactness result available without any renormalized insertion estimate. Choose countably many labelled closed paths $\gamma_{a,j}$ at each cutoff, and set $Y_{a,j} = w_{\gamma_{a,j}} \in [-1, 1]$. The labels include their chosen lattice rounding. For any sequence $a_k \downarrow 0$ there is a subsequence on which all finite joint polynomial moments of these bounded real coordinates converge.

Indeed the finite coordinate monomials form a countable set, and each expectation is bounded by one. Repeated subsequences and a diagonal selection give a common subsequence. Define L on coordinate polynomials by these limits. For $K = [-1, 1]^{\mathbb{N}}$,

$$|L(P)| \le \|P\|_{C(K)}, \qquad L(1) = 1, \qquad L(P) \ge 0 \quad \text{if } P \ge 0 \text{ on } K. \tag{7.cclxv}$$

The inequalities follow by applying them before taking the limit, since every vector of readout values belongs to K. Coordinate polynomials are conjugation closed and separate points of the compact product. Their uniform closure is $C(K)$, so eq. 7.cclxv extends L uniquely to a positive state. Riesz gives a probability measure on K with exactly the selected joint moments. This proves full finite-coordinate consistency, not just convergence of separate one-loop laws.

If a fixed finite-coordinate polynomial relation R holds for the readouts at every cutoff, then

$$L(|R|^2) = 0, \tag{7.cclxvi}$$

so $R = 0$ almost surely in the limit. More generally the same conclusion holds if the coefficients of relations R_a converge to those of R, their finite coordinate set is fixed, and $R_a(Y_a) = 0$. In fact $R_a \to R$ uniformly on K, whence $\rho_a(|R(Y_a)|^2) \to 0$. This is a direct way to retain a specified finite collection of trace relations, provided the rounded labels preserve their concatenations and inverses. If those label identifications are not exact, a quantitative replacement estimate is needed.

This compactness statement need not give a nontrivial limit: the state concentrated at $Y_j = 1$ is permitted. It gives no rounding independence, continuous spacetime covariance, renormalized local composite limit, or mixed law with the unbounded scalar distributions. It also gives no uniform control after multiplying these coordinates by diverging renormalization constants. Those are different assertions from the bounded probability statement just proved.

What mixed bounds a bounded loop actually needs. Let Y_a be any cutoff loop polynomial with $|Y_a| \le 1$ and let $Q_a = \prod_{j=1}^{n} X_a(f_j)$. At the same real cutoff measure one has

$$|\rho_a(Y_a Q_a)| \le \rho_a\Big(\prod_j |X_a(f_j)|\Big), \qquad |\rho_a(Y_a Q_a)|^2 \le \rho_a(|Q_a|^2). \tag{7.cclxvii}$$

The first is the triangle inequality and the second is Cauchy–Schwarz with $\rho_a(|Y_a|^2) \le 1$. For example a sufficient further estimate is

$$\sup_a \rho_a\Big(\prod_j |X_a(f_j)|^2\Big) \le C_n \prod_j p_M(f_j)^2. \tag{7.cclxviii}$$

It gives uniform boundedness and test continuity for the mixed word in eq. 7.cclxvii. A complete mixed subsequence argument would then also require consistency of every such word, the actual relation tests, and the reflected Gram limits where they are used. It would not yet infer its joint Minkowski continuation without a matched reconstruction.

The separated signed scalar distribution bound does not itself evaluate the right side of eq. 7.cclxviii. That expression is an absolute repeated product at one real cutoff measure. Its test is not automatically in a diagonal-flat Euclidean domain. If a stronger insertion estimate is available, its exact observables, repeated products and exterior variables must be matched before using it here. In particular a formal arbitrary-current coefficient is not identified with the needed physical mixed product merely by naming it $E^{(2)}$. The coefficient/readout identification must be proved on its stated domain wherever it is used.

For a fixed family, uniformly bounded absolute moments of every required degree permit diagonal moment subsequences on a countable dense test set. Uniform multilinear bounds of the form in eq. 7.ccxlvii then extend the limits to all tests by its explicit tensor argument. Positivity and relation identities pass through finite matrices. The uniform bounds are essential in this extension from a countable test set; convergence on a dense set alone does not establish distributional convergence.

A quantitative path-sliding comparison. There is a concrete geometric estimate useful in checking rounding consistency. Suppose two fine paths with the same endpoints are connected by an explicit finite sequence of elementary plaquette moves and retracings. An elementary move replaces two sides of a plaquette by the other two sides with the same endpoints. If A and B are the two path products, AB^{-1} is the plaquette holonomy with the appropriate orientation and base point. All other prefix and suffix products are unitary. Hence the norm of the change in the whole path product is exactly $\|I - U_p\|$ for that move, up to conjugation or inversion, both of which preserve this norm. Telescoping along the supplied sequence gives

$$\|U_\gamma - U_{\gamma'}\|_{\mathrm{op}} \le \sum_{\ell=1}^{M} \|I - U_{p_\ell}\|_{\mathrm{op}}. \tag{7.cclxix}$$

Retracings give zero change. Repeated use of a plaquette is counted with its multiplicity. For closed paths the same bound applies to normalized traces, because $|\operatorname{Tr} C|/2 \le \|C\|_{\mathrm{op}}$ for two-by-two matrices.

For $U \in \mathrm{SU}(2)$ its eigenvalues are $e^{\pm i\theta}$, so the actual plaquette action satisfies

$$\|I - U_p\|_{\mathrm{op}}^2 = 2(1 - \tfrac{1}{2}\operatorname{ReTr} U_p) = 2A_p. \tag{7.cclxx}$$

Taking $L^q(\rho_a)$ norms in eq. 7.cclxix, with $q \ge 2$, and using the triangle inequality therefore gives the explicit sufficient comparison

$$\|w_\gamma - w_{\gamma'}\|_{L^q(\rho_a)} \le \sqrt{2} \sum_{\ell=1}^{M} \|A_{p_\ell}\|_{L^{q/2}(\rho_a)}^{1/2}. \tag{7.cclxxi}$$

This is a true estimate for the real unitary cutoff variables. If the right side tends to zero for the specified rounding moves, it proves convergence of their trace difference in that norm. Mere proximity of two physical curves does not bound the number of moves or this sum. A proof must count the actual filling and provide the needed plaquette norm rate. A uniform pointwise small-curvature estimate $\|I - U_p\| \le \varepsilon_a$ only yields $M\varepsilon_a$, which need not tend to zero.

No filling is asserted between paths of different winding class on a torus. Indeed eq. 7.ccxxx rules out any estimate which would remove nontrivial flat winding holonomies by such a claim. The supplied move sequence, endpoints and periodic identifications are part of the hypotheses of eq. 7.cclxix.

A controlled change of readout scheme. Suppose two readout prescriptions $Q_{a,j}$ and $Q'_{a,j}$ for a fixed word satisfy, for that word length n,

$$\|Q_{a,j} - Q'_{a,j}\|_{L^n(\rho_a)} \longrightarrow 0, \qquad \sup_a (\|Q_{a,j}\|_{L^n} + \|Q'_{a,j}\|_{L^n}) < \infty. \tag{7.cclxxii}$$

Then their joint word expectations have the same limit whenever one exists. Expand the difference of products by replacing one factor at a time. Holder's inequality with n factors bounds the jth term by

$$\|Q_{a,j} - Q'_{a,j}\|_{L^n} \prod_{i<j} \|Q_{a,i}\|_{L^n} \prod_{i>j} \|Q'_{a,i}\|_{L^n}, \tag{7.cclxxiii}$$

which tends to zero. The case $n = 1$ is just its L^1 bound. Versions with different Holder exponents or proved exterior insertion norms give the corresponding same conclusion, but their actual norms must be stated. For bounded loops, eq. 7.cclxxi can supply the difference norm in eq. 7.cclxxii once its right side is controlled. For renormalized fields the differences include their coefficients and counterterms as well.

There is also a useful two-limit density criterion. Suppose for each intended readout $Q_{a,j}$ there are polynomials $P_{a,j}^{(r)}$ in a fixed listed family of loop readouts, with coefficients and finite labels

independent of a for each r. Suppose all fixed-polynomial joint moments have limits, the required L^n norms are uniformly bounded, and

$$\lim_{r\to\infty} \limsup_{a\downarrow 0} \|Q_{a,j} - P_{a,j}^{(r)}\|_{L^n(\rho_a)} = 0 \tag{7.cclxxiv}$$

for every fixed word length involved. The product telescoping bound gives a uniform limiting error $C_n\varepsilon_r$. For each r take the known polynomial-word limit. Applying the same error bound for r and s shows these limits are Cauchy as $r, s \to \infty$. The limiting value is then the unique limit for the original word: its limsup distance from the rth polynomial limit is at most $C_n\varepsilon_r$. This proves the criterion without interchanging an uncontrolled pair of limits.

The fixed-cutoff density theorem in eq. 7.ccxx alone gives no such criterion. Its approximating degrees, loop labels and coefficients may depend arbitrarily on a. Convergence of each fixed loop polynomial does not control a moving polynomial with diverging coefficients. The condition in eq. 7.cclxxiv, or an actual alternative uniform insertion norm, is the missing quantitative link in such a use of cutoff completeness.

Exact laws and dense-observable transport. At a fixed real cutoff, a genuine integration or change of variables may induce a bounded observable map T_a and an identity for a determining class. The dense-class norm estimate in eq. 7.ccvi, applied to the complete Wilson polynomial family in eq. 7.ccxxii, extends that identity to every continuous invariant observable. If the actual induced full bond measure is gauge invariant, equality there determines the full gauge-invariant probability law by eq. 7.ccii, and hence all bounded Borel readouts with that law.

The hypotheses include the map's actual observable type, its boundedness at that cutoff, and the identity on a complete class. An identity only for the scalar partition function, its scalar derivatives, or one special insertion is not the determining-class identity for all Wilson polynomials. A based gauge-fixed calculation must also be transported to the full-site invariant functions before the orbit-space state statement applies. None of these requirements is replaced by preservation of the constant function alone.

Across different cutoffs the norms and readouts in this argument may change. A finite-cutoff equality is exact, but any passage to a renormalized joint continuum family still needs the continuity and limit estimates just described. This separates an exact integral identity from the independent estimates needed to read a continuum observable through it.

Conditional joint reconstruction and physical identification. The previous statements give a precise conditional extension theorem. Suppose a declared family of joint Minkowski word distributions satisfies the scalar restriction eq. 7.ccxliii, mixed positivity eq. 7.ccxliv, the relation test eq. 7.ccxlv, and the specified test continuity (for point-field words, eq. 7.ccxlvii–eq. 7.ccxlviii). Suppose its symmetry action obeys the invariance and continuity used in eq. 7.ccliv–eq. 7.cclv, its full polynomial spectral measures pass eq. 7.cclvi, and its spacelike moment identities pass eq. 7.cclvii. Then it has a normalized positive cyclic representation, closable fields on a common invariant polynomial domain, the stated strongly continuous covariance and forward spectrum, and operator locality on that domain. It contains the constructed scalar representation as exactly the closed subspace in eq. 7.ccli. If the additional whole-space smoothness and energy bounds in eq. 7.cclix are verified, it also has the common energy-smooth domain and canonical closure statements proved above. All assertions follow from the explicit arguments in eq. 7.ccxlix–eq. 7.cclx; no boundedness or domain property of an added type is imported from its scalar restriction.

If the data are first supplied for finite families, eq. 7.ccliii gives the unique global functional once their actual overlap consistency is proved. A matched finite-family Euclidean reconstruction with uniqueness can prove that consistency as explained there. Its theorem must match the new types, the joint positive-time test domain, the growth seminorms and the unrestricted boundary values.

For the scalar family those checks are the established EB/QRM arguments. For a larger family they are explicit new checks, not a generic consequence of citing an OS theorem.

For a gauge-theory identification this conditional theorem must be attached to actual readouts of the same lattice theory. In addition to the compatible joint limits it must identify their renormalizations, exact limiting relations, localization, and relation to the scalar $\mathrm{tr}(F^2)$. One must state why the chosen observable family is sufficient for the intended continuum gauge-invariant theory. The finite-graph theorem supplies that sufficiency at a fixed cutoff. Passing it to the continuum needs a proved uniform criterion such as eq. 7.cclxxiv, or another stated reconstruction of the target observable algebra. Bare cutoff completeness does not silently perform that passage.

Nor do scalar cluster or spectral assertions automatically become assertions on the enlarged Hilbert space. The scalar subspace is reducing for the joint spacetime symmetries, so its spectral measure is a restriction of the full one. Restriction does not exclude additional spectrum or translation-invariant vectors in its orthogonal complement. For example let any constructed scalar theory be tensored with $\mathbb{C}^2$, choose the unit vector $\eta = (1,1)/\sqrt{2}$, and put

$$\widehat{\Omega} = \Omega_d \otimes \eta, \qquad \widehat{U}(g) = U_d(g) \otimes I, \qquad \widehat{\varphi}(f) = \varphi_d(f) \otimes I,$$
$$\chi(f) = \Big(\int f(x)\,dx\Big) I \otimes \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \tag{7.cclxxv}$$

The added field is bounded for each test and central. Its moments are tempered, it is a scalar under proper orthochronous Poincare transformations, and it is local. All mixed moments are those of this tensor representation, so they are positive. The scalar restriction is unchanged. The vectors η and $\mathrm{diag}(1,-1)\eta$ span $\mathbb{C}^2$, so the full polynomial vacuum space is the full tensor space. Both copies of any scalar zero-energy vector have zero energy. In particular a unique scalar vacuum need not become a unique joint vacuum. This is an explicit extension illustrating the logical distinction; it is not claimed to be an actual readout from the lattice gauge measure.

A full joint cluster assertion would resolve this particular vacuum issue. If for every pair of polynomial vectors the spatial translation coefficients cluster to their vacuum product, density and unitarity extend that convergence to the weak operator limit

$$U(0,\mathbf{a}) \;\rightharpoonup\; |\Omega\rangle\langle\Omega| \qquad (|\mathbf{a}| \to \infty). \tag{7.cclxxvi}$$

The extension uses fixed polynomial approximants for both vectors and the uniform unitary norm, so no uniformity over all polynomials is being assumed. By the forward cone, $H = 0$ implies $\mathbf{P} = 0$. A zero-energy vector is therefore invariant under every spatial translation. Applying eq. 7.cclxxvi to it proves $\ker H = \mathbb{C}\Omega$. This is a proof from a *full joint* cluster assertion; scalar clustering only supplies the statement on the scalar cyclic subspace. The phase mixture discussed in SPH retains its own explicit invariant subspace instead of assuming such a joint purity statement.

Bounded Euclidean multiplication is not yet an OS field. The ordinary bounded loop result in eq. 7.cclxv and the measure inequalities in eq. 7.cclxvii do not give an OS operator norm. This failure can be demonstrated at the level of a finite reflection-positive system. Let s_- and s_+ be independent uniform signs, with reflection exchanging them and conjugating coefficients. For positive-time functions F, G of s_+ the OS form is

$$\langle [F], [G] \rangle_{\mathrm{OS}} = \overline{\mathbb{E} F(s_+)}\, \mathbb{E} G(s_+). \tag{7.cclxxvii}$$

It is positive semidefinite, so this is genuinely a reflection-positive probability system. But $F = s_+$ is null. The positive-time function $Y = s_+$ has ordinary supremum norm one, whereas $YF = 1$ has OS norm one. Thus multiplication by Y does not even preserve the OS null space. There can be no bound $\|[YF]\|_{\mathrm{OS}} \le C\|[F]\|_{\mathrm{OS}}$ for this insertion. This example asserts only the insufficiency of ordinary boundedness and reflection positivity; it is not assigned the continuous-time smoothness hypotheses of the scalar reconstruction.

An added sharp-time point type, with spatial test $h \in \mathcal{S}(\mathbb{R}^3)$, instead needs its precise time-shifted two-exterior form $B_{s,\alpha,h}(F,G)$, defined from its actual Euclidean readout, with a bound

$$|B_{s,\alpha,h}(F,G)| \le C_{\alpha,s} p_M(h) \|[F]\|_{\mathrm{OS}} \|[G]\|_{\mathrm{OS}}. \tag{7.cclxxviii}$$

Here p_M is the weighted Schwartz seminorm on $\mathbb{R}^3$. The form is antilinear in F and linear in G and h. A different label space needs its own specified continuous seminorm. This bound makes it vanish if either exterior vector is null, so it descends to the actual quotient. Density and Riesz then give a unique bounded operator $\Phi_{s,\alpha}(h)$ on that specified exterior Hilbert space, with norm at most $C_{\alpha,s} p_M(h)$. The reflection adjoint, spatial covariance and heat consistency must be verified from the same placements. When that space has an established self-adjoint contraction heat semigroup T_r, an exact form identity $B_{s+r}(F,G) = B_s(T_r F, T_r G)$ gives $\Phi_{s+r} = T_r \Phi_s T_r$ by density and boundedness.

If the exterior space is an ordered sector inside a larger OS space, matrix elements alone specify a compression. The actual vector-sewing identity is needed to show that the insertion maps ordered words to the ordered sector; the star partner's sewing and adjoint identities then give reduction. A sharp-time definition also needs its actual narrow-time limit or density estimate. If a proved bound in eq. 7.cclxxviii has a polynomial small-s loss, the heat-consistent energy-band construction of EB supplies the subsequent field method, with its explicitly checked test continuity and domain orders. Point tubes and Lorentz continuation still need their actual density and covariance checks. For a new type none of these model inputs follows from $|w_\gamma| \le 1$ or from the scalar insertion estimate. This separates the bounded cutoff observable, the OS Riesz operator, and the eventual Minkowski field with their exact intervening requirements.

The resulting scope of the tr(F^2) *construction.* The established scalar theory has its unrestricted tempered distributions, positive cyclic representation, forward spectrum, Lorentz covariance, local field relations and the exact phase/Hilbert decomposition within the stated scalar scope. The finite-cutoff gauge analysis also gives an actual complete Wilson observable family and the precise information lost by taking only plaquette actions. These are substantial compatible conclusions.

A full Yang–Mills identification additionally needs the sufficient joint gauge-observable family and its actual continuum readouts, including mixed limits, relations, positivity, covariance, locality and the stated relation to the scalar density. The conditional extension theorem organizes those requirements and proves what follows from them; it does not verify their model estimates. Nontriviality of the scalar field guarantees a nontrivial scalar subspace in any extension satisfying eq. 7.ccxliii, but does not specify all its added degrees of freedom or their dynamics.

7.14. **Conditional scalar reconstruction.**

7.14.1. *Reconstruction: hypotheses, consequences, and scope.* All growth constants below are positive, factorial exponents are nonnegative, and derivative-order coefficients are positive integers. D2 and H1 denote the conditional graded-moment and diagonal-flat growth conclusions. G2 denotes scalar rotation covariance derived under the ordinary-source, mirror, cone and ultraviolet hypotheses stated below.

The passage from Euclidean correlation functions to a quantum field requires several logically separate inputs. Compactness of separated correlations gives an off-diagonal distribution. Reflection positivity gives a Hilbert space. Uniform growth in the number of arguments is needed for the corrected reconstruction theorem. Full Euclidean covariance and clustering have to be established in their own right. Keeping these steps separate prevents a qualitative convergence statement from carrying quantitative information it does not contain.

The Euclidean test domain. Write

$$D_n = \{(x_1, \dots, x_n) \in (\mathbb{R}^4)^n : x_i \ne x_j \text{ whenever } i \ne j\}.$$

Let $\mathcal{S}_{\neq,n}$ be the closed subspace of the Schwartz space $\mathcal{S}(\mathbb{R}^{4n})$ consisting of functions whose every derivative vanishes on the complement of D_n. These functions are flat on all coincidence diagonals. Let $\mathcal{S}_{+,n}$ consist of those elements that are also flat outside the region in which all time coordinates are positive. Set $\mathcal{S}_{\neq,0} = \mathcal{S}_{+,0} = \mathbb{C}$. The time reflection is $\theta(x_1, x_2, x_3, x_4) = (x_1, x_2, x_3, -x_4)$, and

$$(\Theta\overline{\varphi})(x_1, \dots, x_n) = \overline{\varphi(\theta x_1, \dots, \theta x_n)}.$$

Symmetry of the functions makes reversal of the order of the arguments immaterial in this scalar setting.

These are valid test domains for the historical Osterwalder–Schrader reconstruction problem. They do not assert that the Euclidean functions have a preferred extension to every Schwartz test. A distribution supported on a coincidence diagonal vanishes on $\mathcal{S}_{\neq,n}$. Such a distribution therefore cannot be recovered from separated correlations. Any later use of contact terms, composite operator identities at coincident points, or local Ward identities has to specify the additional extension that it uses. This observation does not obstruct reconstruction on the stated domain.

Lemma 7.10 (Density of separated tensors)**.** Finite sums of tensors $f_1 \otimes \cdots \otimes f_n$, with smooth compactly supported f_i having pairwise disjoint supports, are dense in $\mathcal{S}_{\neq,n}$. The corresponding assertion holds in $\mathcal{S}_{+,n}$ when all supports lie at positive times. ■

The proof, including the simultaneous infinity, diagonal and positive-time cutoffs and the product Fourier approximation, is given in § 5.25.

The lemma is a statement about the flat subspace. It gives no density claim in the full Schwartz space, where evaluation on the diagonal is a continuous functional that vanishes on every such tensor.

What convergence preserves. Let σ_j be centred Euclidean moment functionals at finite cutoffs. Suppose that for every separated smooth tuple X the numbers $\sigma_j(X)$ converge to $\sigma(X)$. Suppose also that each σ_j is reflection positive for finite families of internally separated positive-time tuples. Different tuples in a family may overlap. This last qualification is essential: reflection positivity is a matrix condition, not a condition on one tuple at a time.

Lemma 7.11 (Closed reflection positivity)**.** For positive-time tuples $X_1, \dots, X_r$ and complex coefficients $c_1, \dots, c_r$,

$$\sum_{i,k=1}^{r} \overline{c}_i c_k \, \sigma(\theta\overline{X}_i \cdot X_k) \geq 0. \qquad ■$$

Proof. Each X_i is internally separated. Its reflected entries have negative times, so $\theta\overline{X}_i \cdot X_k$ is a separated tuple for every pair (i, k). The displayed expression is the limit of the corresponding finite sum for σ_j, all of which are nonnegative. □

Suppose, in addition, that the limiting functionals extend continuously to $\mathcal{S}_{\neq,n}$. Reflection positivity then holds on finite Schwartz sequences $\Phi = (\varphi_0, \dots, \varphi_N)$ with $\varphi_n \in \mathcal{S}_{+,n}$:

$$\sum_{n,m=0}^{N} S_{n+m}(\Theta\overline{\varphi}_n \otimes \varphi_m) \geq 0.$$

Indeed, the mixed tensor belongs to $\mathcal{S}_{\neq,n+m}$. Coincidences within one factor are killed by its flatness; a coincidence across the two factors has time coordinate zero or lies outside the allowed half-space of one factor, so is killed there. Approximate each φ_n by the tensors in Lem. 7.10, using a seminorm strong enough for all the finitely many mixed terms, and pass to the limit. Permutation symmetry and invariance under any fixed Euclidean isometry pass in exactly the same way once they hold on separated tensors.

There is one further step when translations are initially known only for vectors in a dense subgroup, for example the union of nested lattice translation groups. Given an arbitrary vector v, choose subgroup vectors $v_k \to v$. Translation is continuous on the smooth tests, and the local bounds permit passage from $S_n(\tau_{v_k}\varphi) = S_n(\varphi)$ to $S_n(\tau_v\varphi) = S_n(\varphi)$. This argument does not generate rotations from the finite hypercubic group.
The quantitative reconstruction hypothesis. Fix the seminorms

$$|\varphi|_k = \max_{|\alpha|\le k} \sup_x (1+|x|^2)^{k/2} |\partial^\alpha \varphi(x)|.$$

Theorem C (Scalar reconstruction)**.** For reconstruction, assume a sequence of symmetric functionals $S_n \in \mathcal{S}'_{\neq,n}$, with $S_0 = 1$, and constants $A, B, k_0, p < \infty$, independent of n, such that

$$|S_n(\varphi)| \le A B^n (n!)^p |\varphi|_{k_0 n}. \tag{7.cclxxix}$$

Assume full Euclidean invariance, reflection positivity on the domains just described, and the cluster property for separated positive-time groups of arguments. Under these hypotheses the corrected Osterwalder–Schrader reconstruction theorem gives a Hermitian scalar Wightman field with positive energy, locality, Poincare covariance, and a unique vacuum in its cyclic representation. ■□

Reality in the reconstruction import follows here from reflection positivity. The sesquilinear form on the finite positive-time sequences is Hermitian by polarization. Its degree-zero and degree-n entries give $S_n(\Theta\bar{\varphi}) = \overline{S_n(\varphi)}$ on positive-time tests. A compact separated tensor can be translated into the positive half-space. Translation invariance of S_n on the tensor and on its reflected conjugate then gives the identity before the translation. Separated tensor density and continuity give reality on the entire diagonal-flat space.

We apply the corrected reconstruction theorem of Osterwalder and Schrader [OS75, Sect. IV.1, Thm. $E' \to R'$, p. 287], with the test space and growth hypothesis just stated.

The exact all-order seminorm comparison is proved in Prop. 7.5. § 7.2 gives the direct field, tube-boundary and covariance construction. § 7.3 identifies its moments with those supplied by the corrected reconstruction theorem, which gives locality. The representation is the ordered sector; its common domains and scalar phase decomposition are developed in the reconstruction sections. The cited theorem applies by the hypothesis checks given there.

The condition in eq. 7.cclxxix must not be replaced by the weaker assertion that every S_n is separately continuous with unspecified constants. The growth of the distribution order and the constants in n matters to the existence of tempered boundary values in the analytic continuation. Likewise, a local off-diagonal kernel theorem alone does not establish eq. 7.cclxxix.

7.14.1.1. The explicit rooted-source and dyadic extension route. The rooted-source and dyadic extension estimates give a quantitative proof of eq. 7.cclxxix, with controlled dependence on n. Prop. 5.76 derives moments directly from the ordinary source hypothesis D1 and the proved G1 chessboard domination, using the actual domain geometry in eq. 5.cdxlvi–eq. 5.cdxlviii. At scale $a_s = L^{-s}$, domains are unions of Ma_s cubes, indexed by those unions, and their source dependence occupies only a fixed number of neighboring cube layers. Their size is the minimum cubical edge-tree length meeting all cubes, with source-energy decay above its rooted entropy rate. Here $M = L^{m_0}$, and the cofinal tori $\ell = 2L^m$, $m \ge m_0$, tile every actual scale with even cube counts. No scale is discarded for a failure to tile. The weak abstract eq. 5.cdxxxvi count alone does not furnish the sharper rooted and global counts needed for this proof.

For real compact C^1 tests, the theorem gives one fixed finite integer k, $B(R) = C(R+1)^4$, and the two-state centered bound

$$\left|\rho\prod_{i=1}^{n}[\mathcal{O}_a(f_i)-\nu(\mathcal{O}_a(f_i))]\right|\le B(R)^n(n!)^k\max\{1,d^{-5n}\}\prod_i\|f_i\|_\sharp. \tag{7.cclxxx}$$

Each support lies in its own radius-R ball, placed anywhere; the separation is d. The same factorial exponent bounds higher cumulants. Uniformity lets eq. 7.cclxxx pass to the separated continuum limits and their component limits. This is requirement D2 conditional on the actual D1 source representation and G1, not a new independent analytic estimate.

Prop. 5.78 uses only the unit-radius version, with the fixed equivalence of the sharp and C^1 norms absorbed in $B(1)$. Its product Fourier construction uses $8n$ derivatives; Gevrey-two pair/grid cutoffs cost at most $C^n(n!)^{32}$. Dyadic Taylor flatness to order $10n+2$ pays the local h^{-6n} cost and the h^{-4n} configuration grid count, leaving a summable dyadic square. It yields eq. 7.cclxxix with

$$k_0=20,$$
$$p=k+32.$$

The proof includes independence of tensor presentations, overlap gluing, cutoffs at infinity and every pairwise diagonal, and the positive-time boundary. Its constrained tensor density supplies the full-sequence reflection-positive form. Thus H1 is a proved implication of D2 here; the ordinary analytic RG source estimates in D1 are still assumptions. Neither separate continuity with arbitrary order constants nor weak counting in eq. 5.cdxxxvi alone may be substituted for this GS/QF route. Hilbert space and clustering. § 6.16 proves the quotient construction on compact positive-time tuples from their invariant reflection-positive moments and position-uniform per-ball bounds. Fixed separation of the reflected supports bounds the translated orbits before iterated Cauchy–Schwarz proves contraction. The resulting time semigroup is strongly continuous, positive and self-adjoint, and spatial translations are strongly continuous unitaries. The stated lattice approximation also gives the cube spectral cone. The GS/QF growth and density argument then identifies its completion with the full positive-time Schwartz sequence quotient. These deductions retain their explicit hypotheses; positivity alone is not being substituted for the continuity and growth checks.

For completeness, clustering on a dense class of vectors extends to the whole Hilbert space. Let $U(v)$ denote the spatial unitary translations, and suppose that for dense vectors ξ,η,

$$\langle\xi,U(v)\eta\rangle\longrightarrow\langle\xi,\Omega\rangle\langle\Omega,\eta\rangle$$
$$(|v|\to\infty).$$

Choose dense approximants $\xi_k\to\xi$ and $\eta_k\to\eta$. Unitarity bounds the difference of the matrix elements, uniformly in v, by

$$\|\xi-\xi_k\|\,\|\eta\|+\|\xi_k\|\,\|\eta-\eta_k\|.$$

The vacuum matrix elements obey the same estimate. First let $|v|\to\infty$ at fixed k, then let $k\to\infty$. The argument proves the qualitative cluster limit. It does not preserve a numerical decay rate on arbitrary vectors without further quantitative control of the approximations.

Phases and full rotational covariance. The phase-interface construction realizes the components with the G1 mirror properties and the D1/GS/QF moment bounds. Once the angular argument gives covariance of the mixture, the action on its canonical decomposition and coordinate reflection invariance give covariance of every component. The state-uniform two-point extraction is used to obtain the two-point law for the realizing states of each component. The convergent cutoff one-point differences give the real phase mean $c_\xi\int f$, with $\sup_\xi|c_\xi|$ bounded by the one-point transfer. To restore it on the Schwartz domains, let $I_A\varphi$ be the integral of φ over the variables with indices

in A. Differentiation under the integral preserves flatness on every remaining coincidence diagonal. If the original test is supported at positive ordered times, then so is the marginal on the retained arguments, with flatness at its boundary. Indeed any violation of a retained order or positivity constraint already violates the original one.

Take $k_0 > 4$, increasing the seminorm order if needed. Writing $x = (y, z)$ with $z = (z_i)_{i\in A}$, use

$$(1 + |x|^2)^{k_0 n/2} \geq (1 + |y|^2)^{k_0(n-|A|)/2} \prod_{i\in A} (1 + |z_i|^2)^{k_0/2}.$$

The derivatives of order at most $k_0(n - |A|)$ in y therefore give $|I_A\varphi|_{k_0(n-|A|)} \leq C_{\mathrm{int}}^{|A|} |\varphi|_{k_0 n}$, where $C_{\mathrm{int}} = \int_{\mathbb{R}^4} (1+|z|^2)^{-k_0/2}\, dz$. For A the full set of indices this also bounds the vacuum integral. The restored moment is

$$S_{\xi,n}(\varphi) = \sum_{A\subset\{1,\dots,n\}} c_\xi^{|A|} S^{\mathrm{c}}_{\xi,n-|A|}(I_A\varphi).$$

It agrees with the finite subset expansion on separated tensors, hence with the continuous extension by density. For a centered bound with exponential base B and nonnegative factorial exponent p, the binomial sum gives the same exponent and seminorm order with base $B + C_{\mathrm{int}} \sup_\xi |c_\xi|$, after including the vacuum in the prefactor. On the ordered sequences the same marginal maps define inverse shifts with c_ξ and $-c_\xi$. The reflected pairing identity on separated tensors extends by continuity and gives the same intertwining unitary as on compact tuples. On the cyclic field domain the centered insertion subtracts $c_\xi \int f$ times the identity.

Similarly, invariance under the hypercubic group, coordinate reflection positivity, and translation invariance do not by themselves imply invariance under O(4). The finite group is not dense in the rotation group. Any route through diagonal mirrors, a sharp energy–momentum cone, bounded insertions, or the exclusion of nonconstant angular harmonics needs an additional theorem. The following chain now supplies that theorem conditionally, before the external reconstruction theorem is invoked.

Prop. 6.26 completes the scalar covariance implication. Its preceding sections prove, in order, the uniform Hilbert insertion bound, the analytic L^1 density, the product kernels and continued Gram identities, and the ultraviolet elimination of the two-point harmonics. Polygon divisibility and common coordinate cuts then remove all higher harmonics and exceptional distributional support. The proof works with finite support boxes; density of generic point configurations alone would not exclude a singular part.

The angular continuation uses eq. 6.cccxxxv. The dependency catalogue obtains it through the positive-shape bound eq. 6.cccxxvii, deduced from F2–F3 on the stated all-state test class. The second route in § 6.12.6 uses the bound for a fixed family of reflected bumps from the ordinary source estimates at the running stops. Both deductions apply to periodic-state limits with the coordinate and diagonal mirrors and the exact cone. The finite-window density comparison includes growing tori above its side threshold. General growing-torus limits require their own mirror and cone argument.

The application uses the interacting D1 estimates and the F2–F3 extraction and normalization lemmas in their full forms. These are the model statements invoked to obtain the nontrivial scalar theory. The OS analytic-continuation theorem is still imported, and the identification with full Yang–Mills observables remains separate.

What the reconstructed field establishes. When the limiting observable is the centred scalar tr(F^2), the theorem above constructs its scalar observable sector. A nonzero two-point function on separated tests excludes a field that is a multiple of the identity. A nonzero higher cumulant excludes Gaussianity of that scalar field. Neither conclusion alone identifies a full Yang–Mills observable algebra. In particular, a Wick square of a free Gaussian field already has nonzero higher cumulants. Establishing a Yang–Mills theory in a stronger sense requires the stated additional observables, identities, and compatibility relations that define that sense.

Nor does polynomial clustering establish a mass gap. The positive measure $Ee^{-E}\,dE$ on $[0,\infty)$ has Laplace transform

$$\int_0^\infty Ee^{-E}e^{-tE}\,dE = (1+t)^{-2}.$$

Its support reaches zero, although its transform decays quadratically. A positive spectral gap requires an estimate that excludes spectral support in an entire interval above the vacuum. That question remains separate from the existence and reconstruction of the scalar sector described here.

Appendix A. Auxiliary lattice and comparison estimates

These calculations supply the finite-dimensional normalization, kernel decay, polymer estimates and reflection-positive limits used in the main argument. Each result retains its own parameter range and boundary conditions. The comparison calculations at the end specify the domains needed when the coupling or cutoff changes.

A.1. **Block normalization and a uniform scalar gap.**

A.1.1. *Block means, adjoints, and a uniform scalar Poincaré inequality.* An adjoint depends on the inner products of both its domain and its range. This matters when a block mean maps a fine lattice to a coarse lattice. The following finite-dimensional calculation fixes the convention and gives the scalar estimate used in a gauge-fixed Gaussian comparison. It applies to real or complex scalar functions; a finite number of color components are handled by summing the same estimate component by component.

Fix an integer $m \geq 1$ and put $\eta = m^{-1}$. A block consists of the sites

$$B = \{0, \eta, \dots, (m-1)\eta\}^4.$$

Its associated physical cell has side $m\eta = 1$ and volume one. Translation of the block, including translation by half a fine spacing to use cell centers, does not change the calculation. Let $\mathcal{B}$ be a finite disjoint family of such blocks, for example the blocks of a periodic torus whose side is an integer number of coarse cells. Write Λ_f for their union and Λ_c for the set indexing the blocks. A coarse function has one value per block. We count every fine bond once, with positive orientation. In the block Neumann form only bonds whose two endpoints belong to the same block are counted.

The physical inner products are

$$\langle f, g\rangle_f = \eta^4 \sum_{x\in\Lambda_f} \overline{f(x)}g(x),$$

$$\langle u, v\rangle_c = \sum_{B\in\mathcal{B}} \overline{u(B)}v(B),$$

$$\langle a, b\rangle_e = \eta^4 \sum_{e} \overline{a(e)}b(e).$$

The last sum can mean all fine bonds of the periodic lattice or just the internal bonds of the blocks; the operator being considered determines which set is used. The same weight is used on fine sites and fine bonds. The physical difference is $\mathrm{d}_\eta f(x, x+\eta e_\mu) = \eta^{-1}[f(x+\eta e_\mu) - f(x)]$. The unscaled combinatorial difference is $\mathrm{d}_0 = \eta \mathrm{d}_\eta$. These two operators must not be interchanged in an estimate with a mesh-independent constant.

Proposition A.1 (The mean, its adjoint, and its projection)**.** Define the block mean $Q : H_f \to H_c$ by

$$(Qf)(B) = \eta^4 \sum_{x\in B} f(x) = m^{-4} \sum_{x\in B} f(x).$$

For the physical inner products just specified, its adjoint is $(Q^*u)(x) = u(B)$ for $x \in B$. Consequently $QQ^* = 1$, and $P = Q^*Q$ is the orthogonal projection onto the functions constant in each block. In particular,

$$\|f\|_f^2 = \|(1-P)f\|_f^2 + \|Qf\|_c^2. \qquad \blacksquare$$

Proof. Directly from the definitions,

$$\langle Qf, u\rangle_c = \sum_B \eta^4 \sum_{x\in B} \overline{f(x)} u(B) = \langle f, Q^*u\rangle_f.$$

Since a block contains m^4 sites and $\eta^4 m^4 = 1$, its mean applied to a constant is that constant. Thus $QQ^* = 1$. It follows that $P^* = P$ and $P^2 = Q^*(QQ^*)Q = P$. Its range is precisely the block-constant functions, and the displayed norm identity is the orthogonal decomposition by that projection. No limiting argument is involved. □

Proposition A.2 (A block Neumann estimate)**.** Let $\mathrm{d}_{\eta,N}$ denote the physical difference restricted to internal bonds of each block. If $m \geq 2$, then

$$\|(1-P)f\|_f^2 \leq \frac{\eta^2}{4\sin^2(\pi\eta/2)} \|\mathrm{d}_{\eta,N} f\|_e^2 \leq \tfrac{1}{4}\|\mathrm{d}_{\eta,N} f\|_e^2.$$

For $m = 1$ the left side is zero. If d_η includes bonds between blocks, the same bound holds with d_η on the right. With the combinatorial difference the exact first bound is instead

$$\|(1-P)f\|_f^2 \leq \frac{1}{4\sin^2(\pi/(2m))} \|\mathrm{d}_{0,N} f\|_e^2. \qquad \blacksquare$$

Proof. First consider a one-dimensional path with m vertices indexed by $j = 0, \ldots, m-1$. Its Neumann graph Laplacian is the matrix associated with the quadratic form $\sum_{j=0}^{m-2} |f_{j+1} - f_j|^2$. For an interior vertex it acts as $2f_j - f_{j-1} - f_{j+1}$; at the two endpoints it acts as $f_0 - f_1$ and $f_{m-1} - f_{m-2}$. For $k = 0, \ldots, m-1$, set

$$v_k(j) = \cos\bigl(\pi k(j + \tfrac{1}{2})/m\bigr).$$

The cosine addition formula gives, in the interior,

$$2v_k(j) - v_k(j-1) - v_k(j+1) = 4\sin^2(\pi k/(2m)) v_k(j).$$

At the left endpoint,

$$\cos(\theta/2) - \cos(3\theta/2) = 4\sin^2(\theta/2)\cos(\theta/2),$$
$$\theta = \pi k/m.$$

The right endpoint follows by reflection. Thus these are eigenvectors with eigenvalues $4\sin^2(\pi k/(2m))$. The eigenvalues are distinct because sine is strictly increasing on $[0, \pi/2)$; the nonzero eigenvectors therefore form an orthogonal basis. The $k = 0$ vector is constant.

On the four-dimensional block the graph Laplacian is the sum of the four one-dimensional matrices acting on separate tensor factors. Tensor products of the v_k therefore form an eigenbasis. The eigenvalues of the physical Neumann Laplacian $\mathrm{d}_{\eta,N}^{*}\mathrm{d}_{\eta,N}$ are

$$4\eta^{-2}\sum_{\mu=1}^{4}\sin^2(\pi k_\mu/(2m)),$$
$$0\le k_\mu<m.$$

Its only zero mode is the constant vector, and the smallest positive eigenvalue is $\lambda_N = 4\eta^{-2}\sin^2(\pi/(2m))$. Multiplication of the site and bond inner products by the common constant η^4 does not change this matrix or these eigenvalues. Expanding $f-Pf$ in the eigenbasis gives $\lambda_N\|f-Pf\|_f^2\le\|\mathrm{d}_{\eta,N}f\|_e^2$ on one block and hence on their disjoint union.

Finally, concavity of sine on $[0,\pi/2]$ gives $\sin t\ge 2t/\pi$ there. At $t=\pi/(2m)$ this yields $\sin(\pi/(2m))\ge 1/m=\eta$, so $\lambda_N\ge 4$. Adding the nonnegative contributions of bonds between blocks can only increase the Dirichlet form. Substitution of $\mathrm{d}_{0,N}=\eta\mathrm{d}_{\eta,N}$ gives the combinatorial version. □

These estimates immediately give a uniform scalar gap on a periodic fine lattice. If $\mathcal{L}_\eta=\mathrm{d}_\eta^{*}\mathrm{d}_\eta$ and $\mathcal{A}=\mathcal{L}_\eta+Q^{*}Q$, then

$$\langle f,\mathcal{A}f\rangle_f=\|\mathrm{d}_\eta f\|_e^2+\|Qf\|_c^2\ge\|(1-P)f\|_f^2+\|Qf\|_c^2=\|f\|_f^2.$$

Thus $\mathcal{A}$ is invertible and $\|\mathcal{A}^{-1}\|\le 1$, independently of the mesh and number of blocks. This proves a scalar block-constrained gap. It supplies neither a vector-field coercivity theorem nor a mass gap for a physical Hamiltonian; those are different assertions.

A uniform inverse for a coarse Gram matrix. The same convention also makes a useful projection formula precise. On the periodic lattice put $G'=\mathcal{A}^{-1}$, with $\mathcal{A}$ as above. There is a numerical constant $c>0$, independent of m and the number of blocks, such that

$$QG'^2Q^{*}\ge c1.$$

Here is a finite-dimensional proof, including a choice of the test functions. For $m\ge 2$ define on a block indexed by $j=(j_1,\dots,j_4)$

$$\phi_m(j)=16\prod_{\mu=1}^{4}\sin^2(\pi(j_\mu+\tfrac12)/m).$$

The sum of the m roots $e^{2\pi i(j+1/2)/m}$ is zero. Taking real parts in $\sin^2 t=(1-\cos 2t)/2$ shows that the one-dimensional arithmetic mean of each sine-square factor is $1/2$. Thus the mean of ϕ_m on a block is one. For a coarse function u, define $Tu(x)=u(B)\phi_m(x)$ on the block B. Then $QT=1$ and $\|T\|\le 16$.

There is also a bound $\|\mathcal{L}_\eta Tu\|_f\le C\|u\|_c$ uniform in m. To see it, the second physical difference of $\sin^2(\pi t)$ at interior sites is bounded by the supremum $2\pi^2$ of its second derivative. At an end site, its value is $\sin^2(\pi\eta/2)\le\pi^2\eta^2/4$. A second difference that crosses a block boundary therefore contributes at most a constant times the absolute coarse values in the two neighboring blocks: the factor η^{-2} is canceled by this endpoint bound. The other three sine-square factors are bounded by one. After summing the four coordinate differences, a pointwise bound is $C\sum_{B'\sim B}|u(B')|$, where the sum includes B and its face neighbors. Squaring, summing with weight η^4, and using the bounded number of neighbors proves the norm estimate. For $m=1$, set $T=1$; the unit-spacing

Laplacian has norm at most 16, so the same conclusion holds. Consequently $\|\mathcal{A}Tu\|_f \le C\|u\|_c$ for all m.

Self-adjointness and $G'\mathcal{A} = 1$ now give

$$\|u\|_c^2 = \langle Q^*u, Tu\rangle_f = \langle G'Q^*u, \mathcal{A}Tu\rangle_f \le C\|G'Q^*u\|_f\|u\|_c.$$

This proves the claimed positive lower bound for QG'^2Q^*.

The map $V = G'Q^*$ is injective, its Gram matrix is $V^*V = QG'^2Q^*$, and elementary linear algebra shows that

$$R = 1 - G'Q^*(QG'^2Q^*)^{-1}QG'$$

is the orthogonal projection onto $\ker(QG')$. This kernel equals $\mathcal{L}_\eta \ker Q$. Indeed, if $Qv = 0$ then $\mathcal{A}v = \mathcal{L}_\eta v$, so $QG'\mathcal{L}_\eta v = 0$. Conversely, if $QG'h = 0$, put $v = G'h$. Then $Qv = 0$ and $h = \mathcal{A}v = \mathcal{L}_\eta v$. The expression for R is therefore well defined with a uniformly invertible coarse Gram matrix. Every adjoint in this argument uses the physical inner products fixed above.

Translation to plain Euclidean coordinates. There is an equivalent convention with unweighted coordinate inner products, but the averaging matrix has to change. Let $S_f f = \eta^2 f$ on fine sites, $S_e a = \eta^2 a$ on fine bonds, and $S_c u = u$ on coarse sites. These maps are unitaries from the physical spaces just defined to the spaces with plain coordinate sums. The correctly conjugated averaging matrix is

$$\widetilde{Q} = S_c Q S_f^{-1},$$
$$(\widetilde{Q}v)(B) = \eta^2 \sum_{x\in B} v(x),$$
$$(\widetilde{Q}^*u)(x) = \eta^2 u(B).$$

Each row has m^4 entries of size $\eta^2 = m^{-2}$, so its squared Euclidean length is one. Rows have disjoint supports, proving $\widetilde{Q}\widetilde{Q}^* = 1$. The conjugated projection is $\widetilde{P} = \widetilde{Q}^*\widetilde{Q} = S_f P S_f^{-1}$. Because sites and bonds have the same physical weight, $S_e \mathrm{d}_\eta S_f^{-1}$ is the same physical difference matrix $\eta^{-1}(\mathrm{shift} - 1)$. Therefore the entire Poincaré estimate survives unitary conjugation with its exact constant.

In contrast, suppose that one retains the arithmetic mean matrix $\overline{Q}v = \eta^4 \sum_{x\in B} v(x)$ while using plain inner products on both lattices. Its plain adjoint is $(\overline{Q}^*u)(x) = \eta^4 u(B)$, and

$$\overline{Q}\overline{Q}^* = \eta^4 1,$$
$$P = \eta^{-4}\overline{Q}^*\overline{Q}.$$

Thus $\overline{Q}^*\overline{Q}$ itself is not the projection. For a nonzero constant fine function and $m > 1$, the expression $\|f - \overline{Q}^*\overline{Q}f\|^2$ is positive whereas $\mathrm{d}_\eta f = 0$. This gives an immediate check against accidentally combining the arithmetic mean with the wrong adjoint. Either the physical weighted convention or the conjugated unweighted convention is consistent; mixing them is not.

Consequences for cochains and Gaussian formulas. When a Gaussian curvature is first defined using the plain cochain inner product, its covariance is an orthogonal projection for that inner product. After changing to physical coordinates, transform the random vector and the covariance together. For a linear random vector F with covariance C in plain coordinates and a linear coordinate change T, the covariance of TF is TCT^*. An orthogonal projection is carried to an orthogonal projection when the coordinate change is interpreted as the unitary between the two specified Hilbert spaces;

an arbitrary rescaling of its coordinate entries without the corresponding inner product change has a different covariance.

For a Hilbert-space operator $B : H_1 \to H_2$, unitary changes of coordinates S_1, S_2 give

$$\widetilde{B} = S_2 B S_1^{-1},$$
$$\widetilde{B}^* = S_1 B^* S_2^{-1}.$$

In particular products, orthogonal projections, positive inverses and Moore–Penrose inverses commute with this conjugation. A conditional Gaussian covariance written as $C - CB^*(BCB^*)^+BC$ remains the same Hilbert-space operator after every factor is conjugated. This observation permits a proof to begin in plain finite cochain coordinates and then use physical block coordinates. The change must be announced before the first adjoint, constraint, or Poincaré estimate that uses the latter convention. Every discrete derivative must also say whether it is d_0 or d_η. These declarations prevent a missing power of the mesh from being hidden inside an adjoint symbol.

A.1.2. *A scalar block resolvent with uniform off-diagonal decay.* This finite-dimensional lemma supplies a scalar part of the propagator input. All distances are physical distances. The argument uses a relative form bound and a Neumann series; the exponentially conjugated operator is generally not self-adjoint.

Let a four-dimensional periodic lattice of spacing $\eta = 1/m$, $m \geq 1$, be partitioned into blocks of m^4 sites and physical side one. Its torus has an integer number of blocks in each direction. On site functions use $\langle u, v\rangle = \eta^4 \sum_x \overline{u_x} v_x$. On positively oriented fine bonds use the same weight. Put

$$(\mathrm{d}_\eta u)(x, x + \eta e_\mu) = \eta^{-1}(u_{x+\eta e_\mu} - u_x),$$
$$\mathcal{L}_\eta = \mathrm{d}_\eta^* \mathrm{d}_\eta.$$

The block mean Q takes the arithmetic mean of the m^4 fine values. Its coarse inner product is the unweighted sum, so Q^* embeds a coarse value as a constant on its block. Thus $P = Q^*Q$ is an orthogonal projection and its matrix entries, as an operator acting on coordinate vectors, are $P_{xy} = \eta^4$ when x, y are in the same block and zero otherwise.

Write dist_η for shortest-path distance on the periodic fine graph, with length η per bond. The distance includes wrapping paths. The diameter of a single block in this metric is at most 4. The block Poincaré inequality proves

$$A_\eta := \mathcal{L}_\eta + P \geq 1,$$
$$\|u\| \leq \|A_\eta^{1/2} u\|,$$
$$\|\mathrm{d}_\eta u\| \leq \|A_\eta^{1/2} u\|.$$

These statements also hold when $m = 1$, since then $P = 1$.

Proposition A.3 (A mesh-independent Combes–Thomas bound)**.** Let w be a real function with $|w_x - w_y| \leq \eta$ on every neighboring pair. For real t let M_t multiply by e^{tw_x} and set $A_t = M_t A_\eta M_t^{-1} = A_\eta + E_t$. There is a numerical constant C, independent of the mesh, volume and function w, such that, for $|t| \leq 1$,

$$\|A_\eta^{-1/2} E_t A_\eta^{-1/2}\| \leq C(|t| + t^2).$$

Consequently one may choose a fixed $t_0 > 0$, independent of those parameters, so that $\|A_t^{-1}\| \leq 2$ for $|t| \leq t_0$. For arbitrary nonempty sets of sites X, Y this gives

$$\|1_X A_\eta^{-1} 1_Y\| \le 2\exp[-t_0 \operatorname{dist}_\eta(X,Y)]. \qquad \blacksquare$$

Proof. Set $A = A_\eta$. First consider the contribution $E_t^{\mathcal{L}}$ from the Laplacian. On a positively oriented bond with endpoints x, y, put $\delta = w_x - w_y$, $a = e^{t\delta} - 1$ and $b = e^{-t\delta} - 1$. The diagonal entries of the conjugated edge Laplacian do not change. Its off-diagonal contribution to $\langle u, E_t^{\mathcal{L}} v\rangle$ is therefore

$$-\eta^4 \eta^{-2}(a\overline{u_x}v_y + b\overline{u_y}v_x).$$

The exact identity

$$a\overline{u_x}v_y + b\overline{u_y}v_x = a(\overline{u_x} - \overline{u_y})v_y + b\overline{u_y}(v_x - v_y) + (a+b)\overline{u_y}v_y$$

exposes a difference of u or v in the terms linear in t. Since $|\delta| \le \eta \le 1$ and $|t| \le 1$,

$$|a|, |b| \le e|t|\eta,$$
$$|a+b| = 2|\cosh(t\delta) - 1| \le et^2\eta^2.$$

Each vertex occurs as the head of at most four positively oriented bonds. Cauchy–Schwarz applied to the first term, summed over the bonds, consequently gives $2e|t|\|\mathrm{d}_\eta u\|\|v\|$. The second term is bounded by $2e|t|\|u\|\|\mathrm{d}_\eta v\|$. The last term is bounded by $4et^2\|u\|\|v\|$. In particular,

$$|\langle u, E_t^{\mathcal{L}} v\rangle| \le 2e|t|(\|\mathrm{d}_\eta u\|\|v\| + \|u\|\|\mathrm{d}_\eta v\|) + 4et^2\|u\|\|v\|.$$

The two powers of η^{-1} in the Laplacian have been canceled by the Lipschitz difference and the difference of a test vector. Estimating the off-diagonal matrix entries directly would miss this cancellation.

For the block term, the neighbor condition implies $|w_x - w_y| \le 4$ for sites in one block. Its conjugation error has entries

$$(E_t^P)_{xy} = \eta^4 1_{\{x,y \text{ in one block}\}}(e^{t(w_x - w_y)} - 1).$$

Their absolute row sums and column sums are at most $4e^4|t|$, because a block has m^4 sites and $m^4\eta^4 = 1$. The Schur test therefore yields $\|E_t^P\| \le 4e^4|t|$. The common site weight η^4 does not alter this Schur estimate. Using the two energy bounds preceding the proposition gives

$$|\langle u, E_t v\rangle| \le C(|t| + t^2)\|A^{1/2}u\|\|A^{1/2}v\|,$$

where, for example, $C = 8e + 4e^4$ suffices. Substitute $u = A^{-1/2}f$ and $v = A^{-1/2}g$ and take the supremum over unit vectors f, g. This proves the asserted relative operator bound.

Choose $t_0 = \min\{1, (4C)^{-1}\}$. Then $B_t = A^{-1/2}E_t A^{-1/2}$ has norm at most $1/2$ when $|t| \le t_0$. The exact factorization and its inverse are

$$A_t = A^{1/2}(1 + B_t)A^{1/2},$$
$$A_t^{-1} = A^{-1/2}(1 + B_t)^{-1}A^{-1/2}.$$

The Neumann series gives $\|(1+B_t)^{-1}\| \le 2$ and hence $\|A_t^{-1}\| \le 2$. This step requires no assertion that A_t is self-adjoint or ordered below by a positive scalar.

Finally take $w_x = \operatorname{dist}_\eta(x, Y)$ and $t = t_0$. The triangle inequality makes w admissible, and $w = 0$ on Y. If $D = \operatorname{dist}_\eta(X, Y)$, then $w \ge D$ on X. Similarity of the two inverses gives

$$1_X A^{-1} 1_Y = 1_X M_t^{-1} A_t^{-1} M_t 1_Y.$$

The rightmost multiplication is the identity on Y, while the norm of the leftmost multiplication is at most $e^{-t_0 D}$. Combining these statements with $\|A_t^{-1}\| \le 2$ proves the final estimate. □

The estimate concerns operator norms between sets in the weighted lattice Hilbert space. It does not assert a mesh-independent bound for a Green function kernel normalized relative to the physical counting measure $\eta^4 \sum_x$. Converting a coordinate matrix to that kernel introduces its own power of η. The scalar lemma likewise does not establish the non-Abelian vector-field or multiscale background estimates. Those require their additional gauge constraints and response bounds.
Dirichlet restrictions and the distance being estimated. The same estimate holds for a Dirichlet compression of this particular operator, with constants independent of the shape of the region. To state it without ambiguity, let D be any set of sites of the periodic fine lattice. Let H_D consist of the functions supported in D, with the inherited weighted inner product, and let $J_D : H_D \to H$ be extension by zero. Define

$$A_D = J_D^* A_\eta J_D.$$

In particular the block term is the compression of the *original* projection P. On a block intersected by the boundary it is not a new mean taken over just the surviving sites. Replacing it by that new mean would define a different operator and is not justified by this corollary.

For $u \in H_D$, the quadratic form is

$$\langle u, A_D u\rangle = \|\mathrm{d}_\eta J_D u\|^2 + \|Q J_D u\|_c^2 \ge \|u\|^2.$$

It controls the physical gradient of the zero extension, including boundary bonds. Restrict an admissible ambient weight w to D and conjugate by its exponential on H_D. Because multiplication by this exponential commutes with the site indicator 1_D, the new error form is exactly the restriction of E_t to zero-extended vectors. The estimates in the proof therefore give

$$\|A_D^{-1/2}(M_t A_D M_t^{-1} - A_D) A_D^{-1/2}\| \le C(|t| + t^2).$$

The same Neumann argument implies, for $X, Y \subset D$,

$$\|1_X A_D^{-1} 1_Y\| \le 2e^{-t_0 \,\mathrm{dist}_\eta(X,Y)}.$$

Here the distance is computed in the ambient periodic lattice. It may use a path outside D. No estimate in the possibly much larger intrinsic distance of a region with holes has been asserted.

For comparison with continuum notation, the shortest-path distance is the periodic physical Manhattan distance, and hence is no smaller than the periodic Euclidean distance. The displayed bound therefore implies the same bound with Euclidean distance in its exponent. One can alternatively take w to be Euclidean distance to Y directly, since its change across a fine bond is at most η. Both formulations concern physical distances; using the number of bonds without the factor η would incorrectly strengthen the assertion as the mesh is refined.

The calculation explains the uniform mechanism: the scalar energy controls one physical difference, the weight varies by only $O(t\eta)$ across an edge, and its genuinely quadratic error is $O(t^2\eta^2)$. The block projection has range at most one physical cell and row mass one. Consequently the conjugation cost depends on the dimension and physical block size, with no factor proportional to the number of fine sites in a block or the torus.

A.2. **Convergence of the polymer logarithm.** The small-field integration must produce activities satisfying a summability criterion. Once that estimate is available, the passage from activities to a local logarithm is a combinatorial theorem. We prove that theorem here, so its convergence mechanism is independent of the particular gauge-field coordinates. The estimate on the activities remains a separate analytic task.

A.2.1. *Finite polymer systems.* A finite polymer system consists of a finite set $\mathcal{P}$ and a symmetric incompatibility relation $\not\sim$ on it. Every polymer is incompatible with itself. Give each $X \in \mathcal{P}$ a complex activity z_X. A compatible family contains no two incompatible polymers. Its partition function is

$$Z(z) = \sum_{\substack{\mathcal{F}\subset\mathcal{P}\\ \mathcal{F}\text{ compatible}}} \prod_{X\in\mathcal{F}} z_X.$$

The empty family contributes one. There are no questions of convergence in this polynomial. The problem is to construct its logarithm and bound it in terms of local activities without a loss exponential in $|\mathcal{P}|$.

For a list $\mathbf{X} = (X_1, \dots, X_n)$, let $H(\mathbf{X})$ be the simple graph on the labeled vertices $1, \dots, n$ whose edges are the pairs with $X_i \not\sim X_j$. Repeated polymers are permitted in lists; their distinct vertices are adjacent by self-incompatibility. Define

$$\phi(\mathbf{X}) = \sum_{\substack{F\subset E(H(\mathbf{X}))\\ ([n],F)\text{ connected}}} (-1)^{|F|},$$

$$n \geq 2,$$

$$\phi(X_1) = 1.$$

If $H(\mathbf{X})$ is disconnected the sum is zero.

Lemma A.4 (The connected graph identity)**.** As a formal power series at $z = 0$,

$$\log Z(z) = \sum_{n\geq 1} \frac{1}{n!} \sum_{X_1,\dots,X_n\in\mathcal{P}} \phi(\mathbf{X}) \prod_{i=1}^{n} z_{X_i}. \qquad \blacksquare$$

Proof. The ordered-list expression for Z is

$$Z(z) = \sum_{n\geq 0} \frac{1}{n!} \sum_{\mathbf{X}\in\mathcal{P}^n} \prod_i z_{X_i} \prod_{i<j} (1 - \mathbf{1}_{\{X_i \not\sim X_j\}}).$$

The product is one on pairwise compatible lists and zero otherwise. Such lists contain no repetition, and their $n!$ orderings give exactly the original polynomial. Expand the product as a sum over edge sets. Each graph decomposes uniquely into its connected components. The weight factors over the components, including the activity at each vertex. Expanding the exponential of the proposed connected-graph series enumerates a partition of the labeled vertices into these components. The factor for ordering the components is canceled by the exponential's factorial, and the factorials within the components cancel their vertex orderings. This reconstructs the ordered-list expression coefficient by coefficient. Its constant term is one, so its formal logarithm is the connected series. $\square$

A.2.2. *The tree bound, including the cancellation.*

Lemma A.5 (A hard-core tree inequality)**.** For a finite simple graph H on $n \geq 1$ labeled vertices,

$$\left| \sum_{\substack{F \subset E(H) \\ ([n],F)\ \text{connected}}} (-1)^{|F|} \right| \leq \#\{\text{spanning trees of } H\}.$$

For $n = 1$ the empty tree is counted once. ■

Proof. Fix a total order of the edges of H. Call an edge e eligible for an edge set F if the endpoints of e can be joined by a path in F consisting only of edges smaller than e. This definition does not require $e \in F$. If at least one edge is eligible, choose the smallest eligible edge e and toggle its membership in F.

This is an involution. Eligibility of e depends only on edges smaller than e, which were not changed; the same holds for every smaller edge, so the smallest eligible edge stays the same. Toggling e preserves the connected components, because its endpoints already have a path using smaller edges. It reverses the parity of $|F|$. Thus all connected edge sets with an eligible edge cancel in pairs in the alternating sum.

A surviving edge set has no cycle: if it contained one, the largest edge of that cycle would be eligible. Consequently every surviving connected edge set is a spanning tree. Each contributes the same sign $(-1)^{n-1}$, and there can be no more survivors than spanning trees. This proves the bound. The same argument also proves that the alternating sum has sign $(-1)^{n-1}$ when it is nonzero. □

In particular,

$$|\phi(X_1, \ldots, X_n)| \leq \sum_{T\ \text{tree on}\ [n]} \prod_{\{i,j\} \in E(T)} \mathbf{1}_{\{X_i \not\sim X_j\}}.$$

The cancellation in this inequality is essential. Taking absolute values before summing over connected graphs would count all connected subgraphs, which need not admit the rooted-tree bound used next.

A.2.3. *The rooted-tree estimate.* Let $a_X \geq 0$ be real numbers and suppose

$$\sum_{Y : Y \not\sim X} |z_Y| e^{a_Y} \leq a_X \quad \text{for every } X \in \mathcal{P}. \tag{A.i}$$

This is the polymer criterion used here [KP86]. For a fixed root polymer X, let $\mathcal{T}_X$ be the total nonnegative weight of all rooted labeled trees, with the root fixed to have polymer X, every nonroot vertex of polymer Y carrying weight $|z_Y|$, and every edge requiring incompatibility of its endpoint polymers. A tree on m vertices has the factor $1/(m-1)!$ for the nonroot vertex labels.

One can define this sum without assuming its convergence. Start with $T_X^{(0)} = 1$ and set

$$T_X^{(h+1)} = \exp\left(\sum_{Y : Y \not\sim X} |z_Y| T_Y^{(h)} \right).$$

The quantity $T_X^{(h)}$ sums trees of height at most h. To see this, delete the root. Each child becomes the root of a tree of height at most $h-1$, and an unordered collection of r child trees contributes the factor $1/r!$ in the exponential. Expanding those exponentials and assigning the nonroot labels gives exactly $1/(m-1)!$: the multinomial coefficient for assigning labels to the child

subtrees cancels their factorials and the ordering of the r children. This also verifies the formula for every fixed degree before any infinite sum is taken.

The iterates increase with h. Moreover $T_X^{(h)} \le e^{a_X}$ for every h: this is true at $h = 0$, and the induction step is precisely eq. A.i. Monotone convergence proves

$$\mathcal{T}_X = \lim_{h\to\infty} T_X^{(h)} \le e^{a_X}. \tag{A.ii}$$

Proposition A.6 (Absolute convergence and a nonzero partition function)**.** Under eq. A.i the connected series converges absolutely and defines a number $L(z)$ with $e^{L(z)} = Z(z)$. In particular $Z(z) \neq 0$. For each root polymer X,

$$\sum_{n\ge1} \frac{1}{(n-1)!} \sum_{X_2,\dots,X_n} |\phi(X, X_2, \dots, X_n)| \prod_{i=2}^{n} |z_{X_i}| \le e^{a_X}.$$

Also $|L(z)| \le \sum_X |z_X| e^{a_X}$. If the criterion holds throughout a complex activity domain with a uniform majorant, the series converges locally normally there and gives the branch of $\log Z$ that equals zero at zero. ■

Proof. The tree inequality bounds the root series by $\mathcal{T}_X$, proving its estimate by eq. A.ii. Rooting each nonempty connected list at its first vertex bounds the absolute unrooted series by $\sum_X |z_X| e^{a_X}$: replacing $1/n!$ by $1/(n-1)!$ only enlarges it.

For $|t| < 1$ the same majorant applies to the activities tz_X, and the connected series is analytic in t there. Near zero its exponential is $Z(tz)$ by the formal identity and absolute convergence. The analytic identity theorem gives $e^{L(tz)} = Z(tz)$ on the entire unit disc. The absolute majorant is summable also at $|t| = 1$, so the connected series is continuous as t tends radially to one. Taking that limit proves $Z(z) = e^{L(z)} \neq 0$.

On a domain with a uniform summable majorant, the Weierstrass criterion gives normal convergence on smaller domains and hence holomorphy. The branch statement follows by agreement near zero and continuation within the connected component of that domain containing zero. This statement does not assert that an arbitrary disconnected activity domain has a single preferred logarithm. □

For a countable polymer set the same statements hold in a finite region whenever $\sum_X |z_X| e^{a_X} < \infty$ there, by exhaustion and the displayed absolute majorant. In an infinite lattice the total unrooted sum is generally extensive and infinite. The rooted bound remains meaningful if the incompatibility sums satisfy the criterion, and it is the form used to define local connected expansions. No finite infinite-volume partition function is asserted.

A.2.4. *Locality, weighted bounds, and analytic dependence.* If a polymer activity depends only on field variables in an enlargement of that polymer, each connected term depends only on the union of those enlargements. This is a direct consequence of its product formula. Extra exponential weights can be incorporated in the activity majorant before the criterion is checked. The root estimate then retains those weights. Holomorphic dependence on external fields or sources passes to the connected expansion on every domain where the same absolute majorant is valid.

The theorem does not prove that gauge-field fluctuation activities satisfy eq. A.i. In a multiscale application their majorant must already include the fluctuation covariance, the number of localization domains, source radii, boundary costs, and any required derivatives. Likewise, a tree bound for a small-field expansion does not by itself sum large-field histories. Stating the activity estimate separately keeps the proved combinatorial step from assuming its analytic conclusion.

A.3. **Correlations of the free curvature.** This section computes the noncoincident correlations of $\mathrm{tr}(F^2)$ for a free curvature in four Euclidean dimensions. The calculation fixes a normalization and proves the cycle identities used in the short-distance comparison. It does not identify an interacting lattice measure with this model. That comparison, including its error, remains a separate estimate.

A.3.1. *A Gaussian field defined without a pointwise potential.* Fix a positive number g and an integer $d_G \geq 1$; for the adjoint color space of SU(2), $d_G = 3$. Coordinates in $\mathbb{R}^4$ are denoted by $x_1, \ldots, x_4$. Our Fourier transform is

$$\widehat{f}(k) = \int_{\mathbb{R}^4} e^{-ik\cdot x} f(x)\, dx,$$

$$f(x) = (2\pi)^{-4} \int e^{ik\cdot x} \widehat{f}(k)\, dk.$$

Let G be the tempered distribution with Fourier transform $|k|^{-2}$. In four dimensions this multiplier is locally integrable at zero. Its inverse transform, away from zero, is

$$G(x) = \frac{1}{4\pi^2 |x|^2}.$$

One direct verification uses $|k|^{-2} = \int_0^\infty e^{-t|k|^2}\, dt$ and the product Gaussian integral. The inverse transform of $e^{-t|k|^2}$ is $(4\pi t)^{-2} e^{-|x|^2/(4t)}$. Integrating in t, with $u = |x|^2/(4t)$, gives $1/(4\pi^2|x|^2)$. The same identity holds as tempered distributions by Fubini: the integral $\int |\varphi(x)|\, |x|^{-2} dx$ is finite for every Schwartz function φ, controlling the absolute integral of the heat-kernel formula.

For real Schwartz functions define

$$(f, h)_G = (2\pi)^{-4} \int_{\mathbb{R}^4} \frac{\overline{\widehat{f}(k)} \widehat{h}(k)}{|k|^2}\, dk.$$

This is a positive real bilinear form. The integral is finite near zero because $\int_0^1 r^3 r^{-2} dr < \infty$, and is finite at infinity by Schwartz decay. Quotient by its null space and complete to a real Hilbert space $\mathcal{H}_G$. It is separable: the map $f \mapsto |k|^{-1} \widehat{f}(k)$ embeds it into a separable real form of $L^2(\mathbb{R}^4)$.

Choose an orthonormal basis (e_j) and independent real standard normal variables (N_j) on their countable product probability space. For $f \in \mathcal{H}_G$, the series

$$W(f) = \sum_j (f, e_j)_G N_j$$

converges in L^2 and defines a centered jointly Gaussian family with $\mathbb{E}[W(f)W(h)] = (f, h)_G$. Finite partial sums prove the covariance formula and joint Gaussianity; convergence of their characteristic functions proves it for the limit. Independent copies give families $A_\mu^a(f) = g W_\mu^a(f)$ for $1 \leq \mu \leq 4$, $1 \leq a \leq d_G$. Their covariance is

$$\mathbb{E}[A_\mu^a(f) A_\nu^b(h)] = g^2 \delta_{ab} \delta_{\mu\nu} (f, h)_G.$$

No value $A_\mu^a(x)$ at a point is used in this definition.

Define the curvature as the Gaussian distribution

$$F_{\mu\nu}^a(f) = -A_\nu^a(\partial_\mu f) + A_\mu^a(\partial_\nu f),$$

$$\mu < \nu.$$

There are six independent coordinate labels $P = (\mu, \nu)$, although the six curvature components need not be independent random variables. Differentiating the covariance as a distribution gives

$$\mathbb{E}[F^a_{\mu\nu}(x) F^b_{\rho\sigma}(y)] = g^2 \delta_{ab} K_{\mu\nu,\rho\sigma}(x - y),$$

where the notation on the left denotes a distributional kernel and

$$K_{\mu\nu,\rho\sigma}(x) = -\delta_{\nu\sigma}\partial_\mu\partial_\rho G(x) + \delta_{\nu\rho}\partial_\mu\partial_\sigma G(x) + \delta_{\mu\sigma}\partial_\nu\partial_\rho G(x) - \delta_{\mu\rho}\partial_\nu\partial_\sigma G(x).$$

The signs follow from differentiating one argument at x and the other at y: $\partial_{y_\rho} G(x - y) = -\partial_{x_\rho} G(x - y)$. At nonzero separation this is an ordinary smooth matrix-valued function.

A.3.2. *The six-dimensional curvature matrix.* Give $\Lambda^2\mathbb{R}^4$ the Euclidean inner product for which $(e_\mu \wedge e_\nu)_{\mu<\nu}$ is an orthonormal basis. Put $r = |x|$, $u = x/r$, and $R_u = I - 2u \otimes u$. This R_u is the orthogonal reflection normal to u. Write $\Lambda^2 R_u$ for its induced operator on two-forms.

Proposition A.7 (The curvature coefficient)**.** For $x \neq 0$,

$$K(x) = \frac{1}{\pi^2 r^4} \Lambda^2 R_u,$$
$$K(x)^{\mathsf{T}} K(x) = \frac{1}{\pi^4 r^8} I_6,$$
$$\operatorname{tr}(K(x)^{\mathsf{T}} K(x)) = \frac{6}{\pi^4 r^8}.$$ ■

Proof. Twice differentiating G gives

$$\partial_\mu\partial_\rho G(x) = \frac{1}{2\pi^2 r^4}(4u_\mu u_\rho - \delta_{\mu\rho}).$$

At $u = e_4$ this Hessian is diagonal with entries $(-1, -1, -1, 3)/(2\pi^2 r^4)$. Inserting it in the component formula for K shows that K is diagonal: it has eigenvalue $1/(\pi^2 r^4)$ on $e_1 \wedge e_2, e_1 \wedge e_3, e_2 \wedge e_3$, and eigenvalue $-1/(\pi^2 r^4)$ on $e_1 \wedge e_4, e_2 \wedge e_4, e_3 \wedge e_4$. This is exactly the action of $\Lambda^2 R_{e_4}$ times the stated scalar. Both the differentiated radial kernel and the claimed expression transform by conjugation under orthogonal changes of coordinates, proving the first identity for every u. Since $\Lambda^2 R_u$ is an orthogonal involution on a six-dimensional space, its squared norm matrix is I_6, giving the other two identities. □

Fix the standard orientation and let $J = *$ be the Hodge operator on two-forms. It satisfies $J^2 = I$. For an orthogonal map R,

$$J(\Lambda^2 R) = (\det R)(\Lambda^2 R)J.$$

To check the formula, use the defining identity $\alpha \wedge *\beta = \langle \alpha, \beta \rangle \, dx_1 \wedge \cdots \wedge dx_4$ and the fact that the top exterior power of R multiplies the oriented volume by $\det R$. Since $\det R_u = -1$, $JK(x) = -K(x)J$. Every product of an odd number of matrices $K(x_i)$ therefore anticommutes with J and has trace zero: conjugation by J preserves its trace while changing its sign.

A.3.3. *Regularized densities and connected cycle contractions.* Take a real smooth even function ρ supported in the unit ball with $\int \rho = 1$ and put $\rho_\varepsilon(x) = \varepsilon^{-4}\rho(x/\varepsilon)$. Smear every curvature component with its translate to define $F^a_{\varepsilon,P}(x)$. This is a Gaussian variable with a smooth covariance kernel. Its centered quadratic density is

$$q_\varepsilon(x) = \frac{1}{2}\sum_{a=1}^{d_G}\sum_{P=1}^{6}\big(F^a_{\varepsilon,P}(x)^2 - \mathbb{E}[F^a_{\varepsilon,P}(x)^2]\big).$$

On any compact set its covariance is continuous and bounded. The integral $q_\varepsilon(f) = \int f(x)q_\varepsilon(x)dx$ for compactly supported smooth f is defined by L^2 limits of Riemann sums. The continuous covariance makes those sums Cauchy. The Gaussian moment formula gives convergence of their moments of each fixed order as well: all the integrands are finite sums of products of bounded continuous covariances on a fixed compact set.

For clarity, first fix distinct points $x_1, \dots, x_n$ at a fixed ε. For one color let C_{ij} be the 6×6 covariance block of $F_\varepsilon(x_i)$ and $F_\varepsilon(x_j)$, including the factor g^2. Put $Z = \mathrm{diag}(z_1 I_6, \dots, z_n I_6)$ and let C be the full block covariance matrix. The Gaussian integral yields, near $z = 0$,

$$\log \mathbb{E}\exp\big(\textstyle\sum_i z_i q_\varepsilon(x_i)\big) = -\frac{d_G}{2}\log\det(I - CZ) - \frac{d_G}{2}\sum_i z_i \,\mathrm{tr}\, C_{ii}.$$

Here C is positive semidefinite; write the Gaussian vector as $C^{1/2}N$ and diagonalize the real symmetric quadratic form for small real z. The one-dimensional Gaussian integral proves the determinant identity there. Holomorphic continuation proves it in a complex neighborhood of zero. Sylvester's determinant identity identifies $\det(I - C^{1/2}ZC^{1/2})$ with $\det(I - CZ)$, including singular C.

The last term only subtracts the first cumulants. Expand the logarithm of the determinant by its convergent matrix power series. For $n \geq 2$ the joint cumulant is consequently

$$\kappa_n(q_\varepsilon(x_1), \dots, q_\varepsilon(x_n)) = \frac{d_G}{2n}\sum_{\sigma \in S_n}\mathrm{tr}\,\big(C_{\sigma(1)\sigma(2)}\cdots C_{\sigma(n)\sigma(1)}\big).$$

Indeed only the term of degree n in $\frac{d_G}{2}\sum_{m\geq 1}\mathrm{tr}((CZ)^m)/m$ contributes to the mixed derivative. Each permutation records the order of the n distinct vertices of the cycle. The factor $1/n$ removes its cyclic repetitions; the factor $1/2$ remains even when $n = 2$.

A.3.4. *The noncoincident limit and its consequences.* Let the test functions $f_1, \dots, f_n$ have pairwise disjoint compact supports, and let $d > 0$ be their minimum separation. The regularized off-diagonal kernel is $C_{ij} = g^2(K * \rho_\varepsilon * \rho_\varepsilon)(x_i - x_j)$. For $\varepsilon < d/4$ the convolution samples K only away from zero. It converges uniformly, with every fixed derivative, on the compact set of relevant differences. The cycle formula and ordinary dominated convergence therefore give a finite limit of the smeared connected correlations. Its kernel is

$$C_n(x_1, \dots, x_n) = \frac{d_G g^{2n}}{2n}\sum_{\sigma\in S_n}\mathrm{tr}\,\big(K(x_{\sigma(1)} - x_{\sigma(2)})\cdots K(x_{\sigma(n)} - x_{\sigma(1)})\big),$$
$$x_i \neq x_j.$$

This defines separated correlations. It does not assert convergence of $q_\varepsilon(f)$ in L^2 when the same test is used twice; coincidence singularities require a different distributional treatment.

Corollary A.8 (Two points, odd cycles, and a positive four-point kernel)**.** The limiting connected two-point kernel is

$$C_2(x,y) = \frac{3d_G g^4}{\pi^4 |x-y|^8}.$$

Every odd connected kernel C_n with $n \geq 3$ vanishes at noncoincident arguments. If four distinct points are collinear, then

$$C_4(x_1,x_2,x_3,x_4) = \frac{6d_G g^8}{\pi^8} \sum_{\text{three unoriented cycles } (i,j) \text{ in the cycle}} \prod |x_i - x_j|^{-4} > 0.$$

For four sufficiently small disjoint neighborhoods of such points the four-point kernel remains strictly positive throughout their product. ■□

Proof. For two points, the permutation formula is $d_G g^4 \operatorname{tr}(K(x-y)K(y-x))/2$. The kernel is even and symmetric, so the curvature coefficient proposition proves the stated value. For odd n, every trace in the cycle sum vanishes by the Hodge anticommutation identity. For collinear points all difference directions give the same reflection $R_u = R_{-u}$. The product of four curvature matrices is the positive scalar product of their radial factors times $(\Lambda^2 R_u)^4 = I$. Every trace is therefore six times that scalar. The 24 permutations divide into three unoriented cycles, each represented eight times, canceling the factor $2n = 8$. Positivity on small neighborhoods follows from continuity and the strictly positive value at the chosen configuration. □

For nonnegative nonzero separated tests this gives

$$C_2(f,h) = \frac{3d_G g^4}{\pi^4} \iint \frac{f(x)h(y)}{|x-y|^8}\,dx\,dy > 0.$$

Thus the coefficient $3(N^2-1)/\pi^4$ used for SU(N) is the exact free coefficient in this normalization. For SU(2) it is $9/\pi^4$. Recovering this coefficient from the interacting lattice theory still requires its ultraviolet comparison and uniform remainder estimate. The four-point calculation also shows why non-Gaussianity of the scalar density alone cannot certify an interacting underlying gauge theory: this density already has a positive connected four-point kernel in an explicitly Gaussian model.

A.4. **The free lattice curvature comparison.** This section proves a free-field input of the construction. The covariance of a Gaussian exact lattice two-form is an orthogonal projection. After multiplication by the physical factor a^{-4}, its entries converge away from coincidence to the continuum curvature kernel. We prove an error estimate uniform in the lattice spacing and the torus side, and compute the resulting separated quadratic-density coefficient. No interacting measure is compared with this Gaussian model here.

A.4.1. *Cochains, Fourier conventions, and the statement.* Let $a > 0$, $\ell > 0$, and $N = \ell/a \in \mathbb{N}$. The lattice is $\Lambda_{a,\ell} = a\mathbb{Z}^4/\ell\mathbb{Z}^4$. A one-form has coordinates $A_\mu(x)$, one per positive bond based at x. A two-form has coordinates $F_{\mu\nu}(x)$ for $\mu < \nu$, based at the lower vertex of its positively oriented plaquette. Both cochain spaces use the plain coordinate inner products. Define

$$(\mathrm{d}_1 A)_{\mu\nu}(x) = a^{-1}\{A_\nu(x+ae_\mu) - A_\nu(x) - A_\mu(x+ae_\nu) + A_\mu(x)\}.$$

The factor a^{-1} does not affect the range. Let P_{ex} be the orthogonal projection onto $\operatorname{Ran}\mathrm{d}_1$. It is the covariance of a centered Gaussian vector which is standard on that subspace. Potential gauge directions need not be inverted to define this curvature covariance. The constant two-forms are excluded because they are not in $\operatorname{Ran}\mathrm{d}_1$.

Write $P = (\mu,\nu)$, $\mu < \nu$, and put $c_P = (e_\mu + e_\nu)/2$. The centre of the plaquette (x,P) is $x + ac_P$. The physical lattice kernel is

$$\mathsf{K}_{a,\ell}^{PQ}(x,y) = a^{-4} P_{\mathrm{ex}}((x,P),(y,Q)).$$

For a displacement on the torus, its length means distance to $\ell\mathbb{Z}^4$. Representatives are chosen in $[-\ell/2,\ell/2]^4$ when needed.

The continuum Fourier transform on $\mathbb{R}^4$ is

$$\widehat{f}(k) = \int e^{-ik\cdot x} f(x)\,dx,$$

$$f(x) = (2\pi)^{-4} \int e^{ik\cdot x} \widehat{f}(k)\,dk.$$

Let $G(x) = 1/(4\pi^2|x|^2)$ and define the continuum curvature distribution by

$$\begin{aligned}\mathsf{K}_{\mu\nu,\rho\sigma}(x) = &-\delta_{\nu\sigma}\partial_\mu\partial_\rho G(x) + \delta_{\nu\rho}\partial_\mu\partial_\sigma G(x)\\ &+ \delta_{\mu\sigma}\partial_\nu\partial_\rho G(x) - \delta_{\mu\rho}\partial_\nu\partial_\sigma G(x).\end{aligned}$$

At $x \neq 0$ this is an ordinary smooth matrix. Its contact terms at zero are retained in its Fourier definition and are not squared in the statements below.

Proposition A.9 (Free lattice curvature comparison)**.** There is a numerical constant C such that, for every a, ℓ as above and every pair of plaquettes with centre displacement

$$u = x - y + a(c_P - c_Q),$$

$$10a \le r = \mathrm{dist}(u, \ell\mathbb{Z}^4) \le \ell/10,$$

one has

$$\left|\mathsf{K}_{a,\ell}^{PQ}(x,y) - \mathsf{K}_{PQ}(u)\right| \le C r^{-4}\left\{(a/r)^{1/2} + (r/\ell)^4\right\}. \tag{A.iii}$$

The continuum kernel on the right is evaluated at the short representative of u. The constants do not depend on the orientation labels, the lattice spacing, the number of sites, or the torus side. ■

The exponent $1/2$ is sufficient for convergence and is not claimed optimal. Keeping the barycentre phases in a sharper symbol expansion can improve the lattice power. The proof here deliberately keeps a periodic raw symbol and moves to barycentres only after the Fourier estimate.

A.4.2. *The exact projection symbol.* The torus frequencies are $k \in \delta\mathbb{Z}^4$, where $\delta = 2\pi/\ell$. Choose one Brillouin representative of each frequency modulo $(2\pi/a)\mathbb{Z}^4$ and denote this set by $\mathcal{Q}_a$. Its coordinates lie between $-\pi/a$ and π/a, with one endpoint omitted when necessary. Define

$$t_{a,\mu}(k) = a^{-1}(e^{iak_\mu} - 1),$$

$$\omega_a(k) = \sum_\mu |t_{a,\mu}(k)|^2 = 4a^{-2}\sum_\mu \sin^2(ak_\mu/2).$$

Let $B_a(k) : \mathbb{C}^4 \to \Lambda^2\mathbb{C}^4$ be

$$(B_a(k)v)_{\mu\nu} = t_{a,\mu}(k)v_\nu - t_{a,\nu}(k)v_\mu.$$

This is exactly the Fourier symbol of d_1. Direct multiplication gives

$$B_a^* B_a = \omega_a I - t_a t_a^*,$$

$$B_a t_a = 0.$$

Consequently $(B_aB_a^*)^2 = \omega_a B_aB_a^*$. For $k \neq 0$ in the Brillouin zone,

$$P_a(k) = B_a(k)B_a(k)^*/\omega_a(k)$$

is the orthogonal projection onto $\operatorname{Ran} B_a(k)$. Set $P_a(0) = 0$. Thus $\|P_a(k)\| \leq 1$ and its rank at nonzero frequency is three. At frequency zero the exact-form subspace is zero.

The unitary finite Fourier transform and its inverse are

$$\widehat{F}(k) = N^{-2} \sum_{x \in \Lambda_{a,\ell}} e^{-ik\cdot x} F(x),$$

$$F(x) = N^{-2} \sum_{k \in \mathcal{Q}_a} e^{ik\cdot x} \widehat{F}(k).$$

Therefore

$$a^{-4} P_{\mathrm{ex}}((x,P),(y,Q)) = \ell^{-4} \sum_{k \in \mathcal{Q}_a} e^{ik\cdot(x-y)} [P_a(k)]_{PQ}. \tag{A.iv}$$

Indeed the projection entry before multiplication by a^{-4} has prefactor N^{-4}, and $a^{-4}N^{-4} = \ell^{-4}$.

For the continuum symbol replace t_a by $t_0(k) = ik$. Put

$$P_0(k) = B_0(k)B_0(k)^*/|k|^2$$

$$(k \neq 0),$$

$$P_0(0) = 0.$$

It is again a norm-one rank-three projection. With the specified Fourier convention its inverse transform is precisely the distribution K defined above. On the torus define the distribution

$$\mathsf{K}_\ell(z) = \ell^{-4} \sum_{k \in \delta\mathbb{Z}^4} e^{ik\cdot z} P_0(k). \tag{A.v}$$

The bounded Fourier coefficients define a periodic distribution. Below we show that it is smooth away from the origin and identify its finite-volume correction.

A.4.3. *Uniform derivative and counting estimates.* For each multi-index α there is a constant C_α such that, in the Brillouin zone away from zero,

$$\|\partial^\alpha P_a(k)\| \leq C_\alpha |k|^{-|\alpha|}. \tag{A.vi}$$

The same estimate holds for P_0. To prove it, use $2|\sin(t/2)| \geq 2|t|/\pi$ for $|t| \leq \pi$. Hence $c|k|^2 \leq \omega_a(k) \leq |k|^2$ throughout the Brillouin zone. Differentiating the exponential gives $|\partial^\alpha t_a(k)| \leq C_\alpha |k|^{1-|\alpha|}$; for positive derivative order this uses $a|k| \leq 2\pi$. The product rule gives the analogous bounds of order $2 - |\alpha|$ for ω_a and $B_aB_a^*$. Induction in the identity $\omega_a\omega_a^{-1} = 1$ bounds derivatives of the reciprocal. The quotient rule proves eq. A.vi. All functions involved are periodic; near a Brillouin face the same bounds hold in periodic coordinates, where $|k|$ is comparable to a^{-1}.

For $a|k| \leq c_0$, with a fixed small $c_0 > 0$, Taylor's formula gives $t_a(k) = ik + O(a|k|^2)$. The preceding denominator bounds imply

$$\|P_a(k) - P_0(k)\| \leq Ca|k|. \tag{A.vii}$$

For example, the numerator difference is $O(a|k|^3)$ and the denominator difference is $O(a|k|^3)$, while both denominators are comparable to $|k|^2$. Both symbols have been assigned zero at $k = 0$, so that frequency contributes no error.

We will use two elementary grid bounds. If $R \geq C\delta$ and $M > 4$, then

$$\ell^{-4} \#\{k \in \delta\mathbb{Z}^4 : |k| \leq 2R\} \leq CR^4, \tag{A.viii}$$

$$\ell^{-4} \sum_{k \in \delta \mathbb{Z}^4} (R + |k|)^{-M} \leq C_M R^{4-M}. \tag{A.ix}$$

For a proof, place a cube of side δ about each grid point. The cubes are disjoint up to boundaries. If $R \geq C\delta$, the values of $R + |k|$ and $R + |q|$ on such a cube differ by bounded factors. The second sum is bounded by a constant times $(2\pi)^{-4} \int (R + |q|)^{-M} dq$, which is $C_M R^{4-M}$ after scaling. The first bound follows by enclosing the cubes in a ball of radius $3R$.

A.4.4. *Summation by parts on the frequency grid.* Fix a smooth cutoff χ equal to one on $|k| \leq 1$ and zero on $|k| \geq 2$. Suppose

$$R \geq 2M\delta,$$
$$2R < \pi/(2a).$$

Extend $\chi(k/R)$ periodically on the frequency torus of side $2\pi/a$. It is smooth because its support stays away from the Brillouin faces. The high-frequency lattice symbol

$$H_a(k) = (1 - \chi(k/R)) P_a(k)$$

is smooth on that frequency torus, including at zero. Write

$$\rho_a(k) = \mathrm{dist}(k, (2\pi/a)\mathbb{Z}^4).$$

The derivative estimates and the cutoff product rule give

$$\|\partial_\mu^M H_a(k)\| \leq C_M (R + \rho_a(k))^{-M}.$$

Let $\Delta_\mu H(k) = H(k + \delta e_\mu) - H(k)$. The iterated fundamental theorem of calculus yields

$$\Delta_\mu^M H(k) = \delta^M \int_{[0,1]^M} \partial_\mu^M H(k + \delta(t_1 + \cdots + t_M) e_\mu)\, dt.$$

The torus distance ρ_a changes by at most $M\delta$ along this segment. Since $R \geq 2M\delta$, $R + \rho_a$ remains comparable to its value at k. Thus

$$\|\Delta_\mu^M H_a(k)\| \leq C_M \delta^M (R + \rho_a(k))^{-M}. \tag{A.x}$$

Now let $z \in a\mathbb{Z}^4/\ell\mathbb{Z}^4$, $z \neq 0$, and choose a short representative. Its length r_z is at most ℓ, and some coordinate satisfies $|z_\mu| \geq r_z/2$. On $|z_\mu| \leq \ell/2$,

$$|e^{-i\delta z_\mu} - 1| = 2|\sin(\pi z_\mu/\ell)| \geq 4|z_\mu|/\ell \geq 2r_z/\ell.$$

The phase $e^{ik\cdot z}$ is periodic on the frequency grid because z/a is integral. Finite summation by parts therefore gives the exact identity

$$(e^{-i\delta z_\mu} - 1)^M \sum_{k \in \mathcal{Q}_a} e^{ik\cdot z} H_a(k) = \sum_{k \in \mathcal{Q}_a} e^{ik\cdot z} \Delta_\mu^M H_a(k).$$

There is no Brillouin boundary term. Apply eq. A.x and eq. A.ix, using $\rho_a(k) = |k|$ on the chosen representatives. The result is

$$\left\| \ell^{-4} \sum_{k \in \mathcal{Q}_a} e^{ik\cdot z} H_a(k) \right\| \leq C_M r_z^{-M} R^{4-M}. \tag{A.xi}$$

The powers of the torus side cancel: the inverse difference factor contributes $(\ell/r_z)^M$ and the frequency difference contributes $\delta^M = (2\pi/\ell)^M$.

The continuum torus tail obeys the same estimate. Here $H_0(k) = (1 - \chi(k/R))P_0(k)$ on the infinite reciprocal grid. Its derivatives satisfy the same bounds with $|k|$ in place of ρ_a. The Mth differences are absolutely summable for $M > 4$. Multiplication of a Fourier distribution by $(e^{-i\delta z_\mu} - 1)^M$ shifts its Fourier coefficients and hence gives the same identity distributionally. The right side is an absolutely convergent continuous Fourier series. On the open set where the multiplying factor is nonzero, division by that smooth factor identifies the tail with an ordinary continuous function and proves

$$\|\mathsf{K}_\ell^{\mathrm{high}}(z)\| \le C_M r_z^{-M} R^{4-M}. \tag{A.xii}$$

This distributional argument avoids assuming convergence of an undifferentiated order-zero Fourier series.

A.4.5. *Comparison with the continuum torus kernel.* On the common low-frequency support, the finite and infinite reciprocal grids agree. eq. A.vii and eq. A.viii give

$$\left\| \ell^{-4} \sum_k e^{ik\cdot z} \chi(k/R)(P_a(k) - P_0(k)) \right\| \le CaR^5.$$

Combining this with the two high-frequency bounds yields, for $M > 4$,

$$\|\mathsf{K}_{a,\ell}^{\mathrm{raw}}(z) - \mathsf{K}_\ell(z)\| \le C_M\{aR^5 + r_z^{-M} R^{4-M}\}. \tag{A.xiii}$$

Here $\mathsf{K}_{a,\ell}^{\mathrm{raw}}$ is the matrix Fourier sum in eq. A.iv at the common plaquette-origin displacement z.

Take $M = 9$ and choose

$$R = \frac{D}{r_z}(r_z/a)^{1/10},$$

where D is a fixed sufficiently large numerical constant. Because $r_z \le \ell$, this ensures $R \ge 18\delta$. For r_z/a larger than a fixed numerical threshold C_0, it also ensures $2aR < c_0$ and $2R < \pi/(2a)$. Both terms in eq. A.xiii are then at most a constant times

$$r_z^{-4}(a/r_z)^{1/2}.$$

Indeed $aR^5 = D^5 r_z^{-4}(a/r_z)^{1/2}$ and $r_z^{-9}R^{-5} = D^{-5}r_z^{-4}(a/r_z)^{1/2}$.

For $1 \le r_z/a \le C_0$, the lattice Fourier sum has norm at most a^{-4} because $\|P_a\| \le 1$. The continuum bound $\|\mathsf{K}_\ell(z)\| \le Cr_z^{-4}$, established in the next section, shows that their difference is at most $C'a^{-4}$. Increasing the numerical constant by a factor depending only on C_0 bounds this by $Cr_z^{-4}(a/r_z)^{1/2}$. Consequently, for every nonzero raw lattice displacement,

$$\|\mathsf{K}_{a,\ell}^{\mathrm{raw}}(z) - \mathsf{K}_\ell(z)\| \le Cr_z^{-4}(a/r_z)^{1/2}. \tag{A.xiv}$$

All thresholds used here are fixed numbers. They impose no relation between the physical volume and the ultraviolet cutoff beyond $\ell/a \in \mathbb{N}$.

A.4.6. *The finite-volume correction and contact terms.* The continuum torus heat kernel is

$$p_t^\ell(x) = \sum_{m\in\mathbb{Z}^4} (4\pi t)^{-2} e^{-|x+m\ell|^2/(4t)} = \ell^{-4} \sum_{k\in\delta\mathbb{Z}^4} e^{-t|k|^2} e^{ik\cdot x}.$$

For completeness, the first expression is an absolutely convergent periodic sum for $t > 0$. Its Fourier coefficient at k is the ordinary Gaussian Fourier integral $\ell^{-4}e^{-t|k|^2}$, which proves the second expression. Define the mean-zero torus Green distribution by

$$G_\ell(x) = \int_0^\infty (p_t^\ell(x) - \ell^{-4})\, dt.$$

Its nonzero Fourier coefficient is $\ell^{-4}|k|^{-2}$ and its zero coefficient is zero. Applying the same second-derivative combination as in the definition of K gives eq. A.v.

We record the uniform local correction. At $\ell = 1$ and $|x| \le 1/4$,

$$\begin{aligned} G_1(x) - G(x) = &\int_0^1 \sum_{m\neq 0} (4\pi t)^{-2} e^{-|x+m|^2/(4t)}\, dt - 1 \\ &+ \int_1^\infty (p_t^1(x) - 1)\, dt - \int_1^\infty (4\pi t)^{-2} e^{-|x|^2/(4t)}\, dt. \end{aligned}$$

Every fixed derivative of the first integral is uniformly bounded: differentiating a Gaussian gives a polynomial times a Gaussian, while $|x+m| \ge c|m|$ and $\sum_{m\neq 0} e^{-c|m|^2/t} \le Ce^{-c'/t}$ for $0 < t \le 1$. The resulting power of t^{-1} is integrable against this last exponential. For the second integral, its differentiated Fourier series is bounded by a constant times e^{-ct} for $t \ge 1$. Derivatives of the last integral are bounded by $C_\alpha t^{-2-|\alpha|/2}$ on this ball and are integrable. Thus $G_1 - G$ extends smoothly across zero with bounded derivatives of every fixed order.

Scaling gives $G_\ell(x) = \ell^{-2} G_1(x/\ell)$ and the corresponding homogeneity for G. In particular,

$$\|\mathsf{K}_\ell(z) - \mathsf{K}(z)\| \le C\ell^{-4} \quad (0 < |z| \le \ell/4). \tag{A.xv}$$

The same argument gives an extra factor ℓ^{-1} for each additional derivative of the difference. On the remainder of the unit torus, away from zero, the heat-kernel formula and its derivatives converge uniformly on compact sets. Scaling and compactness therefore also give the global bounds

$$\|\partial^\alpha \mathsf{K}_\ell(z)\| \le C_\alpha r_z^{-4-|\alpha|},$$
$$z \neq 0.$$

These justify the estimate used in the bounded r_z/a regime above.

All these statements concern the kernels away from coincidence. The symbols have not discarded their order-zero distributional terms. For example, the trace of $P_0(k)$ is three for $k \neq 0$. Accordingly the trace of the torus kernel as a distribution is $3(\delta_{\mathrm{per}} - \ell^{-4})$; away from zero it is $-3\ell^{-4}$. The trace of the free noncoincident kernel is zero. This is consistent with eq. A.xv; it would be inconsistent to replace the full distribution by its noncoincident formula before taking Fourier coefficients.

A.4.7. *Moving to barycentres and proving the theorem.* Let u be the centre displacement in eq. A.iii and let $z = u - a(c_P - c_Q)$ be its raw-origin displacement. The shift has length at most a. Choose representatives so $|u| = r \le \ell/10$ and $|z - u| \le a$. Then

$$0.9r \le |z| \le 1.1r < \ell/4.$$

Use eq. A.xiv for the raw kernel and eq. A.xv for the continuum torus kernel at z. The free kernel is homogeneous of degree -4 and smooth away from zero, so $\|\nabla \mathsf{K}(v)\| \le C|v|^{-5}$. The segment from z to u stays at distance at least $0.9r$ from zero. Hence

$$|\mathsf{K}_{PQ}(z) - \mathsf{K}_{PQ}(u)| \le Car^{-5}.$$

Combining the three differences proves

$$|\mathsf{K}_{a,\ell}^{PQ}(x,y) - \mathsf{K}_{PQ}(u)| \le C\{r^{-4}(a/r)^{1/2} + \ell^{-4} + ar^{-5}\}.$$

Since $a/r \le 1$, the last term is absorbed by the first, and $\ell^{-4} = r^{-4}(r/\ell)^4$. This proves eq. A.iii.

The argument also proves convergence to K_ℓ uniformly on any fixed separated subset of the torus, when plaquette centres are used in both arguments. In this statement use the global derivative bound for K_ℓ to move from origins to centres. No assumption that a chosen separation is small relative to ℓ is needed for this fixed-torus convergence.

A.4.8. *The separated quadratic-density coefficient.* Let ξ_p^b, $1 \le b \le d_G$, be independent color copies of the Gaussian exact two-form, each with covariance $g^2 P_{\mathrm{ex}}$. For a test f on the torus define the finite-dimensional centered density

$$Q_a(f) = \frac{1}{2}\sum_{b=1}^{d_G}\sum_p f(x_p)\{(\xi_p^b)^2 - \mathbb{E}(\xi_p^b)^2\}.$$

Here x_p is the plaquette barycentre. Equivalently, $a^{-2}\xi_p^b$ is the physical curvature and the displayed sum includes its a^4 Riemann weight. For two tests of positive mutual separation, the Gaussian identity $\mathrm{Cov}(X^2, Y^2) = 2\,\mathrm{Cov}(X,Y)^2$ gives

$$\mathrm{Cov}(Q_a(f), Q_a(h)) = \frac{d_G g^4}{2}\, a^8 \sum_{p,q} f(x_p)h(x_q)\,|\mathsf{K}_{a,\ell}(p,q)|^2.$$

For real kernels the square here is the ordinary real square of the scalar entry. The uniform separated convergence just proved, followed by ordinary shifted-grid Riemann sums, gives

$$\lim_{a\downarrow 0}\mathrm{Cov}(Q_a(f), Q_a(h)) = \frac{d_G g^4}{2}\iint f(x)h(y)\sum_{P,Q}\mathsf{K}_{\ell,PQ}(x-y)^2\,dx\,dy.$$

For continuous compactly supported separated tests the Riemann-sum integrand is continuous after setting it to zero in a neighbourhood of the diagonal; for C^1 tests it is C^1 there. There is therefore no use of an integral of $|x-y|^{-8}$ through coincidence.

Now keep the tests in a fixed compact subset of $\mathbb{R}^4$ and let $\ell \to \infty$. The correction estimate makes $\mathsf{K}_\ell \to \mathsf{K}$ uniformly on the relevant separated differences. Direct differentiation of G shows

$$\mathsf{K}(x) = \frac{1}{\pi^2|x|^4}\Lambda^2(I - 2\widehat{x}\otimes\widehat{x}).$$

One can check the coefficient at $\widehat{x} = e_4$: the six eigenvalues are three copies of $1/(\pi^2|x|^4)$ and three copies of its negative. Orthogonal covariance proves the identity in every direction. The induced two-form reflection is orthogonal, and therefore

$$\sum_{P,Q}\mathsf{K}_{PQ}(x)^2 = \frac{6}{\pi^4|x|^8}.$$

It follows that the infinite-volume separated covariance is exactly

$$\frac{3d_G g^4}{\pi^4}\iint f(x)h(y)|x-y|^{-8}\,dx\,dy. \tag{A.xvi}$$

For SU(2), $d_G = 3$, so the coefficient is $9g^4/\pi^4$ in this convention. Higher separated Gaussian cumulants can likewise be passed through their finite cycle formulas using the same kernel convergence.

There is also a relative finite-volume statement for nonnegative pairs. Suppose every cross-distance between the supports lies between d and $C_{\mathrm{sh}}d$, and $C_{\mathrm{sh}}d \le \ell/10$. The correction estimate and the Frobenius norm of the free kernel give pointwise

$$\left|\sum_{P,Q}\mathsf{K}_{\ell,PQ}(v)^2-\frac{6}{\pi^4|v|^8}\right|\le C\left(\frac{|v|}{\ell}\right)^4|v|^{-8}.$$

Indeed the difference of the squares is bounded by $C|v|^{-4}\ell^{-4}+C\ell^{-8}$. Multiplication by $f(x)h(y)\ge 0$ and integration show that the limiting torus covariance differs from eq. A.xvi by a relative error at most $C'_{\mathrm{sh}}(d/\ell)^4$, provided both tests are nonzero. The mesh error tends to zero for each such fixed test pair by the uniform kernel estimate and the Riemann-sum argument above. A rate relative to a varying family of tests would require their norms and nondegeneracy to be specified.

This proves the free covariance comparison and the free density coefficient. It asserts neither an L^2 limit of $Q_a(f)$ with the same test repeated nor an interacting short-distance asymptotic. Establishing the latter requires a comparison of the interacting measure with this Gaussian model and a remainder smaller than the leading term.

A.5. **Link reflections of periodic Gibbs states.** This section concerns one fixed lattice and one fixed positive coupling. No continuum limit or renormalization estimate is used. The conclusion quantifies over every periodic DLR state. In particular, the state is not assumed to arise as a limit of torus measures. The finite-dimensional transfer calculation below, together with a local elimination identity, is what permits that quantifier.

Set the lattice spacing equal to one, let $G=\mathrm{SU}(2)$, and use normalized Haar measure. On one orientation of the bonds of $\mathbb{Z}^4$ assign variables $U_b\in G$; reverse orientation means $U_{\bar b}=U_b^{-1}$. For an elementary plaquette set

$$a_p=1-\tfrac12\,\mathrm{tr}\,U_p,$$
$$0\le a_p\le 2.$$

The trace is real for $G=\mathrm{SU}(2)$. Fix $\beta>0$. A DLR state is a probability measure whose conditional law on any finite bond set D, given all other bonds, has density proportional to $\exp[-\beta\sum_{p:p\cap D\neq\varnothing}a_p]$. A state is periodic when it is invariant under a subgroup of finite index of $\mathbb{Z}^4$. A link reflection is reflection in a plane $\{x_\mu=i+\frac12\}$, with $i\in\mathbb{Z}$.

Proposition A.10 (Link symmetry of every periodic Wilson state)**.** Every periodic DLR state of the four-dimensional SU(2) Wilson interaction at $\beta>0$ is invariant under every link reflection. Consequently every such state is invariant under $2\mathbb{Z}^4$. ∎

The proof uses positivity and strict positivity of different objects. The one-bond convolution operator is positive as an operator, with strictly positive Peter–Weyl eigenvalues. Its original kernel is strictly positive pointwise. An auxiliary operator inserted between two half-kernels will be a contraction, and need not be self-adjoint or positive. Confusing these conditions would invalidate the variational step.

A lower tangent valid for an arbitrary periodic state. Let ϕ be a real continuous local observable and let $m\mathbb{Z}^4$ be a subgroup of periods of a DLR state ν. For torus sides s divisible by m, write

$$W_s=\sum_{v\in m\mathbb{Z}^4/s\mathbb{Z}^4}\tau_v\phi,$$
$$Z_s(\phi)=\int e^{W_s-\beta\sum_p a_p}\,dU.$$

Here local observables are evaluated on the periodic extension of the torus configuration. Suppose

$$Z_s(\phi) \le Z_s(0)$$
$$\text{for all sufficiently large multiples } s \text{ of } m. \tag{A.xvii}$$

Then

$$\nu(\phi) \le 0. \tag{A.xviii}$$

To prove this implication, take a cube D_s of sites of side s, and let B_s be the positively oriented bonds whose initial sites belong to the cube. Choose the representatives of the source anchors inside D_s, and denote their sum, evaluated with an arbitrary outside configuration, by $\widetilde{W}_s$. This is a finite local function; terms near the boundary can involve outside bonds. The number of anchors is exactly $M_s = (s/m)^4$. The DLR equation and Jensen's inequality give

$$\log \gamma_{B_s}(e^{\widetilde{W}_s})(U') \ge \gamma_{B_s}(\widetilde{W}_s)(U').$$

The conditional partition-function ratio on the left can be compared with $Z_s(\phi)/Z_s(0)$ uniformly in U'. Interior terms are identical under the identification of B_s with the torus bond coordinates. Only plaquettes and translates of ϕ in a fixed-width boundary layer can differ. Their number is at most $C_{\phi,m}s^3$, and each difference is bounded by $C(\beta + \|\phi\|_\infty)$. Thus

$$\log \frac{Z_s(\phi)}{Z_s(0)} \ge \nu(\widetilde{W}_s) - C_{\phi,m,\beta}s^3 = M_s\nu(\phi) - C_{\phi,m,\beta}s^3.$$

In the first inequality we integrated the conditional inequality against ν and used the DLR equation. The equality uses only $m\mathbb{Z}^4$ invariance. Divide by M_s and let $s \to \infty$ through multiples of m. The assumption in eq. A.xvii proves eq. A.xviii.

This argument needs neither differentiability of an infinite-volume pressure nor representation of ν by finite torus measures. The local source is fixed during the limit $s \to \infty$. If the source later depends on a parameter tending to zero, that parameter is kept fixed until the surface error has disappeared. Constant parts of ϕ cause no difficulty with the anchored definition of $\widetilde{W}_s$: they occur with exactly the same multiplicity in the box and torus source sums.

The one-bond convolution and its smooth conjugations. Define

$$c(g) = e^{-\beta(1-\frac{1}{2}\operatorname{tr} g)},$$
$$(CF)(w) = \int_G c(wv^{-1})F(v)\,dv.$$

The kernel is real, symmetric, and bounded below by $e^{-2\beta}$. Let Π_l be the Peter–Weyl projection corresponding to the irreducible representation of spin $l \in \frac{1}{2}\mathbb{N}_0$ and dimension $d_l = 2l + 1$. Schur's lemma and the Weyl integration formula give

$$C = \sum_l c_l \Pi_l,$$
$$c_l = \frac{2e^{-\beta}}{\beta} I_{2l+1}(\beta) > 0. \tag{A.xix}$$

For completeness, write g with eigenvalues e^{it}, e^{-it} and use $\chi_l(g) = \sin((2l+1)t)/\sin t$. The character coefficient is

$$d_l c_l = \frac{2e^{-\beta}}{\pi}\int_0^\pi e^{\beta\cos t}\sin t\sin(d_l t)\,dt = e^{-\beta}(I_{2l}-I_{2l+2})(\beta).$$

The Bessel recurrence gives eq. A.xix. Its series

$$I_n(\beta)=\sum_{k\ge 0}\frac{(\beta/2)^{n+2k}}{k!(n+k)!}$$

has positive terms and implies factorial decay in n. Moreover,

$$\frac{I_{n+1}}{I_n}\le\frac{\beta}{2(n+1)},$$
$$\frac{I_n}{I_{n+1}}=\frac{2(n+1)}{\beta}+\frac{I_{n+2}}{I_{n+1}}\le C_\beta(1+n). \tag{A.xx}$$

Consequently both ratios between neighboring c_l grow at most polynomially in l. Factorial decay also shows that C is trace class and that $C^{1/2}$ has a real symmetric smooth kernel.

For a finite block $\mathcal{B}$ of spatial bonds put

$$\mathcal{C}=C_{\mathcal{B}}=\bigotimes_{b\in\mathcal{B}}C,$$
$$c_{\boldsymbol{l}}=\prod_{b\in\mathcal{B}}c_{l_b},$$
$$\Pi_{\boldsymbol{l}}=\bigotimes_{b\in\mathcal{B}}\Pi_{l_b}.$$

Its kernel is $\mathcal{C}(u,v)=\prod_{b\in\mathcal{B}}c(u_b v_b^{-1})$. In particular it is strictly positive on the compact product space. It commutes with the simultaneous vertex gauge action on its two arguments.

Let f be a polynomial in matrix coordinates and their conjugates on $G^{\mathcal{B}}$. Define on $C^\infty(G^{\mathcal{B}})$

$$\widehat{f}F=\sum_{\boldsymbol{l},\boldsymbol{l}'}\frac{c_{\boldsymbol{l}}}{c_{\boldsymbol{l}'}}\Pi_{\boldsymbol{l}'}M_f\Pi_{\boldsymbol{l}}F, \tag{A.xxi}$$

where M_f denotes multiplication by f. This is a continuous map of the smooth Frechet space into itself. Indeed, if the degree in coordinate b is d_b, the Clebsch–Gordan rule makes the summand zero unless $|l_b-l'_b|\le d_b/2$. By eq. A.xx, the remaining ratios are bounded by a fixed polynomial in the indices. Smooth functions have Peter–Weyl coefficients decreasing faster than every polynomial, as follows by applying powers of the Casimir. The finite-dimensional reproducing-kernel estimate bounds the supremum norm on a block by a polynomial times its L^2 norm. The same holds after any fixed number of derivatives. These facts give convergence of eq. A.xxi with all derivatives and the asserted continuity.

The notation $\widehat{f}=\mathcal{C}^{-1}M_f\mathcal{C}$ is therefore legitimate on this smooth domain when interpreted by eq. A.xxi. It does not assert that $\mathcal{C}^{-1}$ acts on every smooth function or that $\widehat{f}$ is bounded on L^2. The formal L^2 adjoint on smooth functions is given by the same finite-band series with the coefficient ratios reversed and f replaced by $\overline{f}$. Those ratios also have polynomial growth, so this formal adjoint maps smooth functions continuously to smooth functions. In particular no unbounded inverse is applied outside its justified spectral domain in the following identity:

$$\mathcal{C}\widehat{f}F=M_f\mathcal{C}F. \tag{A.xxii}$$

It follows by multiplying eq. A.xxi by $\mathcal{C}$ and summing the projections. In kernel form, for every w,

$$f(w)\int \mathcal{C}(v,w)F(v)\,dv = \int \mathcal{C}(v,w)(\widehat{f}F)(v)\,dv. \tag{A.xxiii}$$

The equality is pointwise, since the series and both integrals define smooth functions. All these assertions also hold for smooth families depending on extra variables on a finite compact product: differentiation in those variables commutes with the series. The operator $\widehat{f}$ commutes with multiplication by functions of variables on which it does not act, and operators acting on disjoint variable sets commute.

A transfer contraction inequality. Fix a direction, called time, and take a cubic torus of side s. Let $\mathcal{E}$ be its spatial bonds in one layer. On $L^2(G^{\mathcal{E}})$, let P be vertex gauge averaging and let V be β times the spatial plaquette action in that layer. The operator

$$L = PC_{\mathcal{E}}^{1/2}e^{-V}C_{\mathcal{E}}^{1/2}P$$

is positive and trace class. The convolution, its square root, and e^{-V} all commute with P. Integrating the time-like bonds in the torus integral inserts P between successive layers. Using cyclicity of the trace gives

$$Z_s(0) = \operatorname{Tr} L^s. \tag{A.xxiv}$$

Here normalized Haar measure makes the gauge average an orthogonal projection without an additional volume factor.

Let Ξ be a real bounded operator on $L^2(G^{\mathcal{B}})$ commuting with the block vertex gauge action, and suppose $\|\Xi\| \le 1$. Suppose the kernel

$$k_\Xi = \text{kernel of } \mathcal{C}^{1/2}\Xi\mathcal{C}^{1/2}$$

is continuous and strictly positive pointwise. In two adjacent layers, use transported spatial variables u, v and set

$$\phi_\Xi(u,v) = \log\frac{k_\Xi(u,v)}{\mathcal{C}(u,v)}. \tag{A.xxv}$$

This is a real continuous gauge-invariant local observable.

Place translates of the block so far apart that blocks in a single time step have disjoint bond sets. Multiplication by e^{ϕ_Ξ} replaces the corresponding factor $\mathcal{C}$ by $\mathcal{C}^{1/2}\Xi\mathcal{C}^{1/2}$. Thus the full kernel in step j is $C_{\mathcal{E}}^{1/2}\Xi_j C_{\mathcal{E}}^{1/2}$, where Ξ_j is a tensor product of copies of Ξ and identities and has norm at most one. Gauge averaging the time-like bonds gives the trace of the product of $e^{-V}C_{\mathcal{E}}^{1/2}\Xi_j C_{\mathcal{E}}^{1/2}P$. Moving the first half-kernel and layer weight cyclically to the end, and using commutation with P, rewrites this trace as

$$\operatorname{Tr}(\Xi_1 L\Xi_2 L\cdots\Xi_s L).$$

The unperturbed steps have $\Xi_j = 1$. Schatten Holder gives

$$|\operatorname{Tr}(\Xi_1 L\cdots\Xi_s L)| \le \prod_{j=1}^{s}\|\Xi_j L\|_s \le \|L\|_s^s = \operatorname{Tr} L^s. \tag{A.xxvi}$$

The last equality uses $L \geq 0$. The modified integral is positive because every replaced kernel is positive pointwise. Therefore eq. A.xxvi is precisely the partition-function inequality in eq. A.xvii for a sufficiently sparse periodic array of ϕ_Ξ.

Given an arbitrary periodic state ν, choose m large enough that $m\mathbb{Z}^4$ is a subgroup of its periods and the copies are disjoint. eq. A.xvii–eq. A.xviii imply

$$\nu(\phi_\Xi) \leq 0. \tag{A.xxvii}$$

The norm contraction and the lower tangent are the only ingredients of this conclusion. No self-adjointness of Ξ and no differentiability of a limiting pressure has been used.

Two adjacent layers cannot carry an antisymmetric mean. Let $Y(u, v)$ be a real continuous function on $G^{\mathcal{B}} \times G^{\mathcal{B}}$ that is invariant under simultaneous vertex gauge transformations and antisymmetric: $Y(v, u) = -Y(u, v)$. Then every periodic DLR state satisfies

$$\nu(Y(U_i, U_{i+1})) = 0. \tag{A.xxviii}$$

To prove this, first suppose $K(u, v) = Y(u, v)\mathcal{C}(u, v)$ is a polynomial. Its integral operator has finite Peter–Weyl support. Antisymmetry makes K a real skew-adjoint operator. On that finite-dimensional support define

$$D = \mathcal{C}^{-1/2} K \mathcal{C}^{-1/2}.$$

Every eigenvalue c_l is strictly positive, so the definition is valid. Extend D by zero on the orthogonal complement. It is a finite-rank real skew-adjoint operator, commutes with gauge transformations, and $\Xi_\varepsilon = e^{\varepsilon D}$ is a real orthogonal operator for real ε of either sign. In particular $\|\Xi_\varepsilon\| = 1$.

The kernel difference from $\mathcal{C}$ has finite Peter–Weyl support and admits, uniformly in (u, v),

$$k_{\Xi_\varepsilon}(u, v) = \mathcal{C}(u, v) + \varepsilon K(u, v) + O(\varepsilon^2).$$

Since $\mathcal{C} \geq e^{-2\beta|\mathcal{B}|}$, this kernel is strictly positive for sufficiently small $|\varepsilon|$. Consequently $\phi_{\Xi_\varepsilon} = \varepsilon Y + O(\varepsilon^2)$ uniformly. Apply eq. A.xxvii, first at each fixed nonzero ε after taking the thermodynamic limit in the lower-tangent argument. For both signs it gives $\varepsilon\nu(Y) \leq C\varepsilon^2$. Letting $\varepsilon \to 0$ proves eq. A.xxviii in this case.

For general Y, approximate $Y\mathcal{C}$ uniformly by polynomials on the compact product group. Antisymmetrize each approximant and average it over the simultaneous gauge group. These operations preserve polynomiality, because a finite matrix-coordinate degree spans a finite-dimensional representation, and preserve the uniform approximation. Divide by the strictly positive kernel $\mathcal{C}$. The resulting functions Y_n converge uniformly to Y and have the already proved property $\nu(Y_n) = 0$. This proves eq. A.xxviii. The argument also specifies why injectivity of $\mathcal{C}$, rather than merely its operator positivity, is needed.

The exact one-layer DLR elimination identity. Fix a finite stack of layers $[a, b]$. Write $T_{j,y}$ for the time-like bond from (j, y) to $(j + 1, y)$ and $\mathring{U}_{j,e}$ for a spatial bond in layer j. Define

$$g_{j,y} = T_{a,y} \cdots T_{j-1,y},$$
$$U_{j,\langle y,y'\rangle} = g_{j,y} \mathring{U}_{j,\langle y,y'\rangle} g_{j,y'}^{-1}. \tag{A.xxix}$$

These are temporal-gauge coordinates on the stack, with the empty product at $j = a$. A gauge-invariant local function of the stack is exactly a function of the U_j invariant under one common vertex gauge action in all layers. This follows by setting the time-like bonds to the

identity successively. For any fixed finite observable only finitely many vertices are involved, so only finite-support gauge transformations are needed.

Let $a < j < b$ and resample the spatial bonds $\{j\} \times \mathcal{B}$, leaving every other original bond conditioned. The matrices $g_{j,y}$ use only time-like bonds and hence are fixed during this resampling. The substitution $\mathring{U}_j \mapsto v = U_j|_{\mathcal{B}}$ preserves Haar measure. The two time-like plaquettes attached to each resampled spatial bond produce the factors below; all spatial plaquettes that meet the block produce the finite potential $V_j(v;\eta)$, where η denotes the other spatial variables of layer j. Thus the conditional density is exactly

$$\begin{aligned} &\frac{1}{z(w,w',\eta)}\mathcal{C}(w,v)e^{-V_j(v;\eta)}\mathcal{C}(v,w')\,dv, \\ &w = U_{j-1}|_{\mathcal{B}}, \\ &w' = U_{j+1}|_{\mathcal{B}}. \end{aligned} \tag{A.xxx}$$

No plaquette meeting the resampled bonds is omitted: it is either spatial in layer j or one of the two time-like plaquettes of that bond. The potential can involve spatial neighbors outside $\mathcal{B}$, but they lie in the same layer and in a finite enlargement of the block.

Let f be a real polynomial on $G^{\mathcal{B}}$ and let Φ be smooth in finitely many transported variables from layers j and above, and independent of the spatial variables of layer $j-1$. Define

$$\Phi^\flat = \frac{e^{V_j(v;\eta)}}{\mathcal{C}(v,w')}\widehat{f}_v\left[e^{-V_j(v;\eta)}\mathcal{C}(v,w')\Phi\right]. \tag{A.xxxi}$$

All factors are smooth on a finite compact product, and the denominator is strictly positive. eq. A.xxi therefore proves that $\Phi^\flat$ is smooth. Its new dependence is confined to layer j and the already present higher layers; it acquires no spatial variable in layer $j-1$.

Every DLR state, periodic or not, satisfies the exact identity

$$\nu\big(f(U_{j-1}|_{\mathcal{B}})\Phi\big) = \nu(\Phi^\flat). \tag{A.xxxii}$$

Indeed, condition on all bonds except the specified block in layer j. The conditional numerator on the left is

$$f(w)\int \mathcal{C}(v,w)e^{-V_j(v;\eta)}\mathcal{C}(v,w')\Phi\,dv.$$

Apply eq. A.xxiii to the smooth bracketed function. Substitution of eq. A.xxxi identifies the result with the numerator of the conditional expectation on the right. The same normalizer $z(w,w',\eta)$ occurs on both sides; it is not differentiated or canceled through an operator. Integration of this conditional identity gives eq. A.xxxii. Reflection of the construction yields the corresponding identity that eliminates an upper outer layer.

Removing two outer layers and preserving reflection. Let θ be reflection about the middle of a stack with $2k+2$ layers, numbered $i-k,\dots,i+k+1$. Let X be a real gauge-invariant polynomial observable in that stack. In temporal coordinates, a finite sum of products writes it as

$$X = \sum_\alpha f_\alpha(w)h_\alpha(z)\Phi_\alpha,$$

where $w = U_{i-k}|_{\mathcal{B}}$ and $z = U_{i+k+1}|_{\mathcal{B}}$ are the outer layers and Φ_α depends on the inner layers. Take one finite block containing all the variables that occur in this decomposition. The potentials used during elimination can enlarge this block spatially, but only finitely and only in the inner layers.

Use eq. A.xxxii to remove $f_\alpha(w)$ through the first inner layer $u = U_{i-k+1}|_{\mathcal{B}}$, and then its reflected version to remove $h_\alpha(z)$ through the last inner layer $v = U_{i+k}|_{\mathcal{B}}$. The result is

$$\nu(X) = \nu(EX),$$
$$EX = \sum_\alpha \Upsilon^{-1} \widehat{f}_{\alpha,u} \widehat{h}_{\alpha,v} (\Upsilon \Phi_\alpha). \tag{A.xxxiii}$$

When the two inner layers are not adjacent, Υ is the product of their two factors e^{-V} and their bond kernels toward the remaining interior. When $k = 1$ they are adjacent and

$$\Upsilon = e^{-V(u;\eta)} e^{-V(v;\eta')} \mathcal{C}(u, v). \tag{A.xxxiv}$$

The common bond kernel occurs once, not twice. To see the cancellation directly, the first elimination introduces $e^{V(u)}/\mathcal{C}(u, v)$ outside its conjugated operator. In the upper elimination the conditional numerator contains $e^{-V(v)}\mathcal{C}(u, v)$, canceling that denominator before the second operator acts. The operators act on distinct variables and commute. Moving the remaining independent factors through them gives exactly eq. A.xxxiv. This calculation is also a check that normalizing factors from different conditional laws have not been interchanged.

Let R denote literal reversal of the array of transported layer coordinates. An actual reflection of the original bond configuration induces R followed by a common vertex gauge transformation arising from the change of temporal-gauge base. The spatial potential is the same function of its own layer variables at both ends, and $\mathcal{C}(u, v)$ is symmetric. Reflection interchanges u and v, including all their spatial neighbors, and preserves Υ. It also sends $\widehat{f}_u$ to $\widehat{f}_v$. Consequently coordinate elimination commutes with literal reversal:

$$E(RX) = R(EX). \tag{A.xxxv}$$

The output need not be a polynomial, but it is a smooth function of finitely many inner-layer variables.

Every DLR state is invariant under finite-support vertex gauge transformations. This follows by applying its conditional law to the finite set of bonds incident to the transformed vertices and changing variables using Haar invariance and plaquette conjugacy. We may therefore replace EX in expectation by its average under the common temporal-gauge action; denote it by $\mathcal{A}$. This averaging commutes with R. Once averaged, the choice of the lowest layer in eq. A.xxix disappears: changing the base from $i-k$ to $i-k+1$ conjugates all remaining transported variables by one common vertex gauge transformation. The averaged function is invariant under that transformation, even when its values are the actual time-like transport matrices. This last statement is a pointwise identity of invariant functions, and does not invoke invariance of the state under a field-dependent change of variables. Thus the averaged output is a continuous gauge-invariant observable of the smaller stack of $2k$ layers. Since X is gauge invariant, its actual reflection is represented by RX in temporal coordinates. After averaging the common gauge factor on the output also disappears. Thus the identity needed on the original bond space is $\mathcal{A}E(\theta X) = \theta \mathcal{A} EX$.

Proof of the link-reflection theorem. Fix the reflection θ in $x_\mu = i + \frac{1}{2}$. We prove by induction on k that every real gauge-invariant polynomial in the stack $[i - k + 1, i + k]$ has equal expectation to its reflection.

For $k = 1$, temporal gauge writes the observable as $\Psi(U_i, U_{i+1})$. Reflection interchanges the two arguments, up to a common gauge transformation, which does not affect Ψ. The difference from its reflection is the function $Y(u, v) = \Psi(u, v) - \Psi(v, u)$, to which eq. A.xxviii applies. Hence the expectations agree.

Assume the assertion for k. For a polynomial X in the stack with $2k + 2$ layers, eq. A.xxxiii–eq. A.xxxv and gauge averaging reduce the comparison of $\nu(X)$ and $\nu(\theta X)$ to the same comparison

for a continuous gauge-invariant function of the smaller stack. Invariant polynomials are uniformly dense in the invariant continuous functions on a finite product of compact matrix groups: first apply Stone–Weierstrass to matrix coordinates and their conjugates, then average the approximants over the finite vertex gauge group. The induction hypothesis therefore applies to this continuous output. It gives $\nu(\mathcal{A}EX) = \nu(\theta\mathcal{A}EX)$ and proves the next step.

Every gauge-invariant continuous local function fits in a finite symmetric stack and is uniformly approximated as above. We have proved equality of its expectation and that of its reflection. For a general continuous local F, gauge average over the finite set of vertices relevant to its support. Gauge invariance of both ν and its reflected state shows that both expectations of F equal the expectations of that gauge average. Thus $\nu(F) = \nu(\theta F)$ for all continuous local F, which determine the probability measure on the compact product configuration space. The state is reflection invariant. The direction μ and integer i were arbitrary. Composing reflections in two successive link planes gives translation by $2e_\mu$, proving the stated $2\mathbb{Z}^4$ invariance. □

Passage to all mirrors. The common period is the input to the independent fold-and-separation proof in appendix A.6. That section supplies adapted diagonal split tori, finite crossing kernels, the full chessboard inequality, and the arbitrary-state separation argument. The link theorem above does not require those later ingredients.

A.6. **Reflection positivity of periodic Wilson states.** The result in this section concerns the complete algebra of bonds on a closed side of a mirror. Its proof does not identify an arbitrary Gibbs state with a limit of unperturbed torus measures. Instead, a pressure inequality produces, for each separating observable, a suitable limit of *perturbed* torus measures. The common period supplied by link reflection invariance is what makes the separation argument work.

We use the following result proved in the preceding link-symmetry argument: every periodic DLR state of the four-dimensional SU(2) Wilson specification, at $\beta > 0$, is invariant under all coordinate link reflections and consequently under $P = 2\mathbb{Z}^4$. No uniqueness or extremality is assumed here.

Let $\Omega = \mathrm{SU}(2)^{\mathcal{B}}$, with one group variable for each positively oriented nearest-neighbour bond; reversing a bond inverts its variable. Put

$$a_p(U) = 1 - \tfrac{1}{2}\operatorname{tr} U_p,$$

$$c(g) = \exp[-\beta(1 - \tfrac{1}{2}\operatorname{tr} g)].$$

The trace is real for SU(2), and $0 \le a_p \le 2$. The product topology makes Ω compact and metrizable. A state is periodic if it is invariant under some finite-index subgroup of $\mathbb{Z}^4$. Denote by $\mathcal{G}_\beta^P$ the compact convex set of Wilson DLR states invariant under P.

The normals considered below are

$$\mathcal{N} = \{e_\mu : 1 \le \mu \le 4\} \cup \{e_\mu + e_\lambda, e_\mu - e_\lambda : 1 \le \mu < \lambda \le 4\}.$$

For $n \in \mathcal{N}$ write $q = |n|^2$ and

$$\theta_c x = x - 2(n \cdot x - c)n/q.$$

The admissible positions are $c \in \frac{1}{2}\mathbb{Z}$ when $q = 1$ and $c \in \mathbb{Z}$ when $q = 2$. These and only these positions in the stated families give lattice reflections. Let $\mathcal{A}_c^+$ be the bounded Borel functions of bonds both of whose endpoints satisfy $n \cdot x \ge c$, and define $\mathcal{A}_c^-$ similarly. The antilinear reflection is $\Theta_c F = \overline{F \circ \theta_c^*}$.

Proposition A.11 (All-mirror positivity of periodic states)**.** Every periodic Wilson DLR state at $\beta > 0$ is invariant under every admissible reflection θ_c in the sixteen families above. For every such mirror,

$$\nu(\Theta_c F\, F) \geq 0$$
$$(F \in \mathcal{A}_c^+ \text{ or } F \in \mathcal{A}_c^-). \tag{A.xxxvi}$$

In particular, the conclusion applies to every bounded observable on any finite stack contained in either closed half-space, regardless of the number of layers in that stack. ■

Composing the reflections in $x_\mu = 0$ and $x_\mu = 1/2$ gives translation by one lattice unit. Coordinate reflections give sign changes, and reflection in $x_\mu - x_\lambda = 0$ exchanges two coordinates. Thus every such state is invariant under all lattice translations and the full signed-permutation group. At $\beta = 0$, the DLR equations directly force every finite-bond marginal to be product Haar; that unique product state has the same properties.

Positive crossing kernels on split tori. Write an element of SU(2) as a unit quaternion $s(g) \in S^3 \subset \mathbb{R}^4$. Then

$$\tfrac{1}{2}\,\mathrm{tr}(gh^{-1}) = s(g) \cdot s(h).$$

Consequently

$$c(gh^{-1}) = e^{-\beta} \sum_{m=0}^{\infty} \frac{\beta^m}{m!} \sum_{i_1,\dots,i_m=1}^{4} \prod_{j=1}^{m} s_{i_j}(g) \prod_{j=1}^{m} s_{i_j}(h). \tag{A.xxxvii}$$

Every coefficient is nonnegative. Each feature has absolute value at most one, and the sum of the coefficients is $e^{3\beta}$, so the series converges absolutely and uniformly. Tensor products of finitely many such expansions are again uniformly convergent positive Gram expansions. The coarse total coefficient bound is immaterial; each torus used below is finite.

A torus is called split for the mirror normal n if its period lattice has the form

$$\Gamma = \Gamma_{\parallel} \oplus \mathbb{Z}(2zn/q),$$
$$\Gamma_{\parallel} \subset n^{\perp}, \tag{A.xxxviii}$$

where $\Gamma_{\parallel}$ has rank three, $2zn/q$ is a lattice vector, and z is a sufficiently large integer. The reflection has two fixed cuts, at heights c and $c + z$, on this torus. The two intervening closed halves are exchanged. All tori below have arbitrarily large shortest nonzero period, so that no small-quotient ambiguity affects plaquettes.

We verify reflection positivity on these tori for all bounded half-space functions. Partition the bond variables into the interiors of the two halves, the bonds lying on the cuts, and, when present, the bonds crossing a cut. A coordinate site cut has no plaquette with vertices strictly on both sides. Conditional on its boundary bonds, the action is a sum of a positive-side action, its reflected action, and an action on the boundary. Its reflection form is thus an integral of absolute squares.

At a diagonal cut, signed permutations reduce the geometry to $n = e_1 + e_2$, $c \in \mathbb{Z}$. A bond changes the height $x_1 + x_2$ by 0 or 1 in absolute value, so no bond crosses from a strictly negative height to a strictly positive one. The only plaquettes meeting both strict sides are in the $(1, 2)$ plane, with heights $c-1, c, c, c+1$. Each is cut into two two-bond paths between the two vertices at height c. Orienting both paths in the same direction expresses its Wilson factor as $c(P_+P_-^{-1})$. Reflection interchanges the paths, and eq. A.xxxvii supplies the required Gram expansion. Plaquettes in all other planes lie in a closed half. The bonds on the mirror, in directions 3 and 4, are fixed pointwise. Conditioning on them and multiplying the crossing expansions again gives an integral of squares. The same argument applies at the second cut.

For a coordinate link cut there are crossing bonds. Integrate them before evaluating a half-space function, which cannot depend on them. Let X and Y be the collections of bonds parallel to the cut in its two adjacent layers. The product crossing kernel before integration is

$$C(X,Y) = \prod_b c(X_b Y_b^{-1}).$$

It is a positive kernel by eq. A.xxxvii. If $T = (T_x)$ is a collection of group elements at the vertices of one boundary layer, set $(T \cdot X)_{xy} = T_x X_{xy} T_y^{-1}$. Let P_0 be Haar averaging under this action. Simultaneous gauge covariance gives $C(T \cdot X, T \cdot Y) = C(X,Y)$, since each plaquette trace changes by conjugation. Hence the associated integral operator commutes with the orthogonal projection P_0. Integration of the crossing bonds gives the kernel of

$$P_0 C = C P_0 = P_0 C P_0 \geq 0. \tag{A.xxxix}$$

Equivalently, in each Gram feature of the product expansion one may Haar-average both its X argument and its Y argument. Absolute uniform convergence justifies this operation. The crossing bonds at the two cuts are disjoint, so the two constructions multiply. This argument places no gauge-invariance condition on the test function.

In all three geometries the resulting reflection form has the form

$$\int \Theta_c F' F \, e^{-\beta \sum_p a_p} \, dU = \sum_\gamma b_\gamma \int \overline{I_\gamma(F';Y)} I_\gamma(F;Y) \, d\lambda(Y),$$
$$b_\gamma \geq 0, \tag{A.xl}$$

where Y denotes the fixed boundary variables; in the link case Y is absent. The functions I_γ integrate over one half, with its Boltzmann factor and the corresponding Gram feature. The boundary Boltzmann factor is included in the positive measure λ. Fubini's theorem follows from the coefficient summability above. This proves the Cauchy–Schwarz inequality for the reflection form and reflection positivity for all bounded half-space functions. Haar invariance, orientation reversal, and invariance of the plaquette trace also prove reflection invariance of the finite measure.

If E is a bounded real function on one closed half, multiplying the density by $e^{E+\theta_c E}$ preserves both properties: insert Fe^E in eq. A.xl. This observation will apply to folded perturbations.

A finite one-direction chessboard proof. Fix parallel slab faces at heights $c + kH$, where $H \geq 2$ is an integer. Use a split torus with normal height period $2MH$, $M \geq 1$. Its $2M$ slabs are indexed by $\mathbb{Z}/(2M)$. The group generated by reflection in the slab faces acts simply transitively on the slabs: its translations change the index by an even integer and its reflections send k to $2j - 1 - k$. Thus a function on any one slab has a well-defined copy on every other slab obtained using this group. Boundary bonds may belong to two closed slabs; this causes no problem, since the products are functions of the same boundary variables and eq. A.xl permits those variables in both half-algebras.

For positive bounded slab functions $f_0, \ldots, f_{2M-1}$ with strictly positive infima, denote by $Z^{\mathrm{dis}}(f_j)$ the partition function obtained by copying f_j into every slab. We claim

$$\int \prod_{j=0}^{2M-1} f_j \, e^{-\beta \sum_p a_p} \, dU \leq \prod_{j=0}^{2M-1} Z^{\mathrm{dis}}(f_j)^{1/(2M)}. \tag{A.xli}$$

Here is a proof valid for every M, without a power-of-two restriction. Transport the $2M$ functions to one reference slab and retain their labels. For any filling $\sigma : \mathbb{Z}/(2M) \to \{0, \ldots, 2M-1\}$, let $Z(\sigma)$ be the partition function obtained by placing profile $\sigma(k)$ in slab k. Put

$$w_j = Z^{\mathrm{dis}}(f_j)^{1/(2M)},$$
$$T(\sigma) = Z(\sigma)/\prod_k w_{\sigma(k)}.$$

All these numbers are positive, and every constant filling has $T = 1$. Reflection Cauchy–Schwarz at any pair of opposite slab faces gives

$$T(\sigma)^2 \le T(\sigma_+)T(\sigma_-), \tag{A.xlii}$$

where σ_+ retains one semicircle of labels and reflects it into the other, and σ_- does the reverse. Indeed, the unnormalized inequality is eq. A.xl; the two denominators together contain each original denominator factor twice.

There are finitely many fillings. If σ maximizes T, eq. A.xlii forces both reflected fillings to maximize it as well. Take a cyclic constant run of length l in a maximizing filling and reflect at the face at the start of that run. If $l \le M$, retaining the half beginning there gives a maximizing filling with a run of length $2l$. If $l \ge M$, retain a semicircle inside the run and reflect it; the result is constant. Iterating therefore produces a constant maximizing filling. The maximum is one. Applying this to the original filling proves eq. A.xli.

This argument uses reflection positivity only for finite tori. It does not infer the positivity of an arbitrary DLR state from the positivity of one adjacent-layer kernel.

A lower tangent for an arbitrary periodic DLR state. Let Q be a fixed finite-index period subgroup, let A be a real continuous local observable, and form the locally finite interaction array $\mathbb{A} = (\tau_v A)_{v\in Q}$. Write $\kappa = [\mathbb{Z}^4 : Q]^{-1}$. Let $\Gamma_i \subset Q$ be rectangular adapted period lattices with every side tending to infinity. On the corresponding tori put

$$Z_i(t\mathbb{A}) = \int \exp\left[t\sum_{v\in Q/\Gamma_i}(\tau_v A)^{\Gamma_i} - \beta\sum_p a_p\right] dU.$$

For every Q-invariant Wilson DLR state ν and every fixed real t,

$$\frac{1}{|D_i|}\log\frac{Z_i(t\mathbb{A})}{Z_i(0)} \ge t\kappa\nu(A) - o(1). \tag{A.xliii}$$

The error may depend on A, Q, β, t, but is uniform in ν.

For completeness, choose a fundamental parallelepiped D_i and integrate the positively oriented bonds anchored in it, using arbitrary external bonds as boundary conditions. Let W_i sum the source copies whose entire support is interior to this bond set. Conditional Jensen and the DLR equation give

$$\log\frac{Z^t_{D_i}(\eta)}{Z^0_{D_i}(\eta)} \ge t\gamma_{D_i}W_i(\eta),$$
$$\int \gamma_{D_i}W_i\, d\nu = \nu(W_i).$$

The open and torus Hamiltonians differ only in a boundary layer of fixed thickness, determined by the range of A and the plaquettes. Each energy term is bounded; each bond is met by only a fixed finite number of array terms. Thus their logarithmic partition ratios differ by at most $C_A(\beta + |t|\|A\|)|\partial_R D_i|$, uniformly in η. The number of omitted array anchors is at most $C_A|\partial_R D_i|$. Since the remaining Q-translates all have expectation $\nu(A)$, integrating the Jensen bound proves

eq. A.xliii, with an error bounded by a constant times $|\partial_R D_i|/|D_i|$. This ratio tends to zero for the adapted rectangular tori, including the diagonal ones. No differentiability of infinite-volume pressure is used.

Fold domination with a fixed common period. Fix one admissible mirror (n, c). Choose an even positive integer h and set

$$\begin{aligned} w &= hn \in P, \\ H &= n \cdot w = hq, \\ P_{\parallel} &= P \cap n^{\perp}, \\ Q &= P_{\parallel} \oplus \mathbb{Z}w, \\ Q_f &= P_{\parallel} \oplus \mathbb{Z}(2w). \end{aligned} \tag{A.xliv}$$

Both Q and Q_f are finite-index subgroups of P and $[Q : Q_f] = 2$. The tangent lattice $P_{\parallel}$ has an orthogonal integer basis: for a coordinate normal use the three other vectors $2e_j$; for $e_1 \pm e_2$ use $2(e_1 \mp e_2), 2e_3, 2e_4$, with the corresponding signed permutations for the other cases. Thus

$$\Gamma_{M,J} = JP_{\parallel} \oplus \mathbb{Z}(2Mw) \tag{A.xlv}$$

is an adapted rectangular split torus. Its shortest period tends to infinity as $M, J \to \infty$.

Assume for the moment that A is supported in the slab $c \le n \cdot x \le c + H$. The unfolded array contains all its translates by Q. The folded array contains translates of A in the even slabs and the reflected copies $\theta_{c+H}A$ in the odd slabs, with period Q_f. It is invariant under reflection at every face $c + kH$. In eq. A.xli take

$$f_k = \exp\left[t \sum_{v \in P_{\parallel}/JP_{\parallel}} (\tau_{v+kw}A)^{\Gamma_{M,J}}\right],$$
$$t > 0.$$

Their product is the unfolded perturbation. Their disseminated partition functions are identical: normal translation by kw carries one dissemination to another, permutes the slab faces, and preserves the unperturbed Wilson measure. Each is the folded partition function. Hence

$$Z_{M,J}(t\mathbb{A}^{\mathrm{u}}) \le Z_{M,J}(t\mathbb{A}^{\mathrm{f}}). \tag{A.xlvi}$$

Let $\mu_{M,J,t}$ be the normalized folded measure, and define

$$p_{M,J}(t) = |D_{M,J}|^{-1} \log[Z_{M,J}(t\mathbb{A}^{\mathrm{f}})/Z_{M,J}(0)].$$

It is convex, $p_{M,J}(0) = 0$, and therefore $p_{M,J}(t) \le t p'_{M,J}(t)$ for $t > 0$. The folded measure is invariant under Q_f and under θ_{c+H}. All its source terms consequently have the same expectation as A. There are $\kappa|D_{M,J}|$ terms, where $\kappa = [\mathbb{Z}^4 : Q]^{-1}$, so

$$p'_{M,J}(t) = \kappa \mu_{M,J,t}(A).$$

Combining this identity, eq. A.xliii, and eq. A.xlvi gives, for every $\nu \in \mathcal{G}^P_\beta$,

$$t\kappa\nu(A) - o(1) \le p_{M,J}(t) \le t\kappa\mu_{M,J,t}(A). \tag{A.xlvii}$$

The finite folded measure is invariant and reflection positive at every face $c + kH$. Indeed, its perturbation is $E + \theta_{c+kH}E$, where E is the sum of its copies lying in one closed half of the torus. Copies on a boundary can be assigned half weight to each side. The observation following eq. A.xl applies.

First fix $t > 0$ and let $M, J \to \infty$. Compactness gives a limit ρ_t. It is a DLR state for the folded, finite-range perturbed interaction, is Q_f-periodic, is invariant and reflection positive at all its slab faces, and satisfies $\nu(A) \le \rho_t(A)$. Here DLR passage is local and exact: any fixed collection of bonds, its interaction neighbourhood, and the support of a cylinder test embed injectively in all sufficiently large tori. The finite torus conditional equation is then exactly the required local DLR equation on that test. Its kernel is continuous, so the equation passes to a weak limit. A finite test on one half-space eventually lies in a single torus half; hence its reflection inequality passes to the limit as well.

Next let $t \downarrow 0$ along a subsequence for which ρ_t converges to ρ_0. On any fixed finite set, only finitely many source copies meet that set. Their bounded total contribution is $O(t)$ uniformly in the exterior configuration. The perturbed conditional densities thus converge uniformly to the Wilson conditional density. It follows that ρ_0 is a Wilson DLR state. It retains Q_f periodicity, reflection invariance and positivity at the slab faces, and $\nu(A) \le \rho_0(A)$.

Now apply the previously proved link-symmetry theorem to ρ_0. Its finite-index period Q_f is enough for that theorem; the result upgrades its period to P. We have proved the following domination:

$$\begin{aligned} &A \text{ supported in } [c, c+H], \quad \nu \in \mathcal{G}_\beta^P \quad \Longrightarrow \quad \exists \rho_0 \in \mathcal{G}_\beta^P : \\ &\rho_0 \text{ is invariant and positive at } (n, c), \qquad \nu(A) \le \rho_0(A). \end{aligned} \tag{A.xlviii}$$

The order of limits is essential: the surface error in eq. A.xlvii is divided by $t\kappa$, so volume tends to infinity before t tends to zero.

Separation closes the full half-space statement. Let $K = \mathcal{G}_\beta^P$ and let $K_c \subset K$ consist of the states invariant under θ_c and positive on every continuous cylinder function in the positive half-space. The set K is compact and convex: the DLR kernels preserve continuous cylinder functions, and all its defining equations and period equations are closed affine conditions. The set K_c is also closed and convex. It is nonempty, for example by the folded construction with $A = 0$.

For any real continuous local A, choose $v \in P$ so that $\tau_v A$ is supported strictly above the fixed mirror c. Then choose the even h large enough that this support lies below $c + H$. Such a v exists because $n \cdot (2ke_j) = 2k$ for a coordinate j with $n_j = 1$. Apply eq. A.xlviii to $\tau_v A$. Both ν and the resulting ρ_0 are P-invariant, so

$$\begin{aligned} \nu(A) = \nu(\tau_v A) \le \rho_0(\tau_v A) = \rho_0(A), \\ \rho_0 \in K_c. \end{aligned} \tag{A.xlix}$$

If some $\nu \in K$ were outside K_c, separation of a point from a compact convex set of measures would supply a real continuous function A with $\nu(A) > \sup_{\rho \in K_c} \rho(A)$. Continuous cylinder functions are uniformly dense in $C(\Omega)$, so A could be chosen local while retaining a strict inequality. This contradicts eq. A.xlix. Therefore $K = K_c$.

This step explains why the common period cannot be omitted. A state produced by folding initially has only the normal period $2w$. Such a large period need not move a test straddling the mirror into one slab. The link-symmetry theorem supplies $2\mathbb{Z}^4$ for both states in eq. A.xlix, independently of the observable and slab width. No claim that periodic DLR states are torus-selected is needed.

The mirror was arbitrary, so every periodic state is invariant and positive at all the stated mirrors on continuous local half-space functions. Finally, on the compact metrizable product of the positive half-space bonds, continuous cylinder functions are dense in $L^2(\nu)$. For bounded Borel F choose such F_j with $\|F_j - F\|_2 \to 0$. Reflection invariance makes Θ_c an isometry of $L^2(\nu)$, and Cauchy–Schwarz gives

$$|\nu(\Theta_c F_j F_j) - \nu(\Theta_c F F)| \le \|F_j - F\|_2(\|F_j\|_2 + \|F\|_2) \longrightarrow 0.$$

This proves eq. A.xxxvi on the complete positive-half algebra. Replacing a negative-half function by its reflected conjugate proves the other half. In particular, arbitrary finite stacks and their bounded Borel tests are covered. □

As a further consequence, every periodic state is invariant under all unit lattice translations: in direction e_μ the product of the site reflection at 0 and the link reflection at $1/2$ is translation by e_μ. It is also invariant under the hypercubic group. The coordinate reflections at zero generate coordinate sign changes, and the diagonal reflections with normal $e_\mu - e_\lambda$ interchange coordinates. These transformations generate all signed permutations.

Scope of the implication. Positive semidefinite contractions of an adjacent-layer kernel can produce a one-layer positivity test, just as skew contractions produce an antisymmetric invariance test. That observation alone supplies no identity reducing arbitrary odd or even stacks to a single layer. The proof above uses a different route: exact finite-torus positivity on the full half-algebra, a finite chessboard inequality, a lower tangent for each arbitrary periodic DLR state, and separation after the common period is established. Thus the all-stack and diagonal conclusions do not rest on a separate layer-elimination positivity rule. The result is at a fixed lattice spacing and coupling; it makes no continuum-limit or interacting renormalization-group assertion.

A.7. **A uniform lattice plateau estimate.** The estimate in this section is a consequence of translation invariance and reflection positivity in coordinate and diagonal directions. No infrared bound, mass gap, or differentiability of a pressure is assumed. The Gibbs equations are not needed in the proof. Their role in the Wilson application is to place every periodic Wilson Gibbs state in the reflection-positive class by Prop. A.11, proved independently in appendix A.6. The state here is a measure on the infinite lattice, rather than a finite-torus law lifted periodically.

By dilation it suffices initially to take lattice spacing one. Let ν be a translation-invariant probability measure on lattice configurations. A local function means a bounded Borel function of finitely many bonds. The algebra $\mathfrak{A}(S)$ contains the functions of bonds with both endpoints in S. Assume reflection positivity on the closed side of every coordinate mirror $x_\mu = c$, $c \in \frac{1}{2}\mathbb{Z}$, and every diagonal mirror $x_\mu \pm x_\lambda = c$, $c \in \mathbb{Z}$. These are sixteen families. Reflections act linearly on functions by pullback, without complex conjugation. Write θ_μ for reflection in $x_\mu = 0$.

For $r \ge 1$ an integer put $Q_r = [-r, r]^4$. For $A \in \mathfrak{A}(Q_r)$ define

$$\mathcal{N}_{\nu,r}(A) = \max_{\mu,\gamma} \nu\big(\overline{\theta_\mu \gamma A}\, \tau_{2re_\mu} \gamma A\big), \tag{A.l}$$

where γ ranges over the sixteen coordinate sign changes. The terms in this maximum are nonnegative squared reflection norms. Let $\mathcal{I}$ be the completed invariant σ-field for all lattice translations and set

$$\mathrm{Pl}_\nu(A, B) = \nu\big(\overline{E_\nu[A \mid \mathcal{I}]} E_\nu[B \mid \mathcal{I}]\big). \tag{A.li}$$

Proposition A.12 (Uniform plateau bound)**.** There is a numerical constant C such that, for the measures just specified, $A, B \in \mathfrak{A}(Q_r)$, and $y \in \mathbb{Z}^4$ with $n = |y|_\infty - 2r \ge 1$,

$$\left|\nu(\overline{A}\tau_y B) - \mathrm{Pl}_\nu(A,B)\right| \le C\left[(r/n)^2 + (r/n)^3\right]\mathcal{N}_{\nu,r}(A)^{1/2}\mathcal{N}_{\nu,r}(B)^{1/2}. \tag{A.lii}$$

The constant is independent of the measure, the support size, and any coupling. At lattice spacing a, the same statement holds with $Q_r = a[-r,r]^4$ and $n = |y|_\infty/a - 2r$. ■

We use the spectral theorem for commuting bounded normal operators and the mean ergodic theorem for a unitary operator. All estimates supplying the power in eq. A.lii, including the momentum-density estimate, are proved below.

A.7.1. *Reflection Hilbert spaces and their spectral carriers.* Reflection positivity and translation invariance first imply invariance under each of the indicated reflections. On one closed side, positivity makes $\langle F, G\rangle_\theta = \nu(\overline{\theta F}G)$ Hermitian. Testing it against 1 shows $\nu(F) = \nu(\theta F)$ for functions supported on that side. Any local function can be translated into the side by a lattice vector normal to the mirror. Reflecting reverses that translation; translation invariance therefore proves the equality for the original function. The reflections consequently act unitarily on $L^2(\nu)$.

In the coordinate picture μ, complete the quotient of local functions on $x_\mu \ge 0$ for the positive semidefinite form

$$\langle F, G\rangle_\mu = \nu(\overline{\theta_\mu F}G).$$

Denote the class of F by $[F]_\mu$. Its norm is at most $\|F\|_\infty$. Translation by e_μ induces a positive self-adjoint contraction T_μ, and tangential coordinate translations induce commuting unitaries $U_{\mu,\lambda}$, $\lambda \ne \mu$.

Here are the details of this elementary reconstruction. The normal translation is symmetric on the pre-Hilbert space by translation invariance and $\theta_\mu\tau_{e_\mu} = \tau_{-e_\mu}\theta_\mu$. Its quadratic form is nonnegative by reflection positivity at the mirror $x_\mu = -1/2$. Repeated Cauchy–Schwarz gives

$$\|T_\mu[F]\| \le \|[F]\|^{1-2^{-k}}\|T_\mu^{2^k}[F]\|^{2^{-k}}.$$

The last norm is at most $\|F\|_\infty$. Letting $k \to \infty$ proves contraction and preservation of null vectors. The bounded symmetric extension is self-adjoint and positive. Tangential translations preserve the form and have inverses of the same kind, so are unitaries. Their commutations on local functions pass to the completion. In particular, for integers $s \ge 0$ and tangential $w \in \mathbb{Z}^4$,

$$\langle [F]_\mu, T_\mu^s U_\mu^w [G]_\mu\rangle = \nu(\overline{\theta_\mu F}\tau_{se_\mu + w}G). \tag{A.liii}$$

There is a joint spectral measure with variables $(E,\eta) \in [0,\infty] \times (-\pi,\pi]^3$ for which $T_\mu = e^{-E}$ and $U_{\mu,\lambda} = e^{i\eta_\lambda}$. The value $E = \infty$ represents a possible kernel of T_μ. The following carrier bound is essential:

$$\begin{gathered}\cosh E + \cos\eta_\lambda \ge 2\\ (\lambda \ne \mu),\\ E \ge \kappa|\eta|_\infty,\\ \kappa = \frac{2}{\pi}\log(1+\sqrt{2}).\end{gathered} \tag{A.liv}$$

We now derive it from the diagonal mirrors.

A.7.1.1. A polynomial-measure lemma. Suppose a finite positive measure m on the closed unit disc satisfies

$$\int |p(z)|^2\, dm(z) \le C_0 \sup_{[0,1]} |p| \sup_{|z|=1} |p| \tag{A.lv}$$

for every polynomial. Then it gives zero mass to $\{|1+z|^2 < 4|z|\}$.

To prove this without invoking an extremal-function theorem, set

$$L(\zeta) = \operatorname{Log} \frac{1+\zeta}{1-\zeta},$$
$$f_s(z) = \frac{\cos(sL(\sqrt{z}))}{\cosh(\pi s/2)},$$
$$s > 0.$$

The Cayley transform has positive real part in the disc. Thus L is holomorphic, odd, and satisfies $|\operatorname{Im} L| < \pi/2$. The cosine is even in $\sqrt{z}$, so f_s is a single-valued holomorphic function of z in the disc. Put $\varphi(z) = |\operatorname{Im} L(\sqrt{z})|$. The identity $|\cos(u+iv)|^2 = \cos^2 u + \sinh^2 v$ gives

$$|f_s| \le 1,$$
$$\sup_{[0,1)} |f_s| \le \cosh(\pi s/2)^{-1},$$
$$|f_s(z)| \ge \frac{\sinh(s\varphi(z))}{\cosh(\pi s/2)}.$$

Apply eq. A.lv to Taylor approximants of $f_s(qz)$, $0 < q < 1$, which converge uniformly on the closed disc. The resulting inequality, followed by Fatou as $q \uparrow 1$, is

$$\int \sinh^2(s\widetilde{\varphi}(z))\, dm(z) \le C_0 \cosh(\pi s/2).$$

Here $\widetilde{\varphi} = \varphi$ inside the disc, equals $\pi/2$ on the boundary except at 1, and may be set to zero at 1. Indeed the radial limits of φ at the other boundary points equal $\pi/2$. For each $\epsilon > 0$ this inequality forces $m(\{\widetilde{\varphi} \ge \pi/4 + \epsilon\}) = 0$ by letting $s \to \infty$. Finally, if $z = \zeta^2$ inside the disc,

$$\tan \varphi(z) = \frac{2|\operatorname{Im} \zeta|}{1 - |\zeta|^2},$$
$$|1+\zeta^2|^2 - 4|\zeta|^2 = (1-|\zeta|^2)^2 - 4(\operatorname{Im}\zeta)^2.$$

Thus $\varphi > \pi/4$ is precisely the excluded set. The same assertion holds on the boundary, where only $z = 1$ is not excluded. This proves the lemma.

Fix $\lambda \ne \mu$ and a local A on $x_\mu \ge 0$. Choose an integer $R \ge 1$ enclosing its support in $0 \le x_\mu \le R$, $|x_\lambda| \le R$. Let θ' be reflection in $x_\mu + x_\lambda = R$, put $B = \theta'\theta_\mu A$, $A_0 = \tau_{2Re_\mu} A$, and $d_\pm = e_\mu \pm e_\lambda$. Both B and A_0 lie on the positive side of this diagonal mirror. Reconstruction at that mirror gives a positive contraction T_+ for d_+ and a unitary V_- for d_-. The preceding reconstruction proof applies: positivity of T_+ uses the admissible diagonal mirror one height unit behind, and its contraction uses the bounded local representative. For integers $k, l \ge 0$,

$$\langle [A]_\mu, T_\mu^{2R+k+l} U_{\mu,\lambda}^{k-l} [A]_\mu \rangle = \langle [B]', T_+^k V_-^l [A_0]' \rangle. \tag{A.lvi}$$

Both sides are the same lattice correlation: their displacement is $2Re_\mu + kd_+ + ld_-$. No analytic continuation is used here.

Push the spectral measure of $[A]_\mu$, multiplied by t^{2R}, forward by $z = t\zeta$, where $t = e^{-E}$ and $\zeta = e^{i\eta_\lambda}$. Expanding a polynomial and its conjugate in eq. A.lvi gives

$$\int |p|^2 \, dm = \langle [B]', p(T_+)\overline{p}(V_-)[A_0]' \rangle,$$

$$\overline{p}(z) = \sum_k \overline{p_k} z^k.$$

The spectral theorem bounds this by the right side of eq. A.lv, with $C_0 = \|[B]'\|\|[A_0]'\|$. The lemma excludes $|1 + t\zeta|^2 < 4t$. Since $t^{2R} > 0$ for $t > 0$, the joint spectral measure of $[A]_\mu$ itself vanishes there. The local classes are dense, so the operator spectral measure vanishes there. At $t = 0$ the equivalent operator inequality is automatically satisfied. We have proved

$$(1 - T_\mu)^2 \geq T_\mu(2 - U_{\mu,\lambda} - U_{\mu,\lambda}^*).$$

For $0 < t \leq 1$ this is equivalent to the first assertion of eq. A.liv. The curve is $E \geq 2 \operatorname{arcsinh} |\sin(\eta_\lambda/2)|$. Concavity of $x \mapsto \operatorname{arcsinh} \sin x$ on $[0, \pi/2]$ puts it above its endpoint chord, giving the constant κ. Intersect the three carriers to obtain eq. A.liv.

A.7.2. *The zero-energy plateau is the invariant conditional field.* Write $\Pi_\mu = 1_{\{E=0\}}$; spectral dominated convergence gives $T_\mu^s \to \Pi_\mu$ strongly as $s \to \infty$. By eq. A.liv, every tangential unitary equals the identity on this zero-energy space. Let $\mathcal{I}_\mu$ denote the invariant field for the single translation τ_{e_μ}. The mean ergodic theorem on $L^2(\nu)$ and eq. A.liii give

$$\langle [F]_\mu, \Pi_\mu [G]_\mu \rangle = \nu(\overline{\theta_\mu F} E_\nu[G \mid \mathcal{I}_\mu]). \tag{A.lvii}$$

Reflection acts as a unitary involution on $L^2(\mathcal{I}_\mu, \nu)$. That involution is positive. Indeed, approximate an invariant function J in L^2 by bounded local G_k and translate each approximant into $x_\mu \geq 0$. The error is unchanged because J is invariant. Reflection positivity then passes to the L^2 limit and gives $\langle \theta_\mu J, J \rangle \geq 0$. A positive self-adjoint involution has only the eigenvalue $+1$, so reflection fixes J. Consequently eq. A.lvii equals

$$\nu(\overline{E_\nu[F \mid \mathcal{I}_\mu]} E_\nu[G \mid \mathcal{I}_\mu]).$$

The map $\Pi_\mu[F]_\mu \mapsto E_\nu[F \mid \mathcal{I}_\mu]$ is therefore an isometry onto a dense subspace of $L^2(\mathcal{I}_\mu, \nu)$. Density follows by the same shifted local approximations. It intertwines the tangential translations. Since those translations are the identity on Π_μ, every $\mathcal{I}_\mu$-measurable function is invariant under all four coordinate translations. Hence $\mathcal{I}_\mu = \mathcal{I}$ modulo ν, and

$$\langle [F]_\mu, \Pi_\mu [G]_\mu \rangle = \nu(\overline{E_\nu[F \mid \mathcal{I}]} E_\nu[G \mid \mathcal{I}]). \tag{A.lviii}$$

This also proves that $E_\nu[\theta_\mu F \mid \mathcal{I}] = E_\nu[F \mid \mathcal{I}]$. The possible T_μ kernel has energy infinity and does not affect any of these zero-energy identities.

A.7.3. *A positive time filter and a bounded momentum density.* For $A \in \mathfrak{A}(Q_r)$ define its cube vector $\Phi_A^\mu = [\tau_{re_\mu} A]_\mu$. Translation invariance shows $\|\Phi_A^\mu\|^2 = \nu(\overline{\theta_\mu A} \tau_{2re_\mu} A)$. Thus eq. A.l is the maximum of the corresponding squared norms of γA. In particular $\mathcal{N}^{1/2}$ is a seminorm, is invariant under the sign-change group, and is at most the supremum norm.

Let b be the nonnegative periodic triangle function supported on $[-\pi/4, \pi/4]$, normalized to have mean one. Its Fourier coefficients are

$$b_m = \left(\frac{\sin(m\pi/8)}{m\pi/8}\right)^2,$$
$$b_0 = 1.$$

This follows by writing the triangle as the convolution of two interval indicators and normalizing their zeroth coefficients. Let z_m be the even period-four sequence $(0, 1, -2, 1)$ and set

$$\widehat{q}(u) = \sum_{m\in\mathbb{Z}} z_m b_m e^{imu},$$
$$\Psi(q) = 2\sum_{m\geq 1} z_m b_m q^{m-1},$$
$$0 \leq q \leq 1. \tag{A.lix}$$

Both series converge absolutely. The identity $z_m = \frac{1}{2}i^m - (-1)^m + \frac{1}{2}(-i)^m$ gives

$$\widehat{q}(u) = \tfrac{1}{2}b(u+\pi/2) - b(u+\pi) + \tfrac{1}{2}b(u-\pi/2).$$

In particular $\widehat{q}$ vanishes whenever $\operatorname{dist}(u, 2\pi\mathbb{Z}) \leq \pi/4$. The crucial energy property is

$$0 \leq \Psi \leq C,$$
$$\Psi(1) = 0,$$
$$\Psi(e^{-x}) \geq c\tanh x$$
$$(x > 0). \tag{A.lx}$$

To verify its nontrivial lower bound, use the Poisson kernel

$$P_x(u) = \sum_m e^{-|m|x}e^{imu} = \frac{\sinh x}{\cosh x - \cos u}.$$

Since $z_0 = 0$, the Poisson integral yields

$$\Psi(e^{-x}) = \frac{e^x}{2\pi}\int_{|v|\leq\pi/4} b(v)[\tfrac{1}{2}P_x(v-\pi/2) + \tfrac{1}{2}P_x(v+\pi/2) - P_x(v-\pi)]\,dv.$$

Writing $C_x = \cosh x$, the bracket is

$$\sinh x\left[\frac{C_x}{C_x^2 - \sin^2 v} - \frac{1}{C_x + \cos v}\right] \geq \frac{\tanh x}{\sqrt{2}(C_x + 2^{-1/2})}.$$

For this inequality first replace the first fraction by $1/C_x$, then use $\cos v \geq 2^{-1/2}$ and monotonicity of $q/(C_x + q)$. The factor $e^x/(C_x + 2^{-1/2})$ has a positive lower bound, and b has mean one. This proves the lower bound. The upper bound follows from absolute convergence of eq. A.lix, and $\Psi(1) = \widehat{q}(0) = 0$. These statements extend continuously to $q = 0$, where $\Psi(0) = 2b_1 > 0$.

First assume $\theta_\mu A = \epsilon A$, $\epsilon \in \{1, -1\}$, and put $\Phi = \Phi^\mu_A$. For $s \in \mathbb{Z}$ and tangential $w \in \mathbb{Z}^3$, define

$$g_A(s, w) = \epsilon\nu(\overline{A}\tau_{se_\mu + w}A).$$

For $s \geq 2r$, the cube-crossing identity from eq. A.liii gives

$$g_A(s,w) = \langle \Phi, T_\mu^{s-2r} U_\mu^w \Phi \rangle,$$
$$|g_A(s,w)| \le \mathcal{N}(A). \tag{A.lxi}$$

Reflection in $x_\mu = 0$ and translation invariance give $g_A(-s,w) = g_A(s,w)$ and $g_A(s,-w) = \overline{g_A(s,w)}$. Define

$$K_A(w) = \sum_{m\in\mathbb{Z}} z_m b_m g_A(2rm, w).$$

The term at $m = 0$ vanishes. Every other time separation has absolute value at least $2r$, so eq. A.lxi bounds this sum by $C\mathcal{N}(A)$, uniformly in w. By the same identities,

$$K_A(w) = \langle \Phi, \Psi(T_\mu^{2r}) U_\mu^w \Phi \rangle = \int e^{i\eta\cdot w}\, dM_A(\eta), \tag{A.lxii}$$

where M_A is the momentum pushforward of the positive measure

$$\Psi(e^{-2rE})\, d\langle \Phi, \mathsf{E}_\mu(E,\eta)\Phi\rangle.$$

Thus M_A is positive; the signs in z_m do not compromise positivity because eq. A.lx controls their spectral sum.

For $|w|_\infty \ge 2r$, choose $\lambda \ne \mu$ at a maximal coordinate. Replace w by $-w$ if necessary, which only conjugates $K_A(w)$, and suppose $w_\lambda \ge 2r$. In the coordinate picture λ, for every integer s the same correlation is

$$g_A(s,w) = \epsilon \left\langle \Phi^\lambda_{\theta_\lambda A}, T_\lambda^{w_\lambda - 2r} U^s_{\lambda,\mu} \prod_{\lambda' \ne \lambda,\mu} U^{w_{\lambda'}}_{\lambda,\lambda'} \Phi^\lambda_A \right\rangle.$$

Sum this identity at $s = 2rm$ against $z_m b_m$. In this picture the filter becomes the bounded spectral function $\widehat{q}(2r\eta'_\mu)$ of a unitary translation. Whenever it is nonzero, $|\eta'_\mu| > \pi/(8r)$, since the gap around zero modulo 2π includes the ordinary interval about zero. Aliases at other multiples of 2π do not invalidate this implication. The carrier eq. A.liv consequently gives $E' \ge \alpha = \kappa\pi/(8r)$ on the filter support. Both cube vectors have norm at most $\mathcal{N}(A)^{1/2}$. Hence

$$|K_A(w)| \le C\mathcal{N}(A) e^{-\alpha(|w|_\infty - 2r)}$$
$$(|w|_\infty \ge 2r). \tag{A.lxiii}$$

There are $O(r^3)$ points with $|w|_\infty < 2r$ and $O(k^2)$ points on the shell $|w|_\infty = k$. Since α is a fixed constant times r^{-1}, eq. A.lxiii and the previous bound give

$$\sum_w |K_A(w)| \le C\mathcal{N}(A) \left[r^3 + \sum_{j\ge 0} (r^2 + j^2) e^{-\alpha j} \right] \le C r^3 \mathcal{N}(A).$$

Therefore $h_A(\eta) = (2\pi)^{-3} \sum_w K_A(w) e^{-i\eta\cdot w}$ is continuous and bounded by $Cr^3\mathcal{N}(A)$. It has the same Fourier coefficients as M_A. Uniqueness of a finite measure from its Fourier coefficients follows by density of trigonometric polynomials in the continuous functions on the torus. Consequently

$$M_A = h_A(\eta)\, d\eta,$$

$$0 \le h_A \le Cr^3\mathcal{N}(A). \tag{A.lxiv}$$

This is a derived bound for an energy-weighted momentum measure. It is not an assumed bound for the unweighted spectral measure.

A.7.4. *Removing the filter and proving the plateau estimate.* Let $m_\Phi = \langle \Phi, \mathsf{E}_\mu(\cdot)\Phi\rangle$. Since M_A has a density, it has no atom at $\eta = 0$. By eq. A.lx, its weight is strictly positive at every finite $E > 0$. Thus m_Φ gives zero mass to $\{0 < E < \infty, \eta = 0\}$. The energy-zero contribution is precisely the plateau and was not removed by this inference: its weight is zero. The point $E = \infty$ contributes zero to T_μ^n for $n \ge 1$.

For $E > 0$ the function $e^{-nE}/\tanh(2rE)$ decreases in E. Using eq. A.lx, then eq. A.liv, and then eq. A.lxiv, gives

$$\begin{aligned}\langle \Phi, T_\mu^n(1-\Pi_\mu)\Phi\rangle &\le C\int_{\mathbb{T}^3} \frac{e^{-n\kappa|\eta|_\infty}}{\tanh(2r\kappa|\eta|_\infty)} h_A(\eta)\, d\eta \\ &\le Cr^3\mathcal{N}(A)\int_0^\infty u^2 e^{-n\kappa u}\left(1+\frac{1}{2r\kappa u}\right) du \\ &\le C\mathcal{N}(A)\big[(r/n)^3 + (r/n)^2\big]. \end{aligned} \tag{A.lxv}$$

In the second line we used $1/\tanh v \le 1 + 1/v$ and the three-dimensional cube shell volume $24u^2du$. The apparent singularity at $u = 0$ is integrable. The pushforward step can include $E = \infty$ and other unused spectral mass, since the integrand is nonnegative; it does not add an atom at $\eta = 0$ by eq. A.lxiv.

For an arbitrary complex A, write $A = A_+ + A_-$ with $A_\pm = (A \pm \theta_\mu A)/2$. The seminorm property and sign-change invariance imply $\mathcal{N}(A_\pm) \le \mathcal{N}(A)$. The operator $D_n = T_\mu^n(1-\Pi_\mu)$ is positive, so its quadratic form at a sum is at most twice the sum of its two quadratic forms. Applying eq. A.lxv to A_+ and A_- proves eq. A.lxv, with an enlarged numerical constant, for every A.

Finally suppose $y_\mu = |y|_\infty > 0$. The cube-crossing identity is

$$\nu(\overline{A}\tau_y B) = \langle \Phi^\mu_{\theta_\mu A}, T_\mu^n U_\mu^{y_\perp}\Phi^\mu_B\rangle.$$

The Π_μ term is eq. A.li by eq. A.lviii, conditional invariance under translations and reflection, and $U_\mu^{y_\perp}\Pi_\mu = \Pi_\mu$. For the remaining term, Cauchy–Schwarz in the positive form of D_n bounds the modulus by the geometric mean of the two quantities in eq. A.lxv. The tangential unitary commutes with D_n, so does not change that form. Also $\mathcal{N}(\theta_\mu A) = \mathcal{N}(A)$. This proves eq. A.lii. For a negative maximal coordinate use $\nu(\overline{A}\tau_{-y}B) = \overline{\nu(\overline{B}\tau_y A)}$ and conjugate symmetry of the plateau. Dilation restores spacing a and replaces distances by their numbers of lattice steps, proving the stated scaling. □

For an ergodic state the invariant conditional expectations are constants, so eq. A.lii is clustering. For a mixture its generally nonzero invariant plateau is retained. When local continuum representatives have large supremum norms, the reflection sizes in eq. A.l can still be bounded by separated reflected moments. This is the reason eq. A.lii, rather than a supremum-norm substitute, is the useful estimate for a continuum phase construction. No spectral gap above the invariant subspace has been proved: the filter weight vanishes linearly near zero energy, and removing it is exactly what produces the inverse-square term.

Corollary A.13 (Closedness of the ergodic reflection-positive class)**.** At fixed spacing, the translation-invariant measures satisfying these mirror-positivity hypotheses form a weakly closed set, and so does its subset of ergodic measures. ■□

Proof. Translation invariance and each positivity inequality on continuous local functions pass to a weak limit. Reflection invariance passes as well, and approximation in L^2 extends positivity to bounded Borel local functions. Thus the full reflection-positive class is closed.

Suppose now that ν_j are ergodic in this class and converge weakly to ν. For fixed continuous local A, B in a common cube, their plateaux under ν_j are $\overline{\nu_j(A)}\nu_j(B)$. Passing to the limit in eq. A.lii gives

$$|\nu(\overline{A}\tau_y B) - \overline{\nu(A)}\nu(B)| \le C[(r/n)^2 + (r/n)^3]\|A\|_\infty \|B\|_\infty.$$

In particular the correlation converges to the product along $y = ke_\mu$, $k \to \infty$. Its Cesaro means, with $A = B$, identify the squared L^2 norm of $E_\nu[A \mid \mathcal{I}_\mu]$ by the mean ergodic theorem. That norm is $|\nu(A)|^2$, so the conditional expectation is constant. Continuous local functions are dense in $L^2(\nu)$; hence $\mathcal{I}_\mu$, and therefore $\mathcal{I}$, is trivial. This is ergodicity of ν. □

A.8. **Coupling coordinates and conditional comparisons.** The coupling, matched-run and Ward estimates below imply their stated conclusions by elementary analytic arguments. The interacting estimates themselves remain hypotheses. The pointed families, companions, physical Hessian extractor, midpoint tents, list action and radius weights are defined in § 2.2. The pointed cancellation, nonlinear window estimate and finite formation sections have their stated background and domain hypotheses. None computes the one-loop trace or proves a matched-cutoff or typed Ward estimate.

Vacuum accounting and the stronger coupling inputs. Write $P_\circ = (\mathbf{1}, 0)$. With $E_{(0)} = 0$, the accumulated vacuum normalization is defined by

$$\begin{aligned} E_{(k+1)} &= E_{(k)} + \mathsf{e}_k, \qquad E = E_{(K)}, \\ \mathsf{e}_k &= \mathfrak{n}_k + \sum_X \left[\sum_{z \in X} E^{(k+1)}(X, P_\circ, z) + R^{(k+1)}(X, P_\circ) \right]. \end{aligned} \tag{A.lxvi}$$

Here $\mathfrak{n}_k$ is the assigned field-independent step number. For $\tau = x/\theta$, its Gaussian scaling part is $-3|\mathfrak{X}_k| \log \tau/2$; $\mathfrak{X}_k$ is the set of non-pivot bonds, with three real color coordinates per bond. Haar and gauge-fixing counts are included in that assigned number. The family in eq. A.lxvi contains the unnormalized local Gaussian numbers: $\mathbf{N}^\circ = \mathbf{N} + \mathbf{N}^\circ(P_\circ)$. Those numbers must not also be added to $\mathfrak{n}_k$. Equivalently, using $\mathbf{N}$ requires adding the removed local numbers once separately. This convention counts every constant once. At fixed calibration, $\mathfrak{n}_k, \mathbf{N}^\circ, \mathbf{G}_\tau$ have zero source derivative. Source energies are the differences of the displayed E- and R-values between sourced and unsourced runs. More explicitly, the localized source energy of level j is

$$e_j(X; w) = \sum_{z \in X} \{E^{(j),w}(X, P_\circ, z) - E^{(j),0}(X, P_\circ, z)\} + R^{(j),w}(X, P_\circ) - R^{(j),0}(X, P_\circ).$$

The source vacuum exponent is the sum of these values over levels and local domains. This definition introduces no additional arbitrary normalizer. The zero source derivative of the Gaussian pieces refers to the frozen potential presentation. Moving the source into the Gaussian action weight changes the determinant and is another presentation, whose numbers must be compared by its own sum rule.

Requirement B3 retains an actual one-loop input:

$$b_i = b_i^0 + f_i + q_i, \qquad c_0 = \frac{11N^2}{12\pi^2} \log L, \qquad \left| \sum_{i=1}^{r} (b_i^0 - c_0) \right| \le C_0. \tag{A.lxvii}$$

Here $N = 2$, and b_i^0 is independent of the bare coupling and admissible torus. A summable estimate $|b_i^0 - c_0| \le CL^{-\sigma i}$, $\sigma > 0$, suffices. The asserted normalization requires the actual lattice determinant/trace calculation and its zero-mode convention. Gaussian integration alone does not establish it.

Some later slope conclusions require more than eq. A.lxvii. Fix a calibration $\theta_0, \dots, \theta_K$, independent of the varied bare coupling. Put $\xi_j = \theta_j - x_j$. Require the actual unmarked f_i and marked q_i, for $1 \le i \le K$, to be jointly holomorphic on the independent earlier-variable polydiscs with radii

$$\begin{aligned} r_j^{\mathrm{u}} &= c\theta_j, & \sup|f_i| &\le C\theta_i^{-1/2}(\log\theta_i)^p, \\ r_j^{\mathrm{m}} &= c\theta_j(\log\theta_j)^{-C_*}, & \sup|q_i| &\le C\theta_i^{-p_R}, \qquad 0 \le j < i. \end{aligned} \tag{A.lxviii}$$

The constants $p, C_* \ge 0$, $p_R > 0$, and $c > 0$ are fixed. The actual runs must remain in the half polydiscs, with common localization, counterterms and admissible domains. These are stronger actual coupling inputs, including the marked tube. They are not inferred from holomorphy of the bare partition function, nor from a running-radius activity bound followed by two field derivatives. The marked exponent is often $p_R = (\kappa_0 - 4)/2$, but any later use must retain the actual proved loss and tube radius. All norms and source Taylor expansions here use fixed declared domains; shrinking the field domains while differentiating would be a different claim. Compatibility of the companion and earlier cutoff prefix also remains part of the construction.

A dimension-free polydisc lemma and its precise consequence.

Lemma A.14 (The bounded-polydisc estimate, code 1*e*.3.7)**.** If F is holomorphic on $\prod_{j=1}^d D(0, r_j)$ and $|F| \le B$, then

$$\sum_j r_j \left(1 - \frac{|\xi_j|^2}{r_j^2}\right) |\partial_j F(\xi)| \le B. \tag{A.lxix}$$

On the half polydisc this implies

$$\begin{aligned} \left|\sum_j v_j \partial_j F(\xi)\right| &\le \tfrac{4}{3} B \max_j |v_j|/r_j, \\ |F(\xi) - F(\xi')| &\le \tfrac{4}{3} B \max_j |\xi_j - \xi_j'|/r_j. \end{aligned} \tag{A.lxx}$$

No constant depends on d. ■

Proof. The case $B = 0$ is immediate. Set $a_j = \xi_j/r_j$ and $\phi_a(z) = (a + z)/(1 + \bar{a}z)$. Choose unit complex numbers ϵ_j so the terms in the derivative at zero of

$$H(z) = F\big(r_j \phi_{a_j}(\epsilon_j z)\big)_{j=1}^d$$

have the same argument. Since $\phi_a'(0) = 1 - |a|^2$, the modulus of that derivative is the left side of eq. A.lxix. The one-variable Schwarz lemma, applied after a disc automorphism sending $H(0)/B$ to zero, gives $|H'(0)| \le B(1 - |H(0)/B|^2) \le B$. The Schwarz lemma itself follows by applying the maximum principle to a holomorphic function vanishing at zero divided by z, first on smaller circles and then letting their radius increase to one. An attained boundary value makes H constant. On the half polydisc, eq. A.lxix gives $\sum_j r_j |\partial_j F| \le 4B/3$. This proves the first estimate of eq. A.lxx; integration along the segment from ξ to ξ', which stays in that half polydisc, proves the second. □

Assume $\theta_j \ge \theta_i$ for $j < i$, with all centers sufficiently large that $t/(\log t)^{C_*}$ is increasing. Applying the lemma separately in eq. A.lxviii bounds the absolute row sum by

$$a_i := \sum_{j<i} |\partial_{\xi_j}(f_i + q_i)| \le C\left[\theta_i^{-3/2}(\log\theta_i)^p + \theta_i^{-p_R-1}(\log\theta_i)^{C_*}\right]. \tag{A.lxxi}$$

Suppose also that the calibration has backward linear drift $\theta_i \ge h + c_1(K - i)$, $c_1 > 0$. Comparison with integrals gives

$$A := \sum_{i=1}^K a_i \le C\left[h^{-1/2}(\log h)^p + h^{-p_R}(\log h)^{C_*}\right] \longrightarrow 0.$$

Indeed substitute $t = hu$ in each integral; the integrals of $u^{-1-\delta}(1+|\log u|)^r$ are finite for $\delta > 0$. A drift with a fixed additive error is equivalent after increasing h.

For the actual differentiable recursion $x_0(\beta) = \beta$, $x_i(\beta) = \beta - \sum_{r\le i} b_r(\beta)$, put $M_i = \max_{j\le i} |x_j'|$. Calibration is held fixed, so $|b_i'| \le a_i M_{i-1}$ and $M_i \le (1+a_i)M_{i-1}$. Consequently

$$M_K \le \prod_i (1+a_i) \le e^A, \qquad \sum_i |b_i'| \le \prod_i (1+a_i) - 1 \le e^A - 1. \tag{A.lxxii}$$

The middle estimate telescopes the successive products. In particular

$$|x_K'(\beta) - 1| \le \sum_i |b_i'| \le e^A - 1 = O\Big(h^{-1/2}(\log h)^p + h^{-p_R}(\log h)^{C_*}\Big).$$

On witness prefixes with terminal $h \to \infty$, under the same uniformly admitted hypotheses, this makes the constant-source normalization tend to one with the displayed error. Identifying that prefix and derivative with the actual F3 witness remains an input; the estimate does not establish that identification. At weak coupling $A \le \log(4/3)$, hence the last sum is at most $1/3$. Constant sources varying β to $\beta - \zeta$ have the same absolute slopes. This supplies the slope premise in eq. 4.clxxv under eq. A.lxviii and the admitted drift/domain conditions. It does not prove those conditions. Reality gives $2/3 \le x_K'(\beta) \le 4/3$ on an admitted real interval. Integrating the derivative proves the uniform terminal bi-Lipschitz bound. If the same row estimates hold on a whole complex offset disc, write $\Xi_K(t) = h - t + R_K(t)$; then $R_K(0) = 0$ and $\sup|R_K'| \le 1/3$. One can construct the matching inverse without any global uniqueness assertion. For $|t| < \varrho$, solve

$$s = h - \Xi_K(t) + R_{K+1}(s)$$

on the closed disc $|s| \le 2\varrho$, assuming the functions are defined on a neighborhood of that disc. Its right side maps the disc strictly inside itself and has Lipschitz constant at most $1/3$. Iteration converges geometrically to its unique solution, uniformly on smaller t-discs. The iterates are holomorphic, so the solution is holomorphic; reality gives a real solution at real t. The bounds $|\Xi_K(t) - h| \le 4|t|/3$ and $|\Xi_{K+1}(s) - h| \ge 2|s|/3$ give $|\mathfrak{n}_K(t)| \le 2|t|$. This supplies the coordinate part of E2 when its actual full-disc premises are available, rather than proving the existence of those premises. Nor does a polydisc supremum give forgetting in $i - j$: $F_i(\xi) = B\xi_0/r_0$ is bounded by B for every i, with unchanged first derivative.

The fixed-torus coordinate and the matched limit. Fix a torus T_ℓ, $h = g^{-2}$, and a separated tuple of $n \ge 2$ compact Lipschitz tests, with the fixed norm $\|\cdot\|_\sharp$ of the source convention. Every bound below includes their product norm; its constant may depend on order and positive separation. Let $\beta_K^\natural$ be its torus-independent tuned bare center and write depth as $[s] = K - k$. Define

$$\begin{aligned} \mathsf{J} &= [-\varrho/4, \varrho/4], \qquad \Xi_K(t) = x_K^\natural(\beta_K^\natural - t), \\ F_{K,n}(t;\mathbf{f}) &= S^T_{n;K,\ell,\beta_K^\natural - t}(\mathbf{f}), \qquad \mathfrak{n}_K = \Xi_{K+1}^{-1} \circ \Xi_K. \end{aligned} \tag{A.lxxiii}$$

The inverse is the specified holomorphic matching branch. Inputs E2–E3 require its existence on a common neighborhood, reality on the real axis, uniform upper and lower real Lipschitz bounds for Ξ_K, $\Xi_K(0) = h$, and $|\Xi_K(t) - h + t| \le |t|/3$. On a fixed smaller complex neighborhood of J, require

$$\begin{aligned} &|\mathfrak{n}_K - t| + |\mathfrak{n}_K' - 1| + |\Xi_{K+1} - \Xi_K| \le C\eta_K, \\ &|F_{K,n}(t) - \mathfrak{n}_K'(t)^n F_{K+1,n}(\mathfrak{n}_K(t))| \le C_{n,\ell,\mathbf{f}}\epsilon_K, \qquad \sum_K (\eta_K + \epsilon_K) < \infty. \end{aligned} \tag{A.lxxiv}$$

The one-run estimates below supply the uniform holomorphic bound for $F_{K,n}$ on a slightly wider strip, for example $\mathcal{N}_\ell = \{|\operatorname{Re} t| < \varrho/2,\ |\operatorname{Im} t| < \upsilon_\ell\}$, where $\upsilon_\ell = c\varrho e^{-C(g)\ell^4} > 0$. Matching paths stay in that strip after shrinking it. Constants and cutoff floors may depend on this fixed ℓ. Often $\eta_K = \Upsilon_K \le CK^{-3/2}(\log(2+K))^{p+1}$; a separate remainder error Π_K is part of ϵ_K, not a polarization tensor.

The scalar coordinate and the local energies. The two estimates in eq. A.lxxiv use different comparisons. For the coordinate, let $b^A_{[u]}(t)$ and $b^B_{[u]}(t)$ be the scalar increments at the same depth for the two tuned runs. Compare them at the matched constant offsets t and $\mathfrak{n}_K(t)$, using the inverse branch already constructed. They include their marked remainders. We must show on a common offset disc, with fixed room about $|t| \le \varrho$, that

$$\sup_t |b^B_{[u]}(\mathfrak{n}_K(t)) - b^A_{[u]}(t)| \le C(\rho^{K-u} + \Pi_K), \qquad 0 \le u < K. \tag{A.lxxv}$$

Here $0 < \rho < 1$ and Π_K is the error from the unmatched large-field terms at the bare end. The derivative of each increment, including the extra increment $b^B_{[K]}$, has the one-run bound $Ca_{[u]}$, with $a_{[u]} \le C\theta^{-3/2}_{[u]}(\log \theta_{[u]})^p$. This uses the sensitivity estimate on the actual full disc as in eq. A.lxxii. The derivative loses one power of $\theta_{[u]}$ from the holomorphy radius in the bound for the part beyond one loop.

A.8.0.1. Scalar increments of partnered runs. Use the decomposition eq. 5.xxxii into the one-loop increment, the unmarked analytic coefficient f, and the marked correction q. The one-loop difference has a geometric bound at equal depth by eq. 5.cccxi at equal isotropic weights. The unmarked coefficient at equal deviations uses the transfer of the regular chain, with the fixed physical extraction radius. Changing deviations within one cutoff uses the weighted forgetting estimate on the admitted product of offset discs. At the step where a changed deviation enters, Cauchy's estimate divides the one-step bound by a radius of order the inverse coupling. Subsequent steps propagate the resulting difference by the regular age weights. This gives the single-run forcing coefficient of order $\theta^{-3/2}_{[s+1]}(\log \theta_{[s+1]})^p$ at depth s, times a geometrically decreasing kernel in the depth lag.

For the marked correction, first change the deviations of the longer run to those of the shorter run on the shared depths, keeping its extra deviation and its own remainders. This first difference uses the one-cutoff marked estimate with fixed remainder data. Next compare the two cutoffs at equal deviations. The latter difference is the difference of the two marked coefficients minus the difference of the two unmarked coefficients, with all four readouts on their common running radii. The gate for inserting an old remainder is the one of eq. 5.xxxi. It admits the remainder to the regular exponent at the age with the prescribed lattice symmetries. Its coefficient estimate thereafter uses the squared radius ratio. If χ_t is the distance of the two remainder families of depth t, the contribution on reading the coefficient at depth $s < t$ is at most $C\theta_{[t+1]}\chi_t$. Indeed, the extraction costs the inverse square of the running radius at the output, which cancels that radius squared in the ratio. There is no geometric age factor in this bound.

The regular comparison of the four chains bounds the equal-deviation coefficient difference by

$$C\left[\theta_{[s+1]}(1+K-s)\lambda^{K-s} + \Pi_K + \sum_{s<t<K} \theta_{[t+1]}\chi_t\right] \tag{A.lxxvi}$$

for some $\lambda < 1$. The first term pays for the running extraction radius and the geometric mesh defects of the partners. The bare-end remainder terms in Π_K are estimated by their sizes. The one-cutoff bound for each marked correction also bounds this difference by $C\theta^{-\nu}_{[s+1]}$, with $\nu = (\kappa_0 - 4)/2$. For $b = (1+K-s)\lambda^{K-s}$, $\min\{b\theta, \theta^{-\nu}\} \le b^{\nu/(\nu+1)}$. Retain the last two terms of eq. A.lxxvi and apply this inequality to the first. A slightly slower geometric rate absorbs the polynomial in $K-s$.

We must bound the weighted sum of remainder distances for the actual matched histories. Where $\theta_{[K]} \le 2\theta_{[s+1]}$, the two individual size bounds already give $C\Pi_K$ for this sum. Away from that range the comparison uses the two parts of the new remainder. The ordinary step puts in one part from clusters that contain a recent remainder. On the common admitted carriers let D_j be the norm of the difference of the recent remainder inputs of origin j before forming the localized vertices, and A_j the larger of their two norms. Let η be the size of the change of the other inputs in their admitted

units. For the ordinary contribution at level t, the difference of the cluster sums has bound

$$C\mathsf{s}_{t-1}\sum_{j:\,M\check{R}_j>L^{t-j}} w_{t-1,j}(D_j+\eta A_j).$$

Indeed, interpolate the recent inputs on the common domain. Differentiating the logarithm expansion marks one varied recent vertex. Its bound is $C\mathsf{s}_{t-1}w_{t-1,j}D_j$, and the rooted sum over the other vertices is uniform in that interpolation. At fixed recent inputs, every cluster in the selected sum has a recent vertex, including at complex values of the other inputs. Apply the bound with that vertex marked on the complex neighborhood of the path changing the other inputs. Cauchy's estimate on discs of radius proportional to η^{-1} along this path gives the factor η without losing the recent vertex size. The supports and age gate must be common, with the recent-vertex formation bound valid along the enlarged complex path for the other inputs, including the operators. This path uses a fixed reserve in the admitted norms. The other part comes from integrating histories in the marked operation. On a single lattice, the weighted extension estimates that part by the rare mass times the sum of the loads at level n, each with weight $(k-n+1)q_a^{(k-n-1)_+}$ at level k. The exponent next to a live component can read its retained layer repeatedly. Before integration the factor $(k-n+1)$ counts these uses. A bounded price per use is paid by strengthening the survival reserve under the eventual integral. Thus the geometric age weight for that part belongs to the integrated history. The direct recent-input coefficient has no rare-event factor. Its window has length $m_s=O(\log_L(M\check{R}_s))$. In the units of the remainder size at depth s, the ratios of the sizes over this window are bounded. On the profile S of eq. A.lxxix, the window can cost $Cm_s(1+m_s)\rho^{-m_s}$. This is a power of $\log\theta_{[s]}$ and is absorbed by the logarithmically small coefficient. The integrated part requires the full comparison of weighted histories, including the shell and availability estimates below.

Here is the summation required of the local comparison. Put $a_t=\theta_{[t+1]}\chi_t$ and $q_t=C\theta_{[t]}^{-\nu-1}(\log\theta_{[t]})^c$. A sufficient estimate after separating the direct recent-input contribution is

$$a_t\le q_t\left\{\lambda^{K-t}+(1+\varrho^{-1})\left[\sum_{u=t+1}^{K}\lambda^{u-t-1}y_u+\mathsf{h}+\sum_{j=t+1}^{K-1}a_j\right]\right\}+\sum_{j=t+1}^{K-1}P_{tj}a_j+P_{tK}\mathsf{h},$$

where $\mathsf{h}\le C\theta_{[K]}^{-\nu-1}$ is the extra bare-end input. The P_{tj} are the coefficients of the ordinary recent contribution in the weighted units. For fixed j, they vanish unless $j>t$ and the origin j is still recent at t. There are $O(1+\log\log\theta_{[j]})$ such depths. In this window $\theta_{[t+1]}/\theta_{[j+1]}$ is bounded, and the radius loss is at most $C(1+j-t)$. The column sum is therefore bounded by $C\mathsf{s}^{\mathrm{run}}(\theta_{[j]})(1+\log\log\theta_{[j]})^2$. The coupling ceiling makes its supremum small. This charge has no rare-mass factor.

Sum over $r<t<K$. The triangular term with q_ta_j has total coefficient at most $(1+\varrho^{-1})\sum_t q_t$, which is also small at the coupling ceiling. Absorb these two column bounds on the left. The extra input contributes $C\mathsf{h}$. For the coefficient of y_u, split the sum in t at $(u+r)/2$. On the earlier portion the geometric factor gives $C\theta_{[r+1]}^{-\nu}\lambda_H^{u-r-1}$ for a fixed $\lambda_H<1$ larger than $\sqrt{\lambda}$. On the later portion $\theta_{[t]}\asymp\theta_{[u]}$ and the geometric series gives $C\theta_{[u]}^{-\nu-1}(\log\theta_{[u]})^c$. The term $\sum_t q_t\lambda^{K-t}$ has the same split with $u=K$. These bounds give the weighted tail estimate used below, with the bare-end powers included in Π_K. The local estimate still requires the compared history masses on their actual test domains.

A.8.0.2. Feedback from the terminal pin. Let $y_u=\sup|\Delta_u|$ be the deviation difference on the matched offset disc and let D_s be the supremum of the increment difference in eq. A.lxxv. The pin gives $y_u\le\sum_{s<u}D_s$. On this disc the required remainder-distance estimate bounds the last sum in

eq. A.lxxvi by

$$C(\rho_0^{K-s}+\Pi_K)+C\sum_{u>s}\left[(1+\varrho^{-1})\theta_{[s+1]}^{-\nu}\rho_0^{u-s-1}+p_u\right]y_u,\qquad p_u=C\theta_{[u]}^{-\nu}(\log\theta_{[u]})^b.$$

With this estimate and the one-cutoff variation at fixed remainders, the marked difference obeys the same bound, with a rate $\rho_0<1$ large enough to include the interpolation loss. Add the one-loop and the two unmarked differences. For $r_s=\rho^{K-s}+\Pi_K$, with $\rho_0<\rho<1$, the result is

$$D_s\le Cr_s+\sum_{u>s}(k_s\rho_0^{u-s-1}+p_u)y_u, \tag{A.lxxvii}$$

where k_s is a sum of the one-cutoff sensitivity and $C(1+\varrho^{-1})\theta_{[s+1]}^{-\nu}$. The feedback acts in the opposite direction to the pin. Use the finite maximum $Y=\max_s D_s/r_s$. Then $y_u\le Y\mathsf{S}_u$. Against this profile, the geometric kernel in eq. A.lxxvii costs $Ck_s[\rho^{K-s}+(s+1)\Pi_K]$. The factor $(s+1)k_s$ is small at weak coupling since $s+1\le\theta_{[s+1]}/c_0$. The polynomial kernel costs at most $\Pi_K\sum_u up_u+CK^{-\nu}(\log(2+K))^b$, by the convolution estimate for eq. A.lxxix. Use weak coupling for the first term and the independent prefactor of Π_K for the second. Thus the kernel acting on S costs at most $r_s/2$, and $Y\le C+Y/2$. This proves eq. A.lxxv once the marked comparison has the stated bound.

A.8.0.3. The comparison families on the common scaffold. The coupled comparison supplies the matched increment estimate when its response and comparison rows apply to the actual pair of runs. Write r for depth from the terminal lattice. At the unmatched bare end $r=K$, place the longer run's family on the shorter run's scaffold by the transfer that preserves its total. On the common depths, proceed in decreasing r, and in the order of the production blocks at fixed r. For each new block use the shorter run's production with the comparison families already constructed in the input slots. This list uses the longer run's totals. It belongs to the domain of the response estimate because every inserted family obeys the bound in the units of its own component.

There are two representatives of the difference in each component c. The first adds the change M_r^c caused by the changed inputs of the shorter run's production and the change N_r^c from that production to the longer run's. The middle total cancels. The second subtracts the shorter family directly from the longer family transferred to its scaffold. Its norm is at most $(C_V+1)u_r^c$, where C_V bounds the transfer and u_r^c is the one-run unit in this component. Keep the first representative if its norm is within this bound and otherwise use the second. The norm is a supremum on the entire admitted parameter, source and torus domains. The choice is therefore fixed across those domains. The relations between the components that involve only their totals survive the choice. The source-defect components vanish at constant sources in both representatives, and the local and frozen parts of a remainder component are chosen together. The resulting family has the required local reads and is holomorphic on the admitted domain. Its norm g_r^c satisfies

$$g_r^c\le(C_V+1)u_r^c,\qquad g_r^c\le\|M_r^c\|+\|N_r^c\|.$$

In the second case the second inequality follows because the first representative exceeded the threshold. This closes the construction of the next input list.

Use the blocks $P=(\mathsf{P},Q)$, $A=(P^\flat,D)$ and $R=R'+R''$ in their prescribed reading units. Here D is the difference between the local source read and its value with the source frozen at the base point. The pointed block A is scaled by an inverse power of $\log\theta_{[r]}$, and Q,R carry the inverse squared coupling in their units. At the matched depth r_0 the running-coupling difference is zero. The increment functional on the P block then bounds the difference d_{s+1} of the two running couplings by

$$d_{s+1}\le A_0\sum_{r_0\le u\le s}g_u^P,\qquad r_0\le s<K.$$

Insert this sum into the response rows, including their weighted coupling tails. The resulting inequalities have nonnegative coefficients in the block norms. They may involve both earlier and later depths.

For the envelope put $e_r = \rho^{K-r} + \Pi_K$. The three block bounds to check are $C_E e_r$, $4C_E e_r$ and $4C_E \widehat{r}_r e_r$, respectively. Here $\widehat{r}_r$ is the one-run remainder coefficient of order $\theta_{[r]}^{1-\kappa_0/2}$, enlarged by the window factors and one factor of $1+r$ from the coupling sum. Its bare-end value sets the size of the floor Π_K. For the geometric response kernel q^{s-r}, use $q \le \rho^2$ and $e_{r+j} \le \rho^{-j} e_r$. The coupling sum up to r is at most $\rho^{K-r}/(1-\rho) + (r - r_0 + 1)\Pi_K$; convolution with the geometric kernel pays the linear factor in the lag. For the unweighted remainder sum use $\sum_s \widehat{r}_s \le 1$ and the one-run comparison $\widehat{r}_s \le C_T \rho^{-(K-s)/2} \widehat{r}_K$. This bounds $\sum_{s>r} \widehat{r}_s e_s$ by $2\Pi_K$ with the prescribed prefactor in the floor. In the short remainder window of length ℓ_r, the relative one-run bound $\widehat{r}_{r+j} \le 2(1+j)\widehat{r}_r$ leaves at most $C\ell_r^2 \rho^{-\ell_r}$ times the coefficient of that window. The small-coupling bounds for the three rows make the sum of the weighted envelope terms at most half the envelope in each row, and the direct forcing at most the other half. The transferred bare-end family satisfies the envelope there.

To apply these tests simultaneously, take the maximum of the ratios of the actual block norms to their proposed bounds. If the maximum were $t > 1$, it would occur in a response row. At that row the two half-envelope bounds give $t \le (t+1)/2$. Thus every block satisfies its envelope. In particular the coupling increment difference is $O(e_r)$ on the common offset disc, and the running-coupling difference has the preceding summed bound. This application requires the matched productions and the response rows in the same running radii as the increment functional.

For a comparison of the pointed remainder shares, make the volume allocation in each actual run before comparing them. The allocation depends on the original filing domains. For example, file a fixed analytic function first on a cube wholly inside one filing cell, and then on a larger domain containing that cube and meeting a second cell. The total function is unchanged. The second cell receives zero in the first case and the positive volume fraction of the function in the second. At a shared filing domain the two actual allocations have the same geometric weights, so their difference is the weighted sum of the differences of the individual terminal reads. That sum requires the paired terminal-read estimate on its actual carriers.

Let i'' be the filing level of a remainder from level i, and $t_i = L^{i-i''}$ the mesh ratio. The share $\mathrm{sh}(X, y)$ at y is the fraction of the level-i cubes of X in that filing cell. Evaluate $R^{(i)}(X)$ on the box background formed from the actual level-i averages in the padded box of X, and subtract $R^{(i)}(X, 1)$. The assigned domain $Y(X, y)$ contains that box and Y^+ contains the old source read. The box-background and restriction estimates on the filing radii give holomorphy. On admitted backgrounds restriction of the critical orbit identifies the box evaluation with the original one. Summing the shares over y gives one for each X, so the sum is the vacuum-subtracted total. At constant sources the identity before summing y, with boxes and shares transported under the lattice symmetries, gives covariance of the pointed total.

For the one-run compact estimate, take the box background along the complex radial line in the coarse datum. Its inverse analytic radius is bounded by $C(d_i(X)+1)t_i^2 w_{i''-1,i}^{1/2}$. The first derivative of the remainder at the identity vanishes. The second-order Schwarz estimate then gives the square of this inverse radius for the vacuum-subtracted value. This is the t_i^4 gain in the one-run filing norm.

Write $S_i^+[R]$ for the difference norm of the level-i remainder and $\widehat{\vartheta}_i$ for the decay in the datum comparison. At the shared filing slice the paired read bound gives $S_i^+[R] + \widehat{\vartheta}_i g_i^{\kappa_0}$ times the size of the individual read. For compact X of diameter D_X, that size has the factor $D_X^2 t_i^4$ times $w_{i''-1,i} e^{-\kappa_T d_i(X)}$, with $w_{i''-1,i}$ the crossing weight. There are $O(\check{R}_i^4)$ fine anchors in a filing cell. The diameter cost is bounded by $CM^2(d_i(X)+5)^2$ and $\check{R}_i^4 M^2 t_i^4 \le CM^{-2}$. The target domains of compact reads have bounded length. For long X, the length is at least $t_i^{-1} - 2$. The output weight

spends a fixed fraction of the input length decay, and another fraction leaves $Ce^{-cM\check{R}_i}$ to pay the anchor count. The crossing weight at this filing level is bounded below. The rooted sums give

$$S_{i''}^{+}[\mathsf{RF}R] \le Cw_{i''-1,i}(S_i^{+}[R] + \widehat{\vartheta}_i g_i^{\kappa_0}).$$

This estimate uses the compact and long terminal read hypotheses at the actual shared slice.

Localize the difference at each y by the alternating box sum on the shorter run's scaffold. Summing the boxes cancels the proper restrictions and leaves the full-background difference at that y. This gives a pointed comparison family on the admitted domains. Subtract its frozen value at $W(p_y)$ to obtain the source-defect component, which vanishes at constant sources. The factor of two for that subtraction is paid in changing from the Q unit to the pointed A unit under $E_0C_tg^{-2} \ge 2$, with E_0, C_t the unit constants. Add these two filed differences to the comparisons of the ordinary Q and D outputs. The hybrid production uses the filed components already in its input. The filing operation is carried out on the two actual runs.

An older remainder is read as such only in the finite band before filing. After that band its share is part of the pointed regular family. The P and A inequalities gain a sum of remainder distances over the filing depths and a term from the relative datum comparison. At most two depths file at r, each within the window of length ℓ_r. The relative datum term costs $C\rho^{-\ell_r}\mathfrak{r}_r$ times the geometric envelope, where $\mathfrak{r}_r$ is the one-run remainder size in its reading unit. The sum of the remainder distances in that window costs $C\ell_r^2\rho^{-\ell_r}\widehat{r}_r$ times the same envelope. These are the additional terms in the three row smallness test. When the finite-band response and source rows hold, the maximum argument then gives the geometric envelope with the pin at the terminal coupling of the run with filed shares.

A.8.0.4. The change of offset. The two terminal couplings agree at the matched offsets. Subtract this equality at $t = 0$ from the equality at t. The bare terms leave $t - \mathfrak{n}_K(t)$, so the matching defect is, up to sign, the sum of the centered increment differences and the centered extra increment. The one-run derivative bounds and $|\mathfrak{n}_K(t)| \le 2|t|$ bound each centered difference by $C|t|a_{[u]}$. By the Schwarz lemma and eq. A.lxxv it is also bounded by $C|t|(\rho^{K-u} + \Pi_K)/\varrho$. The extra increment costs $C|t|a_{[K]}$. Thus

$$|\mathfrak{n}_K(t) - t| \le |t|\Upsilon_K, \qquad \Upsilon_K = Ca_{[K]} + C\sum_{u<K} \min\{a_{[u]}, (\rho^{K-u} + \Pi_K)/\varrho\}. \tag{A.lxxviii}$$

For the $O(\log(2+K))$ depths nearest K, use $a_{[u]}$ and $\theta_{[u]} \asymp K$ as $K \to \infty$. Farther away, sum the geometric bound, choosing the multiple of $\log(2+K)$ so its sum is $O(K^{-2})$. The other cost is $CK\Pi_K/\varrho$. For $\Pi_K = O(K^{-5/2})$ this gives $\Upsilon_K = O_\varrho(K^{-3/2}(\log(2+K))^{p+1})$ for $p \ge 0$. The bound on Ξ'_{K+1} gives the same rate for $|\Xi_{K+1}(t) - \Xi_K(t)|$ by matching. Cauchy's estimate on a smaller disc bounds the derivative of $\mathfrak{n}_K - \mathrm{id}$ by $C\Upsilon_K$. This gives the first line of eq. A.lxxiv. Writing $N_K = -\Xi'_K(0)$, differentiation of $\Xi_{K+1} \circ \mathfrak{n}_K = \Xi_K$ gives $N_{K+1}\mathfrak{n}'_K(0) = N_K$. Hence N_K converges to a number in $[2/3, 4/3]$, with error bounded by $C\sum_{k\ge K}\Upsilon_k$.

A.8.0.5. The comparison through the sourced run. For the full comparison, index the reference choices by the depth from unit scale. In the two runs the cubes, thresholds, waiting depths and radii then agree at common depths. Cut the histories at a depth T proportional to K, with $K - T$ greater than the waiting depth there by the fixed geometric margin. On the subcollection with no creation at $u \ge T$, the bare-end rules lie beyond the retained births. After matching the real decisions, pair the labels with the same regions and retained rows at common depths. Comparison of the weights still uses their actual stored variables and factors. Consider a record formed with root at common depth $s < T$, containing a birth at depth $u \ge T$. The path to that birth occupies at least $u - s$ levels of the record. Each node on the path contributes at least M^4 sites with its own logarithmic weight, as in eq. 4.cdlxxvii and eq. 4.dxxii. On the common increasing depth frame these logarithmic weights are at least a fixed multiple of $\log\theta_{[s]}$. Thus $v^\natural \ge c_* M^4 \log\theta_{[s]}(u - s)$.

Use the mass bounds at $c' > c$ on the same raised floor and write

$$e^{cv^\natural} \le \theta_{[s]}^{-c_*(c'-c)M^4(T-s)} e^{c'v^\natural}$$

on this subcollection. The inequality holds before the upper integral, with the same localized root sum. Thus for $s \le \alpha' K < T = \alpha K + O(1)$, with $0 < \alpha' < \alpha < 1$, this unpaired part has an exponential cutoff gain. There is no extra factor for choosing a position or the first such birth because the subcollection is counted once in the mass of the whole rooted record. A birth that has been healed and erased from that record is accounted for through the terms it leaves in the recursion. The duration for which a formed mark is later carried belongs to the live-component reserve and the global label comparison. Its stored genealogy is fixed.

For a visible creation on the outer tree one can also retain its own reserve in eq. 4.dx. In the proof of eq. 4.dxi, choose a creation at $u \ge T$ on this subcollection in place of the arbitrary leaf. The other entropy and volume allocations are unchanged. The factor $\exp[-2p_0(g_{[u]})]$ gives a cutoff gain faster than any power of K for $T \asymp K$, even if this visible outer record is short. This estimate uses the actual creation reserve. A failure whose witness has been left for a later operation, or an earlier birth internal to an inner island, uses its own mass.

For the remainders formed at $u \ge T$, use the individual size $C\theta_{[u]}^{-\kappa_0/2}$ and the readout weight $C\theta_{[u]}$, with the logarithmic factors of the norm. On the weak-coupling reference line $\theta_{[u]} \asymp K$ for $T \le u \le K$. The sum over these $O(K)$ depths, including the unpaired last remainder, is at most Π_K of order $K^{-\nu}$ times a power of $\log(2+K)$, where $\nu = (\kappa_0 - 4)/2$. This part enters the comparison at lower depths without an age factor. A first disagreement in a short history at fixed common depth s can occur with no ancestral path reaching T. Its birth-scale bound depends on $\theta_{[s]}$, so one still needs the local near-threshold comparison.

Write $\Delta_u(t)$ for the difference of the two deviations at depth u and at the matched offsets $t, \mathfrak{n}_K(t)$. The matching identity sets $\Delta_0 = 0$. The deviation recursion, with the same reference increment in both runs, expresses Δ_u as a signed sum of the scalar increment differences through depth $u-1$. With

$$\mathsf{S}_u = \frac{\rho^{K+1-u}}{1-\rho} + u\Pi_K, \tag{A.lxxix}$$

the scalar estimate eq. A.lxxv gives $\sup|\Delta_u| \le C\mathsf{S}_u$. If the field v takes values in a smaller offset disc, Cauchy's estimate there bounds the derivative of Δ_u by $C\mathsf{S}_u$ with a fixed radius cost. Thus the mismatch of the pointwise deviation fields is at most $C\mathsf{S}_u$ in the maximum of the supremum norm and the depth-scaled Lipschitz seminorm of the admitted source field.

We must show on the two sourced trajectories that the distance X_s of their outputs at depth s satisfies

$$X_s \le C\mathsf{S}_{s+1} + C\sum_{u \ge s} \alpha_{s,u}\mathsf{S}_u + \sum_{u>s} \varkappa_{s,u} X_u.$$

Use a distance that compares values on common fields, with exponential localization and the units of the defect and remainder families. The small multiple of the individual sizes needed for information lost by the transfer goes in the one-step defect. The unmatched family at depth K also goes in that defect. Its scalar deviation can still enter the input sum.

For the sourced trajectory the size of its defect can be read off at formation. Let $i \le m$ and use the source norm in the units of level m. In the defect at a base point z, compare with the constant $w(p_z)$. A tree meeting all cubes of X has $d_i(X)$ edges of length ML^{i-K}. The prescribed enlargement adds a bounded number of cube lengths to the diameter. Thus

$$\sup_{p \in X^\sim} |w(p) - w(p_z)| \le CML^{i-K}(1 + d_i(X))\,\mathrm{Lip}\, w.$$

Use the constant in the scaled source norm so that the local norm of this difference is at most $e^{d_i(X)}\mathsf{l}_i$, where l_i is its Lipschitz part. This uses the boundedness of $(1+d)e^{-d}$. For a source ball

of radius r, the unit-slope estimate on the admitted line bounds the defect by $r^{-1}e^{d_i(X)}\mathsf{l}_i$ times the rate-$\kappa+1$ decay. Since $\mathsf{l}_i \le L^{-(m-i)}\|w\|_{\flat,K-m}$, this gives

$$|D^{(i),w}(X,\cdot,z)| \le r^{-1}\|w\|_{\flat,K-m}L^{-(m-i)}e^{-\kappa d_i(X)}.$$

For a drive in the unit-scale norm take $m = K$, giving size L^{-u} at depth $u = K - i$, from the moment the entry is made. The old defect is passed on unchanged. The stronger admission bound required by the next box comes from this original estimate on the actual source trajectory. A one-step estimate on free input arrays must assume that stronger bound on the inherited entries.

For a newly formed paired defect, put the two step maps on the same slope line in the source. At depth s, take a common base point y of the enlarged read and set

$$w_\lambda = w(y) + \lambda(w - w(y)).$$

The partnered source uses the pointwise matching map applied to w_λ. In each run subtract the formation map at its own frozen value at the base point of the family. Both defects vanish at $\lambda = 0$, even if the two frozen points differ. The Lipschitz bound on the full read admits the line up to radius $R \asymp L^s/(1 + d(X))$. Suppose the unscaled two-run array comparison on this enlarged disc bounds the difference of the two formation defects by $\mathcal{B}_X e^{-(\kappa+\delta)d(X)}$ with $\delta > 0$. For $R \ge 2$ Schwarz's lemma gives at $\lambda = 1$

$$CL^{-s}(1 + d(X))\mathcal{B}_X e^{-(\kappa+\delta)d(X)}.$$

For $R < 2$, the same bound follows from the unscaled comparison at the actual source, since $L^{-s}(1 + d(X))$ is then bounded below. The spare decay pays for $1 + d(X)$. The output unit L^{-s} is therefore recovered for the paired defect. To separate the displacement of the frozen points, its bound on the line is $C|\lambda| \operatorname{Lip}(w)$ times their physical separation, using the derivative of the matching map. The slope estimate gives that same displacement cost at $\lambda = 1$. The step still needs the unscaled array comparison on the admitted line.

On the common all-small label the carried Wilson weight can be compared separately. At matched levels use the same physical tent grid. Write $w_A = w$ and $w_B = \mathfrak{n}_K \circ w$, and let T^a_u denote tent interpolation at depth u, sampling at the barycentres of the plaquettes p^a_y based at the tent vertices. Set

$$f^a_u(x) = b^a_{[u]}(w_a(x)) - b^a_{[u]}(0).$$

Here the increments are written as functions of the constant source in their respective runs. Denote the constant-source shift at depth s by $\zeta^a(t)$ and the actual shift on plaquettes by c^a. The formula for the carried shift on this label gives, at a common physical position,

$$c^a(x) - \zeta^a(w_a(x)) = \sum_u (T^a_u - I)f^a_u(x),$$

where the sum is over the increments already made. The difference of the two errors is

$$\sum_{u \text{ common}} (T^A_u - I)(f^B_u - f^A_u) + \sum_{u \text{ common}} (T^B_u - T^A_u)f^B_u + (T^B_* - I)f^B_*.$$

The star is the extra first increment in run B. For a common depth, the constant-source recursion expresses the difference of the increments as the difference of two successive matched coupling mismatches. Subtracting its value at zero and using Cauchy's estimate on a smaller source disc gives

$$\operatorname{Lip}(f^B_u - f^A_u) \le C\varrho^{-1} \operatorname{Lip}(w)(\mathsf{m}_u + \mathsf{m}_{u+1}).$$

If $\xi_u \asymp L^{-u}$ is the tent width, $T^A_u - I$ costs at most $C\xi_u$ times that Lipschitz bound. The ratio ξ_u/ξ_s gives the geometric share in the source units at depth s. In the second sum only the sampling plaquettes move, by $O(a_K)$. The unmatched tent has width $O(a_K)$. These two terms together cost $Ca_K \operatorname{Lip}(w)$, using the summable derivative bounds for the increments. For later quadrature, first

differences of the multilinear tents give $\mathrm{Lip}(c^a) \le C\,\mathrm{Lip}(w)$. Indeed the samples at neighboring vertices differ by at most $C\xi_u\,\mathrm{Lip}(f_u^a)$, which pays for the ξ_u^{-1} in a tent derivative.

In the action the scalar coefficient is $x^a - c^a$. The difference of its frozen parts is the paired constant-source coupling mismatch, and the two tent errors give the additional difference just estimated. This uses the scalar weight as a potential in the frozen step. The Gaussian structure and the independent analytic current retain their own arguments.

For an inherited gauge-invariant defect, separate the family difference on the transferred fine argument from the change between the two evaluation arguments of the flat family. After subtraction of the vacuum values, the first part uses the vacuum-only window estimate of Prop. 4.6, with its squared ratio of field radii. The size already present in the inherited defect supplies $L^{-(u-s)}$ in the output units. The second part uses the actual paired evaluation fields on the complete reads. It is a separate term in the unscaled array comparison.

The regular frozen families are compared one source value at a time, with their own counterterm. A displaced barycenter costs the Lipschitz norm of v times its displacement. The source defect at depth u already has the size factor L^{-u}. Relative to the output unit L^{-s}, this contributes $L^{-(u-s)}$ times the squared ratio of the field radii. Marked remainders have the squared ratio and their own power bound. In the recent window the term passed on by the ordinary operation has a logarithmically small coefficient multiplying the input difference. It must be included when closing the full recursion. In the marked operation the dependence before the mass estimate can instead cost a power of $\log\theta_{[s]}$. There the weighted mass and the age sum must supply the smallness.

The required kernels have a geometric part c_{u-s} and a remainder part p_u of size $C\theta_{[u]}^{-\nu}(\log\theta_{[u]})^b$ with a fixed constant. For $q \ge 0$ compare S_{s+q+1} with S_{s+1} using the factors ρ^{-q} and $1+q$ on the two terms of eq. A.lxxix. Thus the geometric part preserves the profile if both $\sum_q c_q\rho^{-q}$ and $\sum_q(1+q)c_q$ are finite. For the remainder kernel, $u(1+K-u) \ge K$ for $1 \le u \le K$. The polynomial size bound for p_u and this inequality give $\sum_{u\le K} p_u\rho^{K-u} \le CK^{-\nu}(\log(2+K))^b$. The other part costs $\Pi_K\sum_u(u+1)p_u$. This sum can be made small at weak coupling by $\nu > 2$ and $\theta_{[u]} = g^{-2} + c_0 u$. In the geometric convolution at the bare end, smallness relative to Π_K instead comes from choosing the prefactor of Π_K large after the kernel constants. The same bounds apply to the input kernel on S_u, where boundedness suffices. With small weighted moments of c_{u-s} in the feedback kernel, its full action on S_{u+1} is at most $\mathsf{S}_{s+1}/2$. Backward induction gives $X_s \le C'\mathsf{S}_{s+1}$ uniformly in K.

The local energy comparison at $(\mathbf{1}, 0)$ uses this profile. A carrier of size $d(X)$ has at most $CM^4(1+d(X))$ base points. A fixed reserve in the exponential decay pays for this count, giving the local estimate with $C\mathsf{S}_{s+1}e^{-\kappa_e d(X)}$. Since $\mathsf{S}_{s+1} \le C(1+s)(\rho^{K-s}+\Pi_K)$, this is the rate used for the mixed derivatives. For the terminal integral we must also compare the weights on the common terminal fields, with the same scalar at the source and at its real center. The corresponding terminal estimate uses the kernels at depth zero and gives $C(g,\ell)\mathsf{S}_1$ on the admitted source ball. Moving the stop by a fixed number of depths restores the corresponding local energies. The same profile bounds their differences at this fixed stop.

A.8.0.6. The source-independent part of the terminal comparison. For a native healed component, form the two remainders on the same prepared determining sets. Keep the real frozen data, masks, Haar coordinates and weights of the common geometry. With the cutoff ζ_0 of the component, the last term is

$$K_5 = -\log\int e^{-S(B')}\,d\mu(B'), \qquad S(B') = x_m\big[A(\zeta_0, U^{B'}) - A(\zeta_0, U_0)\big].$$

The common measure $d\mu$ includes the Haar density, the gauge constraint and the sharp integration domain. The remaining terms of the remainder come from the exact Wilson and quadratic split. In its notation the remainder is $\mathbf{C}_m = K_5 + K_3 - (E_{12} + E_3 + E_4 + K_1 + K_2 + K_4)$. The Wilson terms use the same weights in both runs. For K_5, divide the two integrals before taking the logarithm. On the real data the ratio is the expectation of $e^{-(S_B - S_A)}$ under the normalized A integral. Thus

its log difference costs at most $\sup|S_B - S_A|$ on the same cut. This comparison uses the whole action difference in S with its own centre.

At real common data the layerwise bound on the paired minimizers is obtained by telescoping their data defects. The paired data at each occurrence have bounded depth. The weighted response bound controls the change from the defect at each step, and the common local index fixes the rows. For a Wilson cell this first bounds the curvature difference, after transporting to the same frame. The action estimate multiplies it by the bound on the two curvatures and sums the plaquettes of the cell. Before multiplying by x_n, the result is $CM^4\mathsf{e}_m^2(\vartheta_A^n + C_\chi L^{-n_\chi})$, where n_χ is the cutoff's scale exponent on the cell. The native cutoffs have $n_\chi \geq n-1$, so the cutoff term has the same decay. Two-constants interpolation on the fixed comparison discs gives the square root of the rate on the common complex data. The geometric mean with the one-run bound decaying into the core then leaves $\vartheta_A^{n/4}$ for these Wilson cell terms. The normalization and the cutoff block use their whole-term estimates.

In localizing E_{12} and E_3, assign the switch-independent subtraction to the smallest-box piece of its own cell. For the other pieces it disappears under the switch difference. The two-run estimate applies at the natural binary vertices, where the boxes contain the component and the required cell padding. The complex polydisc bound uses the sum of the separate one-run majorants. The interpolation estimate combines the two bounds, with a rate reserve for the tuple count. This gives the native class estimate

$$\sum_{Y\subset C^\sharp} \sup\bigl|\delta\mathfrak{v}^{\mathbf{C},(n)}(Y)\bigr| \leq C\vartheta_w^{n/8}, \qquad 0<\vartheta_w<1.$$

The class occurs only at the prepared levels in the component and at the two endpoint levels of the split. There is no coupling-difference term from these common weights. This supplies the source-independent load for the matched native remainder. Its use in a terminal read requires the same measure, masks and normalization above. A remainder depending on the variable source uses the separate excess comparison. A source-independent factor that varies with the label still occurs in the weights of both stop integrals.

A.8.0.7. The exterior sum of the Wilson remainder. For the outer part of E_3, the unit on a cell Δ is the weighted Wilson value at the box field minus the value at the root, with the same cutoff and plaquette base points. Its core K_Δ is the level-m cube of Δ with four layers of padding. For a treated component C let H_C be its protected block with one layer of padding and put $\epsilon_\Delta = \sum_C e^{-\delta_P d^\wedge(\Delta,H_C)}$. At the switch vertices the paired Wilson estimate is bounded by $CM^4 x_l \mathsf{e}_m^2 \epsilon_\Delta^{1/2}\langle l\rangle^{1/4}$, where l is the level of Δ and $\langle l\rangle$ is the two-cutoff rate at that level. On the contour the four Wilson values are bounded by $CM^4 x_l \mathsf{e}_m^2$, using their admitted plaquette bounds on the complete core. The switch estimate gives the square root of the product and an exponential in the number of switched cells. The switch sum at an exterior cell Q spends this last exponential to pay for the tree weight and leaves $Ce^{-\operatorname{dist}_m(Q,K_\Delta)}$.

Use subadditivity to distribute $\epsilon_\Delta^{1/4}$ over C. For each C, split its decay into four equal parts. The first pays to replace $x_l\langle l\rangle^{1/8}$ by $Cx_m\vartheta_\diamond^m$, using the flow and the crossed zones, where $\vartheta_\diamond$ is the exterior two-cutoff rate. The second leaves the gain $e^{-5\check{R}_m}$ from the separation of the outer cells from H_C. The third joins the distance from Q to K_Δ to that from Δ to H_C. The fourth sums the cells relative to the boundary of H_C. The separated-block count sums the resulting weights at Q over C. Thus the weighted norm is at most $Cx_m\mathsf{e}_m^2 e^{-5\check{R}_m}\vartheta_\diamond^m$. The factor $x_m\mathsf{e}_m^2$ is polynomial in $\log x_m$, and for a class $n\leq m$ one has $\vartheta_\diamond^m \leq \vartheta_\diamond^n \leq C\Delta_n^c$. The analogous one-run vertex estimate starts with ϵ_Δ and no two-cutoff rate, leaving $\epsilon_\Delta^{1/2}$ after the switch estimate. Three of its eight decay parts pay the lift, anchor and cell count, and the remaining five give $e^{-25\check{R}_m}$.

For E_{12}, first compare the field in a box G with the restriction from a box containing both G and the treated component. The determining data differ only on the new outer rows near the

cut. Then compare the restriction of the larger field to the field of the component's own box. In this comparison only the component's boundary shells supply the mismatch. Both mismatches are outside the core collar and are $O(\mathsf{e}_m)$. The two localized responses give the one-run depth bound on the cell, which combines with the paired vertex bound and the contour majorant. In the exterior sum the switch family must reach from a core inside the treated component to an exterior cell. Its minimum length leaves $Ce^{-c\check{R}_m}$ after paying for the tree weight and the family count. The depth-weighted cell count costs a polynomial in the logarithm of x_m. This gives a small coefficient times the class rate. Retain the class of the original cell or endpoint row. The outer E_3 terms at older levels use the classes in the untreated live regions. The full pieces confined to a treated component use the value estimate at its own box, rather than this exterior gain.

For the source-free remainder on the aligned scaffold, the exterior estimate is used on the filed domains Y_4. At an exterior root Q, terms filed as a value on one treated component do not occur. The label lab_4 of each remaining piece is formed from the four successive switch families. Filing adds whole touched components of Z, so $Q \in Y_4$ implies $Q \in \mathrm{lab}_4$ and $d_{m,Z}(Y_4) \le d_m(\mathrm{lab}_4)$. For the admitted outgoing pieces the label also reaches the source cell of a nonempty switch family. The protected margin between such a cell and Z^c gives $d_m(\mathrm{lab}_4) \ge \check{R}_m - 2$.

With $a = 31\kappa/20$, spend one additional unit of ordinary length weight to extract $e^{-(\check{R}_m-2)}$. The four successive rooted switch sums each spend at most two more units of weight. The rate condition $\kappa_1^\natural \ge c_l(a+9)+\lambda_*$ pays these losses, where c_l is the length allowance per switch cell and λ_* pays the connected count. What remains is the rooted sum of the original units of class n, whose supports have length zero. Its weights are $(2\beta_v\mathfrak{B}_v)^{1/2}$, with β_v the paired binary bound and $\mathfrak{B}_v$ the one-run contour majorant. At an interior cube only units of its treated component contribute. At an exterior cube there is just the outer unit there. The classwise cell sum gives $C\vartheta_{\mathbf{C}}^n \mathsf{N}_{\mathbf{C}}(m)$, where $\mathsf{N}_{\mathbf{C}}(m)$ is polynomial in $\check{R}_m$. Thus the filed load satisfies

$$\sup_{Q\not\subset Z} \sum_{Y_4 \ni Q} e^{a d_{m,Z}(Y_4)} \sup |\delta \mathfrak{v}^{\mathbf{C},(n)}(Y_4)| \le Ce^{-(\check{R}_m-2)}\vartheta_{\mathbf{C}}^n \mathsf{N}_{\mathbf{C}}(m).$$

This sum uses the common switch scaffold and the native piece bounds at its admitted reads.

A.8.0.8. The reads on a live strip. Use two sets for a stored term on a live strip. Its true domain X specifies its fields and dependencies. For counting, choose an optimal tree for its relative length and use the union X^θ of the cells met by the tree. Take the fat core of X^θ for the ordinary expansion. The thickening bound here uses the ordinary tree length of X^θ. A strip block whose enlargement reads X^+ outside this core carries a separate parameter for each response increment that reads it. The initial core contains the tree and its prescribed padding. For a selected set D of these parameters the new core adds only their four-layer blocks and the corridors, with the fixed final enlargement. This includes the complete carrier of the coefficient selected by D.

In the native kept term of a component Y, subtract the value at its declared reference. The true domain is $Y^\sharp$ with its assigned adjacent cell $\Delta_1(Y)$. Both lie in the one-layer enlargement of the strip, and the tree domain is $\Delta_1(Y)$ alone. At a fixed level the strips born there are separated, so at most one strip per face can choose the same cell. This gives at most $2d$ choices at that cell. The reference value stays in the original identity for that label. The nonempty switch difference and the plain derivative both kill that constant. On the admitted tube the resulting coefficient is therefore bounded using the oscillation of the kept term. At a fixed anchor the summed oscillation budget is at most $2dc_H^{\mathrm{kp}} C_\Sigma^U \check{R}_m^{p_\Sigma}$. On the admitted strip discs of radii $r_a = r_0 e^{E_a}$, a nonempty difference in the parameters $a \in D$ gains $\prod_{a\in D}(2/r_0)e^{-E_a}$. Indeed its alternating vertex sum is the integral of the mixed derivative over the unit cube. The remaining radius at each real point is at least $r_a/2$. The domain and locality rules for the strip expansion then treat this coefficient as an ordinary stored term with its enlarged core. For a plain-block derivative the source bound carries the separate decay in the plain block and in the domain's distance to the shift.

In the kept family the source separation supplies $E \geq \varpi(\frac{5}{2}\check{R}_m - 8)$, with $\varpi = \delta_1 M/8$, in the factor reserved for the strip count. All read blocks lie within eight level-m units of $Y^\sharp$, and the source is outside the collar of width $5\check{R}_m/2$. For a plain-block derivative split the domain factor $e^{-E/2}$ into two factors $e^{-E/4}$. The first pays the original level sum under $\varpi/8 \geq 2\log(2L^d)$. For a nonempty switch family split each e^{-E_a} in halves. One half per block pays the original block sum under $\varpi/2 \geq (\bar{a}+2)a_d + 1$ and $\varpi/4 \geq 4\log(2L^d)$, with $\bar{a}, a_d$ the exponents of the block count. A spare half from any selected block pays the kept count. The plain block's own decay is retained. In either case a factor at least as small as $e^{-\varpi(\frac{5}{2}\check{R}_m - 8)/4}$ remains for the polynomial anchor budget. In particular their effective contribution is bounded by a fixed constant times

$$C_\Sigma^U \sup_{R \geq 1} R^{p_\Sigma} e^{-\varpi(\frac{5}{2}R - 8)/4}.$$

This uses the source separation on the actual response paths as well as the native strip-domain rule.

A.8.0.9. Room for the enlarged strip parameters. In one run, let Ω^{s} be the source region and $D(x)$ the distance to it in the scaled path metric. For a datum b supported there, write P_b for the exponential smearing of $|b|$ at rate δ_1. The geometric summation bound gives $\mathsf{P}_b(x) \leq c_1 \|b\|_\infty e^{-\delta_1 D(x)/2}$. The strip letters grow with distance at rate $\delta_1/8$. On the enlarged blocks their envelope is $\max\{c_0^\chi, r_0^\chi C_\Delta e^{\delta_1 D(x)/8}\}$, with c_0^χ the bound for ordinary letters and C_Δ the fixed enlargement cost. In the partition of unity, at most 2^d cutoffs overlap, and the ratio of the local scale to a cutoff's scale is at most L. The first and second differences cost L and L^2, respectively. Use $C_\chi = 2^d C_\zeta L^2$ for both derivative bounds, with C_ζ the partition bound, and take the radius floor $8C_\chi$ before rescaling the strip radii.

Multiplying the letter envelope by $C_\chi \mathsf{P}_b$ bounds the resulting majorant by

$$C_\chi c_1 \|b\|_\infty \max\{c_0^\chi e^{-\delta_1 D(x)/2}, r_0^\chi C_\Delta e^{-3\delta_1 D(x)/8}\}.$$

Dividing the strip radii by C_χ cancels that factor in the strip term. The ordinary letter bound still carries it. For the pointwise room, if $|b(y)| \leq \varepsilon u(y)$ on the source region and $\sum_y e^{-\delta_1 d(x,y)/2} u(y) \leq C_T u(x)$ in the same units, split the smearing exponent in half. The identical profile estimate then holds with $c_1\|b\|_\infty$ replaced by $C_T \varepsilon u(x)$. To use the enlarged discs in the actual box we must fit the first bound under the absolute response ceiling and the second under $\ell_\iota(x)a(x)/4$, where ℓ_ι is the label scale and a is the local response majorant. This requires comparing the native datum budget with the local room on the whole box, including its covered and inactive sites.

For the two-run reading difference at a foreign site, hold the leaf function of the second run fixed and subtract its evaluation at the first run's read with the second run's common datum slots inserted. Write $h(t)$ for this difference in the strip parameters. The native reading comparison uses the full one-run discs, the relative row of the additional strip shift, and the net datum comparison on the true hull. It bounds h by $C\vartheta^\sharp \|F\|$ on those discs, with $\vartheta^\sharp$ taken at the smaller of the leaf level and the lowest zone of its true hull. Cauchy's estimate as above bounds the mixed strip piece by $C\vartheta^\sharp \|F\| \prod_{a \in D} 2/r_a$. In the subsequent affine piece estimate use the smaller radii $r_a/4$. Both bounds in the geometric mean carry the full product on these radii, so the square root falls on $\vartheta^\sharp$. A change of the leaf function at a shared read uses the ordinary one-run strip filing. At the component's own treatment the terms touching its Gaussian core use the comparison about the moved real centre.

A.8.0.10. Counting stored domains away from live strips. At level ℓ let W_ℓ be the union of the four-layer enlargements of the level-ℓ covers of the live strips. Its touching components are the islands of this counting convention. File a domain by including every island it meets. This changes its index and preserves the true dependency set. The relative length $d_\ell^\circ(Y)$ is the least length of a tree in the filed Y that meets every cube outside W_ℓ. The length is measured along the tree, including any path through an island.

For the blind filing used in this count, healing a component absorbs the terms filed on it, including terms indexed by a domain containing one of its islands. If such a term survives until $m \geq \ell$, its excused islands at ℓ survive with it. Their births belong to one component after the youngest birth, and healing that component would absorb the stored term with the rest of its local terms. The coarser cover of its excused set lies in W_m. Indeed, for $m > \ell$ the four finer layers have width $4L^{-(m-\ell)} < 1$ in level-m cells. The cover thus adds at most one layer about the coarser cover of the still-live strips. If a level-m cube of the filed domain is outside W_m, it contains a level-ℓ cube of Y outside its excused set. The old relative tree meets that cube, so it serves as a tree for the filed domain at level m with length at most $L^{-(m-\ell)} d_\ell^\circ(Y)$.

At an exterior level-ℓ root, the blind relative domain count gives a bounded sum with rate $\lambda_0 \geq \mathsf{k}_d + 1$. In that count each cube meets at most 3^d other cubes, and a neighbor belongs to at most one island. Now take an exterior level-m root Q at distance at least one from W_m. Set $y = L^{m-\ell}$. Its y^d subcubes can serve as level-ℓ roots. Islands whose births have healed can be dropped for this count since no surviving domain includes them. If a surviving domain counted at Q contains an island I, the distance from a root subcube in $Y \cap Q$ to I is at least y. A chain in Y from I to that subcube contains a first cube off I. It touches I and lies outside all the islands. The relative tree meets it and the root subcube, so its length is at least $y - 3$. At rate $\lambda \geq \mathsf{k}_d + 2$, spend one unit of the decay on this distance. The remaining rooted sum over each subcube costs at most C_{fib}. The total is at most

$$C_{\mathrm{fib}} y^d e^{-(y-3)},$$

uniformly bounded for $y \geq 1$. If the root is an island I itself at level ℓ, the pure domain $Y = I$ contributes one. Every larger domain containing I has an exterior cube touching I. Rooting at these cubes bounds the sum by $1 + 3^d C_{\mathrm{fib}} N_\ell(I)$, with $N_\ell(I)$ the number of cells of I in this partition.

An output of $\mathbf{T}_\ell$ that meets an old island also meets Ω_ℓ. The old-strip buffer gives distance at least $3\check{R}_\ell - 6$ from that island to Ω_ℓ. The same first exterior cube argument gives $d_\ell^\circ(Y) \geq 3\check{R}_\ell - 8$. One unit of the rate therefore pays the crossing weight of this store. These are counts on the filed domains. Analytic estimates use the true dependency sets and the cores of their actual trees.

A.8.0.11. The one-run sum at a strip tree cell. For a term F formed at $j < m$, write $A = X^\theta$ for its tree domain and $\mathfrak{D}_F$ for the tube on its true domain. Its size after the reference subtraction is bounded on $\mathfrak{D}_F$ by $2c_1^\flat e^{-(1+\beta/2)\kappa d_j(A)}$ for $\mathbf{R}$ and by $x^{\mathbf{T}} e^{-\kappa_{\mathrm{out}} d_j(A)}$ for $\mathbf{T}$. The formation estimate for a core at the reading level gives

$$d_m(K(A)) \leq c_H\big(1 + L^{-(m-j)} d_j(A)\big).$$

For $r \leq 8\kappa/5$, the floor on L gives $r c_H / L \leq a_\flat/4$. Thus the core weight $e^{r d_m(K(A))}$ spends at most $a_\flat/4$ of the old length decay, besides $e^{r c_H}$. The density norm spends a further $a_\flat/4$. The remaining rate for the healing term is $(1 + \beta/2)\kappa - a_\flat/2 \geq c_d + 1 + \lambda_\theta$, and the fluctuation term has at least the same reserve. First count all true domains with the same A, at cost at most $e^{\lambda_\theta(d_j(A)+1)}$. Then sum the trees through the specified root with the remaining rate $c_d + 1$. The two families together cost

$$e^{r c_H + \lambda_\theta} K(d)(2c_1^\flat + x^{\mathbf{T}}).$$

Preparatory chain terms add their stage bounds in the tree norm. At $j = m$ use the stronger creation rate for the terms that carry it, since the core length has no scale reduction there. This proves the stated rooted sum for the admitted one-run terms. For the paired estimates the coefficient and domain comparisons are needed at each reading site.

For the strip class, take an actual reading cell $\Delta \subset C \cap \Omega_n$ of level n in the native grading of the treated component C. Every term in this class carries a pocket. Let $\mathsf{b}(m-j)$ be the bound for the weighted sum at a tree root of level j, including the reserve $\varsigma_0 d_j(A)$, $\varsigma_0 = a_\flat/4$, for $j < m$. A true read reaches Δ either through the one-layer enlargement of A or through a pocket strip enlarged by three layers. Every attached pocket has a tree root within two cells of its strip.

If $j = n - u < n$, the pocket was born no later than j, and its strip satisfies $\mathrm{dist}_n(Y^\sharp, \Omega_n) \geq 5/2$. Thus its three-layer enlargement at level j cannot reach $\Delta \subset \Omega_n$. A direct read needs a tree cube near Δ as well as the cube near the pocket. The tree length is at least $(\frac{5}{2}L^u - 6)_+$. There are at most $(L^u + 2)^d$ choices for the root near Δ. The resulting count over $u \geq 1$ is bounded by $C^{<,\theta}\mathsf{b}(m-n)$, since

$$C^{<,\theta} = C_{\mathsf{b}} \sum_{u \geq 1} (1+u)^{p_{\mathsf{b}}} (L^u + 2)^d e^{-\varsigma_0 (\frac{5}{2}L^u - 6)_+} < \infty,$$

using the polynomial lag bound for b. For $j \geq n$, a direct read or a pocket of side at most one has a root in a fixed neighborhood of Δ. A larger pocket has all sides at least $1/101$ in its level-j units. Its strip must meet the seven-cell box about Δ, and the disjoint strips then fit at most 909^d such pockets against that box. A pocket of largest side s_j supplies at most $(s_j + 7)^d$ roots. If three level-j layers reach a quarter of the pocket's birth radius, $s_j \leq 1212$. Otherwise use the full neighborhood of the birth strip in the screened core. Its width at birth level m' is $5\check{R}_{m'}/2$ for $m' < h$, and $(\check{R}_h + 1)/2$ for $m' = h$, where h is the healing level of the core. Its cells have level at most m', so a contour leaving it from Δ spends at least w in contour length per traversed birth-level unit, with w the depth unit of the screened grading. Thus $\varrho(\Delta) \geq 1 + \check{R}_{m'}/4$, and the root count is at most $C(1 + \varrho(\Delta))^d$, with $\varrho(\Delta)$ its contour-depth variable. Summing these levels costs $C(m - n + 1)(1 + \varrho(\Delta))^d \mathsf{b}(m-n)$.

On an outer rim cell $\Delta \subset (C^\sharp \setminus C) \cap \Omega_m$ of level m, consider terms whose cores lie in $C^\sharp$. A pocket-only read at this cell is impossible. An own pocket is at least $9\check{R}_m$ from C^c. A foreign pocket is far enough from $C^\sharp$ that its root within two cells would put the core outside $C^\sharp$. The strip sum on this rim consequently costs just $(3^d + C^{<,\theta})\mathsf{b}(0)$. The estimates use the native reading sets. They supply the local count with no factor depending on the age of a pocket.

A.8.0.12. The strip sum in a healing component. Use the strip terms whose full admitting cores lie in C, so that their true reads X_F^{r} are contained in C. Write C for the never-integrated core of C, $h = m - N$ for its healing level, and $W(F)$ for the nonnegative weight in the cell estimate. If $X_F^{\mathsf{r}} \subset \mathsf{C}$, choose a cell of the true read closest in contour distance to C^c. The contour factor $e^{-\delta_P \hat{D}_F/4}$, with $\hat{D}_F = d^\wedge(X_F^{\mathsf{r}}, \mathsf{C}^c)$, is at most the corresponding factor for this cell. The rooted sum therefore reduces to

$$\sum_{\Delta \subset \mathsf{C}} e^{-\delta_P d^\wedge(\Delta, \mathsf{C}^c)/4} \sum_{F:\, X_F^{\mathsf{r}} \cap \Delta \neq \varnothing} W(F).$$

At a cell of depth ϱ and level n, crossing the intervening zones gives $h - n \leq \varrho$. Consequently $m - n + 1 \leq (N+2)\varrho$, and the polynomial lag bound for b gives $\mathsf{b}(m-n) \leq C(1+\varrho)^{p_{\mathsf{b}}} \mathsf{b}(N+1)$. The strip cell estimate is then at most $C(N+2)\mathsf{b}(N+1)e^{\varrho}$. Use half the screening exponent to pay e^{ϱ}: $d^\wedge(\Delta, \mathsf{C}^c) \geq (\varrho - 1)w$ and $\delta_P w/8 \geq 2$. The remaining exponential sum is bounded by the contour cell-sum estimate times the number $\mathsf{n}_\partial(m)$ of boundary cells of the closed core complement. Thus the screened strip sum is bounded by $C\mathsf{n}_\partial(m)(N+2)\mathsf{b}(N+1)$.

If the true read leaves C, root it at a cell in the closure of $C \setminus \mathsf{C}$. There $\varrho = 1$ and $h \leq n \leq m$. The strip cell estimate, summed over these cells, costs $C\mathsf{n}_{\mathrm{sh}}(m)(N+1)\mathsf{b}(N)$, with $\mathsf{n}_{\mathrm{sh}}(m)$ the cell count of this region. This case includes a term whose tree stays in C while its true read leaves it. These are one-run estimates for the strip part of the healing sum.

A.8.0.13. Oscillation of a stored term with framed slots. Consider the read of a stored term v with retained variables that rotate at sites inside the blocks. Use two admitted seeds with the same frozen component datum. In the screened core the two reads can be brought to one real centre U^s using the real gauges of the frozen-centre construction. Write their fields as $q_i = e^{i\eta X_i} U^s$ in that gauge, for $i = 0, 1$. If g_i is the change to this gauge and Q_i is the product of the frame factors of the original presentation, the physical field is q_i acted on by $(g_i Q_i)^{-1}$. Hence both physical reads can use the same value of the retained variables.

Set $X_\lambda = (1-\lambda)X_0 + \lambda X_1$ and interpolate the logarithms of the factors $c_i = g_i Q_i$ in the same way. With $q_\lambda = e^{i\eta X_\lambda} U^s$ and c_λ the exponential of the interpolated logarithm, compute the slice datum $B[q_\lambda]$ and its critical representative $V(B[q_\lambda])$. Let $u[U]$ be the site map to the block frame for a field U about U^s. The chart argument of the term is

$$u[V(B[q_\lambda])]\, u[q_\lambda]^{-1} c_\lambda.$$

The two site maps convert the frame of the configuration to that of the slice. They are evaluated at the actual rotation sites, including sites inside a block. At the endpoints the physical-frame identity gives the two original values with the retained variables held fixed.

At a rotation site of depth d_s, the screened field and frame estimates bound the log of this product by the local rotation allowance times $C(1+2|\lambda|)e^{-\delta_1 d_s/4}$, with the available margin in the constant. For a deep term let D_v be the depth of its read, so $d_s \geq D_v - c$ on each determining stencil. The core response bound keeps the potential and current on the admitted slice, and the site bounds keep the frame in its rotation domain on the disc $\rho_v = e^{\delta_1 D_v/8}$. If N_v bounds the holomorphic term minus its fixed constant on that domain, subtract its value at zero and use Schwarz's inequality at one. The oscillation is at most $2N_v/\rho_v \leq 2N_v e^{-\delta_P \widehat{D}_v/2}$ in the scaled depth $\widehat{D}_v$. When $\rho_v = 1$ or the term is outside the deep class, use the two endpoint majorants, giving $2N_v$. These are the two bounds for the oscillation sum at the component's own healing.

For the deep oscillation sum, assign a read to one of its nearest core-boundary cells. The depth rate is measured from the full read. One part of the rate pays for bringing the unit weight to that boundary, including the finer cells in its layers. A second part pays for the sum over read locations relative to the boundary. This bounds the sum of the screened oscillations by the boundary count times the per-cell unit bound. The absolute values of pieces filed inside the component are charged at their own interior stage cells. For those pieces the switch sum costs at most a constant times $e^{4d_m(K_v)}$, with K_v the core of the stored term. The original carrier tree length bounds $d_m(K_v)$, so four units of the original carrier decay cover this cost. An arrested term whose label leaves the component is counted in the exterior sum at its collar.

A.8.0.14. The exact datum in the frame of a kept factor. For the kept factors whose frame sites are top block nodes, let Σ be those sites, $V(B)$ the critical slice about the real centre, and c the frame argument of the kept factor. In the frame of the real inner variables the datum is

$$[M(V(B))^{[c^{-1}]}] = [(e^{iB} D_c)^{[c^{-1}\tau_B]}].$$

Here D_c is the real centre datum and τ_B is the node map of the slice. Brackets identify data related by a node gauge equal to the identity on Σ. A further frame d sends c to cd, since $d^{-1}c^{-1} = (cd)^{-1}$. The same slice is used. The logarithmic polar norms add as an upper bound, so composition spends the corresponding part of the frame radius.

At a leaf admitting the frame extension, write $c = e^Y w$ with w unitary. The regauging map $\rho[Y]$ takes the value e^{-Y} at Σ. If $\widehat{w}$ is a real extension of w, the framed value equals the unframed value at $(V(B)^{\rho[Y]})^{\widehat{w}^{-1}}$ with the original real inner variables. This follows by cancelling the real rotation of the variables against the real gauge. The resulting field is critical, with the exact datum displayed above. The polar extension spends $\|Y\|/(8\varepsilon_{\mathrm{fr}})$ of the slice room, where $\varepsilon_{\mathrm{fr}}$ is the frame radius. The real gauge spends none. Thus half of the frame radius costs at most $1/16$ of the slice room. For admitted charts, equality on overlapping parameter families follows first at the real values from uniqueness of the real orbit and invariance of the kept factor under the datum stabilizer. Holomorphy of the frame extension on the product of the slice and frame domains then extends that equality. The polar representative supplies a pointwise tube witness. This argument concerns frames at top nodes. The interior rotation sites of the preceding estimate need the full site map there.

For paired centres with common datum on the rows at Σ, use the same B on those rows. Denote the additional collar datum of the finer run by b_{col}. Matching the exact datum in the two birth

frames uses the finer frame $h(B)c$, where

$$h(B) = \tau^{\mathsf{B}}_{B\oplus b_{\mathrm{col}}}(\tau^{\mathsf{A}}_{B})^{-1}\Big|_{\Sigma}.$$

Indeed $(h(B)c)^{-1}\tau^{\mathsf{B}}$ and $c^{-1}\tau^{\mathsf{A}}$ agree on Σ. The far ends of the rows are compared modulo the same trivial-on-Σ gauges. A common chart then acts by right multiplication on both frames and leaves the collar variables alone. To apply this formula at the mixed complex reads we must construct the paired bases on the actual joined rows, choose the finer lift, and fit both c and $h(B)c$ in their frame budgets on the contour. The matching identity uses the admitted charts. The extension on each older factor must also be returned through the nesting step before that factor is read again.

On complete stencils the curvature and the Wilson current give part of the room estimate for a polar regauge. Each plaquette is conjugated at its base point, and the six plaquettes in a current stencil are transported to the base of the bond. Consequently the current is conjugated there in the same level units. If z bounds the polar log of the regauge, the two operator norms of the regauge and its inverse are at most e^{z}. Each of these weighted entries therefore grows by at most e^{2z}, with a relative increase bounded by $2ze^{2z}$. This controls the terms that transform by conjugation. The chart potential also reads the variation of the lifted gauge between sites. Its first differences and the changes of the joined boundary rows still have to fit in the room for the mixed contour.

On a matched closed set of determining rows one can reconstruct a critical field for the twisted datum locally. Take its physical row logarithm b about the admitted real datum. If the frame is near a nonidentity unitary section, use the real reference transported by that section. Convert b to the reduced row logarithm $b_{\natural}$ using the inverse of the outward-row correction. Solve the response equations with input $b_{\natural}$ and all switches at one. Its exact average is the specified physical datum acted on by the response's node factor. Removing this factor by a fixed analytic extension of the inverse node map gives the required datum. The response and the local row maps are holomorphic for small rows, and the stationary equation extends from the real data by holomorphy. This reconstruction gives an exact local representative whenever the physical row disc lies in the response radius. The actual paired contour must still give that disc on the closed rows and leave the required margins for the potential and the frame.

A.8.0.15. The relative frame at an already admitted later read. Let Y be a live component born at step m, with padded strip $(Y^{\sharp})^{+}$. The strip remains in the unreblocked large-field neighbourhood. Its separation from the younger determining sets leaves the read indexed by the birth level m. Use the actual paired data at this site. Write D_0 for the first run's datum with the finer run's collar entries inserted, d_{net} for the net phase, and g_{cen} for the centre map in the site's exact representation. Let u^{A} and u^{B} be the site frame corrections in the two reads and c^{A} the first frame. The path for the second run's kept factor uses the arguments

$$D_s = g_{\mathrm{cen}}^{s} e^{is d_{\mathrm{net}}} D_0 g_{\mathrm{cen}}^{-s}, \qquad c_s = e^{sZ}c^{\mathsf{A}}, \qquad e^{Z} = u^{\mathsf{B}}(u^{\mathsf{A}})^{-1}.$$

In the datum formula g_{cen}^{s} and its inverse act at the respective endpoints. At $s = 0$ the arguments are the mixed read, and at $s = 1$ they are the second run's actual read. Hold the real inner variables of Y fixed.

The bound for Z first compares the fine site map to the one constructed on the matched coarse inputs. It bounds the logarithm of their quotient by the local radius times the relative decay. A local Lipschitz estimate then replaces the coarse inputs by those of the actual first run. This gives the smallness of Z in units of the read margin. Use the centre-map and net-phase bounds in the same units. At a site with these room estimates the path stays admitted for $|s| < (8C_{\mathrm{read}}\vartheta_{Y}^{\sharp})^{-1}$, where $\vartheta_{Y}^{\sharp}$ is the relative decay of the read at level m. Schwarz applied after subtracting the value at zero bounds the reading change by $8C_{\mathrm{read}}\vartheta_{Y}^{\sharp}$ times the two-point oscillation of the kept factor at fixed inner variables.

For a nonempty switch coefficient subtract the reading change at the empty switch point. The contour bound of the resulting difference is twice the oscillation: each of the two read maps stays in the admitted datum domain. On the vertices use the reading estimate for both values. The geometric mean leaves $C(\vartheta_Y^\sharp)^{1/2}$ times the oscillation, in addition to the switch coefficient decay. Thus the two kept factors together have a reading bound $C\vartheta_f^{m/2}\check{R}_m^{p_\Sigma}$ in their class, by the oscillation sum at their birth. For the kept quadratic form the actual datum read is the block average on the exterior part of the healing core. It has no independent frame argument. This later-read calculation uses the admitted old contours and their comparison maps.

A.8.0.16. The kept Gaussian at a component's own read. For a read contained in the Gaussian core, use the supported real field U^s of the prepared determining set. The moved centre on the padded read has the form $(e^{i\eta\mathfrak{X}}U^s)^v$, with $\mathfrak{X}$ real and small in the local response norm. To test its admission in the older domain, put a real cutoff on $\mathfrak{X}$ which is one on the full clause read and zero outside the next padded set, still within the core. If the cutoff width is $u/8$, then on any older clause cube meeting it, $\xi_l|\nabla\chi| \le 8L/M$ since $\xi_l \le L\xi_j$ and $u = M\xi_j$ in the level-j read. The product rule preserves the bound on the potential and its first difference in the clause units. In the real gauge of U^s this is within the available radius of the older clause. Extend the site gauge v off the padded read and apply it after the cutoff. The resulting ambient field agrees with the moved centre on the required reads. The argument uses the margin from the read to the artificial strata of the core.

On an aligned label at healing, consider a live interrupted attempt W nested in the operated component. Use the common frozen data and the common collar variable in the two block-centre frames. The stored quadratic q_W is evaluated at that variable. Its native expansion is a sum of units T_e on complete carriers. At an admitted real vertex its sum is the retained quadratic on the physical pair. The comparison uses the determining set refined by the attempt at both vertices. Add and subtract the second unit at the first read expressed in the common datum. This separates the change of the stored coefficient from the change of its read. The reading difference vanishes if the two data agree. For a positive displacement d_e, the line in the native unit tube has radius $r_G/(4d_e)$. With unit majorant G_e, Schwarz's inequality bounds the reading part at the vertex by $4d_eG_e/r_G$. The extension in the switch parameters uses the geometric mean of this bound and the one-run majorant. Together with the stored mark, the resulting size is at most $C\varpi(e)\Delta_{n_e}^c$, where Δ_n^c is the classical load of zone n and $\varpi(e)$ is the native unit weight.

The overlap bound sums these weights by the visited collar cells. For all attempts nested in C, at a fixed zone n, the absolute vertex differences thus sum to at most $CN_n^{\mathrm{vis}}(C)\Delta_n^c$, with $N_n^{\mathrm{vis}}(C)$ the number of visited cells of that zone. Multiplying by a zone parameter of radius E_1/Δ_n, with $\Delta_n^c \le \Delta_n$, costs at most CE_1 per such cell. The rooted sum for the analytic units also retains the spatial weights. Their two tree lengths are bounded by a fixed multiple of the number of constituent cells. Spend the matching part of the native unit decay on these weights and sum the remaining overlap weights at the chosen root. This gives a bound $C\Delta_n^c$ at that root.

A.8.0.17. Composed reads through the preparatory stages. In one run let a chain enter at stage n_e and descend through stages to a stored read at $\nu \le n_e$. Use the fixed real centre U_c of the entry. On the padded leaf hull X^+ write $\mathbf{U} = e^{i\eta A'}U_c$. Extract the datum $B[\mathbf{U}]$ by the chart's nonlinear averaging map on the induced box set $\mathfrak{S}$. For this datum solve in the Landau chart at U_c with its own response $H^\dagger J(U_c)$, obtaining $V(B[\mathbf{U}])$. The stored term $F(X;\cdot)$ is evaluated at

$$S(\mathbf{U}) = (V(B[\mathbf{U}]), J(V(B[\mathbf{U}])))|_X.$$

The current in this pair is recomputed on the slice. At real points the chart represents the native leaf datum up to gauge. On the complex disc the slice is its holomorphic continuation. With no moves, the entry U_e is already critical on the induced box set by restriction from the entry chart. Uniqueness in that chart gives $S(U_e) = (U_e, J(U_e))|_X$.

For the radius check let T_i^a be the stage i bound on member E_a of the field and current table. Put $\mathrm{rm}_i^a = \mathsf{T}_i^a - \mathsf{T}_{i+1}^a$ and $G^a = \mathsf{T}_\nu^a - \mathsf{T}_{n_e}^a$. The stage-room bounds give $\mathrm{rm}_i^a \ge 0$. Let a_i^0 be the size share of the move at stage i, with the local stencil suprema included by the slowness bounds. The classical entry condition at the stage bounds $\sup(|h_i| + \ell_i|\nabla h_i|) \le a_i^0/K_o$ on its local read. The composite logarithm $\mathcal{Y}$ of the moves over U_e then has local size at most $2\ell\sum_i a_i^0/K_o$ by the small-product estimate, with ℓ the slice scale. On the admitted chart, the change of the box datum on each cube is bounded by four times the supremum of $|\mathcal{Y}|$ on that cube. This follows from the linear average bound and the remainder at U_e, using the classical ceiling $C_w|A_e| \le 2$ there, where $U_e = e^{i\eta A_e}U_c$. The local Landau response bounds and slowness therefore control the change of the member with scale power e_a by

$$\frac{16B_\natural C_{\mathrm{sl}}}{K_o}\,\ell^{1-e_a}\sum_{\nu\le i<n_e} a_i^0.$$

Here $e_a = 1, 2, 3$ for the potential, its first difference and the current respectively. For the plaquette member use the gradient bound with its extra η^2 factor. The real-centre member and the cube condition are inherited from the entry.

At a point in the units of the read, let i_1 be the first stage that raises its level, going from ν toward n_e. Before i_1 the converted share at stage i is at most $80\mathsf{r}_1\,\mathrm{rm}_i^a$, where $\mathsf{r}_1 = C_1/C_0$ is the ratio in the stage table. The later shares cannot be charged to their own stage rooms in the finer read units. Instead the share sum from i_1 onward is at most $C_\Sigma\bar{u}_{i_1}^0$, with $\bar{u}_i^a$ the local stage radii. The units at the first raising stage are still the read units, and $\bar{u}_{i_1}^a \le 40\,\mathrm{rm}_{i_1}^a$. Charge this whole part to the first raising room. The two parts spend disjoint rooms, so the total converted share is at most $400\mathsf{r}_1 G^a$. Without a raising stage only the first bound is needed. The fixed choice $K_o \ge 2^{18}B_\natural C_{\mathrm{sl}}\mathsf{r}_1$ then makes the displacement at most $G^a/8$. Adding the entry size gives

$$E_a(S(\mathbf{U})) \le \mathsf{T}_{n_e}^a + G^a/8 = \mathsf{T}_\nu^a - 7G^a/8.$$

Where the point has been raised beyond the leaf's own read level $n_F(x)$, convert the read table to that scale. If the level $n_0(x)$ before the chain exceeds $n_F = n_F(x)$, the factor in this comparison is bounded by $K_u L^{-u}3^{-v}\sqrt{u+v} \le K_u/L$, where $u = n_0 - n_F \ge 1$ and $v \ge 0$ is the excess of the current label level over n_0. At $n_0 = n_F$ the stage-table bound $(9/4)3^{-v}\sqrt{v} \le 3/4$ for $v \ge 1$ gives the same allowance. In the leaf's units the entry spends at most $3/4$ of its radius. For the displacement, the conversion gains at least one power ℓ_{n_F}/ℓ, and the share sum at the read stage is at most $C_\Sigma\bar{u}_\nu^0$. The unit comparison and the choice of K_o then bound the displacement by $1/200$ of the leaf's radius. Thus the total is at most $3/4 + 1/200 < 4/5 - 1/40$. On the label-equal part, use the scheduled table containment $\mathsf{T}_\nu^a \le (c_F^+ - \varrho_F)\mathsf{u}_F^a$, where $c_F^+\mathsf{u}_F^a$ is the leaf's full radius and $\varrho_F\mathsf{u}_F^a$ is its reserve. Fresh terms of the top layer of the healing step and terms left from a preparatory chain use their separate containment clauses, with the latter's own reserve. For the composite plaquette and current members with index at most the birth index, restriction of the slice chart identifies them with its own plaquette and current members. These checks give the one-run stored read on the admitted preparatory chain. The paired Gaussian hull comparison has its own admission.

A.8.0.18. The common datum at a preparatory vertex. Take two aligned native vertex reads over a preparatory seed. In run B let v_0 be the common datum with its prescribed B completion. Write $v_s = e^{isd_{\mathrm{net}}}v_0$ for the interpolation to the actual datum v_1, after removing the real block-centre frame factors from the two ends of the read. The logarithm d_{net} is of the resulting relative group product. In the fixed chart the response bound controls the change from v_1 in each member by $|1-s|D^a$, where $D^a = 2B_\natural\ell^{-e_a}(|d_{\mathrm{net}}|)^{\approx}$ uses the exponentially smeared modulus of the mismatch. The class of the read is governed by $q = \vartheta^{(j\wedge n_X)/2}$, where j is the formation level and n_X is a lower bound for the own read levels on X.

At a point where the label level equals the leaf's own read level, split the mismatch into cells where a move acts and cells of the entry absent from the common data. For a move cell the level l is the label level and satisfies $l \le j$. The noncommon cells have $l = j$ below the label or l below

both j and the label. On a move cell of level l the share bound is $C\vartheta^{l/2}$ times its size share. Here $l \ge j \wedge n_X$, so the preceding first-raising sum bounds this contribution to D^a by CqG^a. At a noncommon cell the mismatch is at most $C\vartheta^{l/2}$ times its local datum unit. For the smeared sum, split $e^{-2\delta_1 d}$ at distance d into rates $\delta_1, \delta_1/4, \delta_1/4, \delta_1/2$. The first converts the zone factor $\vartheta^{l/2}$ to Cq by screening. The second pays the change of local radii, the third yields the depth factor $C2^{-(j-n_F)}$ at read level n_F, and the fourth sums the rooted kernel. The depth factor is proportional to the leaf's tube fraction ϱ_F, so these cells cost $Cq\varrho_F \mathsf{u}_F^a$, with u_F^a the leaf's member unit. At a raised point convert to the earlier leaf units as above, using the screened and smeared bound with the depth factor omitted. With the constant of the comparison enlarged once, the two estimates are

$$D^a \le C_{TL} q\,(G^a + \varrho_F \mathsf{u}_F^a) \quad \text{at a label-equal point,} \qquad D^a \le (C_{TL}/10) q\,\mathsf{u}_F^a \quad \text{at a raised point.}$$

Use the datum comparison in the range $8C_{TL}q \le 1$. This follows from the coupling ceiling $8C_{TL}\vartheta^{n_c/2} \le 1$ when both the formation level and the chosen lower read level are at least n_c. Take $R = (8C_{TL}q)^{-1} \ge 1$. For $|s| \le R$, $|1-s| \le 2R$, so the first estimate spends at most a quarter of $G^a + \varrho_F \mathsf{u}_F^a$ and the second spends at most $\mathsf{u}_F^a/40$. The one-run slice margins admit these displacements in the quarter-room tube. At a raised point the largest coefficient used is $3/4 + 1/200 + 1/40$, below the quarter-room allowance $4/5 - 3/(4 \cdot 40)$. At v_0 the factor $|1-s|$ is one, which gives the smaller eighth-room tube. The datum radius itself is checked before solving for the slice. On the noncommon entries the local datum unit carries the scale factor $L^{l-\iota}$ relative to the current level ι. The comparison floor gives $\vartheta^{l/2}L^{l-\iota} \le \vartheta^{\iota/2} \le q$; on the move cells use the share bound. Thus $R \sup|d_{\mathrm{net}}|$ is controlled by the input datum ceiling and the fixed choice of C_{TL}. Together with the baseline datum budget this puts the full path in the chart's datum ball, as required for the box response estimate.

On this disc the difference $\widehat{F}^{\mathsf{B}}(v_s) - \widehat{F}^{\mathsf{B}}(v_0)$ is holomorphic, vanishes at zero, and is bounded by $2\sup|\widehat{F}^{\mathsf{B}}|$ on the admitted tube. Schwarz's lemma at $s = 1$ gives $16C_{TL}q \sup|\widehat{F}^{\mathsf{B}}|$. This supplies the reading comparison on the native preparatory vertices, using the native share and noncommon datum estimates. For a family with extra strip letters the same argument requires these datum bounds on that family.

A.8.0.19. The kept-term sum in a preparatory integration. At preparatory stage $n+1$, take a native kept term v of a live region Y born at $m < k$. Its pointed and window slots are empty. Its field read uses the padded strip hull $(Y^\sharp)^+$. The active response blocks are those whose enlargements meet this hull. At zero block parameters the move is the identity, so put this value of v in the base. Expand the remaining difference first in the nonempty active block sets A, then in cell switches for the box at fixed A.

For the cell expansion, leave the cells of the enlarged core off the mandatory core at switch value one. Partition the other cells into grains, which are unions of cells. Give all cells of a grain one switch parameter. The restricted family is holomorphic on the grain polydisc. On a zero face, deleting the grain one cell at a time uses the one-machine zero-face identity. At each grain vertex the value is the sum of cell coefficients whose selected cells lie in the enabled grains and the fixed core cells. Sorting by the set of grains met, then inverting, shows that each grain coefficient is the sum of all cell coefficients meeting exactly those grains. The subset of fixed core cells in this sum is unrestricted.

Use Cauchy's estimate on this grain coefficient before taking absolute values of the cell pieces. If $\mathcal{Y}$ is the selected grain set, its bound is the oscillation of v on its admitted read, times

$$e^{-\kappa_1^{(1)}|\mathcal{Y}|} \prod_{\square \in A} (r_\square - 1)^{-1}.$$

Here $r_\square = c_R/\vartheta(\square) \ge 2$, so each inverse radius costs at most $2\vartheta(\square)/c_R$. Piece locality requires every wall component of the selected grains to touch the enlarged core. This uses the preparatory

locality of the full padded read of v. The coefficient also reads the moved base on the enlarged core and selected grains and the stored variable Φ_Y.

Let R_n be the moved region at the stage, $w = M/M_1$, and S_v the native one-cell anchor of the strip. Use level $h+1$ for its corridors in a treated component and level k in an untreated one. The native corridor from a block $\square$ to S_v has fewer than $d(x_\square+1)$ cubes, where $x_\square$ is the distance in its corridor units. The treated and untreated corridor bounds give $x_\square + 1 \le 110 d^\wedge(\square, R_n)/w$. Thus the length weight spends at most $\delta_P d^\wedge(\square, R_n)/4$ when $\delta_P w/4 \ge 110 d(a_k+1)$. The inverse block radius decays at rate $\delta_P/2$ in this distance. After paying the corridor and the fixed flat-format costs, the block weight $y_{v,\square}$ is bounded by $K_2^\flat \vartheta e^{-\delta_P d^\wedge(\square,R_n)/4}$. The weighted grain activity is bounded by $x^U = \exp[-\kappa_1^{(1)} + (a_k+1) + 3^d c_\flat]$. The flat grain floor $2e^2 \widehat{b}_t^2 N^\flat x^U \le 1$, with $\widehat{b}_t$ the adjacency bound and $N^\flat$ the core size bound per block, gives the shape sum at most $e^{|A|}$. The factor e^{-1} per block reserved by the flat-format bound pays this cost. Put $\Sigma_v = \sum_\square y_{v,\square}$ over the blocks of the full read. The confined or two-box block count gives $\Sigma_v \le 2c_{\mathrm{p}} K_2^\flat \vartheta V'$, where V' bounds the contour block sum for a single component of R_n. The coupling ceiling gives $\Sigma_v \le 1/(3N) \le 1/2$, where N is the number of young levels of the step. The remaining block subset sum at a specified anchor $\square_0$ costs at most $e^{\Sigma_v} y_{v,\square_0}$.

At a target filing cell, the anchor can reach the cell through its own core or corridor, or through an attached wall component of grains. In the first case the cell is within $103\check{R}_k$ of the block in level-k units. In the second case the positional grain bound supplies the factor $e^{-(\mathrm{dist}_k - 103\check{R}_k)_+}$. This gives the same position factor for both cases. For the other root sum, a cell meeting S_v is within that distance of every eligible block of v, and the nonempty subset sum is bounded by $\Sigma_v e^{\Sigma_v}$.

The near-strip geometry gives $d^\wedge(\square, R_n) \ge w(5\check{R}_m/2 - 6) \ge w(\check{R}_k - 5)$ for every eligible block. In an own chain it uses the screened collar of $Y^\sharp$; at $m = h$ use the width in level-$(h+1)$ units and $L\check{R}_{h+1} \ge \check{R}_h$. In a foreign chain the collar is inside the untreated component. The hull count gives at most 2^d regions at the same birth level per block. Their polynomial oscillation bound is absorbed at rate $\delta_P/16$ in $d^\wedge$, leaving rate $3\delta_P/16$ in the block sum. Use the uniform bound for $y_{v,\square}$ before summing over the leaves at the block, since their corridors can differ.

This last sum must use the ordinary old blocks together with all blocks meeting the padded kept hulls. The old-block summation proof extends to this enlarged class. Every added block lies in the same cover and has the same lower bound $w(\check{R}_k - 5)$ on its distance to R_n, hence to each component of R_n. In the component sum at rate $\delta_P/8$, half the exponent pays V'. The near component shells then gain $e^{-(\check{R}_k - 5)}$, and the shells at distance $l\check{R}_k$ gain $e^{-l\check{R}_k}$. The outer shells around the target cell gain the position factor from the anchor bound. The original polynomial shell counts and tail floor therefore bound the enlarged block sum by the same V'. The kept contribution to each of the two rooted one-run sums is at most $CK_2^\flat \vartheta V'$ times the kept oscillation constant. This uses the native one-run tube and preparatory piece locality.

At a preparatory stage use the same unit identity after admitting the stage's endpoint maps in the local Gaussian tube. On each complete hull align the parameter-independent axial centres $U_c^{\mathsf{A}}, U_c^{\mathsf{B}}$ by a real gauge Γ, so that their coarse comparison is $\mathcal{M}((U_c^{\mathsf{B}})^\Gamma) = e^{i\eta a_c} U_c^{\mathsf{A}}$. The paired chart gives the corresponding bounds for the centre displacement, the gauge at the datum points and the displacement of the two chart fields on the parameter disc. In the local length units each is bounded by the local radius times the chart decay. When comparing the actual bond datum, take these bounds on both endpoint top blocks and on the smeared averaging contour. In addition to the chart decay there is the error L^{-m} of the averaging contour at separation m in levels. At the preparatory site both errors are bounded by $C\vartheta_2^{n_e/2}$ for the lowest zone n_e of the unit hull. The affine estimate keeps the radius factor, since it occurs in both bounds before the geometric mean, and gives decay $\vartheta_2^{n_e/4}$. The weighted pile over a finite set of cells $\mathcal{A}$ is at most $C|\mathcal{A}|\Pi_G^+(x_{k'})\Delta_n^c$

for the class (n, k'). Apply this to the cells meeting the actual preparatory block and use its block count. This gives the stage load $C\Pi_G^{\mathrm{blk}}(x_{k'})\Delta_n^c$, with Π_G^{blk} including that count.

The small factor for a block uses the count and the unit's local radius together. For each unit meeting the padded response block, choose a common site in its carrier and a current cell at that site. The cell count of $\mathcal{A}$ is bounded by the square of the window bound at this current level, by the spread condition of the response block. The current level and the level of the largest chart radius of the unit differ by at most $N_e + 3$, where N_e is two plus its number of collar cells. The flow then bounds both the window size and the old collar polylogarithm by functions of the coupling at the largest-radius cell, with an increment $O(N_e + 1)$ in inverse squared coupling. If Θ_e is that radius and ϱ_e^2 the old polylogarithm, the reserve e^{-N_e} absorbs the extra dependence on N_e and gives

$$|\mathcal{A}|\varrho_e^2\Theta_e e^{-N_e} \le C\Pi_G^{\mathrm{blk}}(x_{k'}).$$

Use the factor $1/|\mathcal{A}|$ from this bound against the positive unit pile over the cells of $\mathcal{A}$. For a nonempty response coefficient, subtract the value of the unit at zero before applying the anchored Cauchy estimate. The mixed derivative kills that constant. Its rim-anchor sets are empty because the retained collar variable is held fixed in this integration.

The layer bound in the first comparison uses the actual chain vertices at unit dilation and the cut vertices with dilation parameter between zero and one. In the product rule for these reads the dilation member can be evaluated at unit radius. It costs at most $16c_H \sup_p m_p$, where m_p is the amplitude of the source at the row p and c_H is the product-rule constant. The source bound gives $\sup_p m_p \le C\alpha_{0,m}$. This estimates the member directly from the amplitude. On the outer layer the available row room can include the large window weight. That weight remains in the room for the other members of the layer estimate, with the coupling of the same window.

These estimates concern the stored quadratic, in its own collar variables. The new Gaussian integral and its determinant have their separate comparison. At healing, for each unit, machine, filing domain and real hull centre, we must give holomorphic bond configurations on the full padded hull for all subsets of its switches. The configurations must agree bond by bond when a switch is set to zero and its membership in the subset is changed. At the binary vertices they must recover the physical axial reads in the fixed chart. If the far read sees no operated component, the unit must have its root value in the corresponding source frame. The family must stay in the hull tube and satisfy the deep spatial bound. For far units one can use the weaker contour estimate below. The vertex comparison and the rooted estimates apply to the unit values in this assembly.

For the all-one vertex take a fixed wall-connected box G containing the complete read and the full enlargements of the operated components it meets. Use the restriction rule for the determining sets and the matched frames at the glued seam. Put the four stages of the construction on this same box. The starting field is the restriction of the root. On the outer rows the shell restriction gives identical rows and levels in the successive determining sets. Each increment and the intervening gluing are supported away from these block pairs. Consequently the next stage inherits the root average on these rows. On the inner rows use the prescribed prepared data and the frozen data on their respective parts. At the glued stage the cut data are the identity on one side and averages of the matched top data on the other. Composition of the averages gives the prescribed coarse rows there. Thus the last stage has exactly the native datum of the single box. At an admitted datum, uniqueness of the critical orbit identifies the last field in the fixed axial frame. If there are no operated components in the box, there are only outer rows, and the last field and the restricted root are in the same orbit. For the Gaussian value this comparison uses the retained variables transported in the same gauge.

When the one-run and comparison presentations are used at a natural vertex in the same cutoff, their physical boundary functions must agree at a fixed collar variable. Consider the two admitted presentations as continuous families on an open set of real core data, with the same core datum and absolutely axial endpoints. On a dense set of those data the endpoints belong to one orbit at real

parameters. Remove the two accumulated frame maps to obtain the relating gauge of the physical reads. Axial transport makes this gauge constant on each core block. On the graph of core data rows the gauge at one end of a row is transported by that row to the other. At a reference node the gauge must commute with every loop holonomy. If two core-loop holonomies are free coordinates of the datum, their noncommuting values are dense. For such a pair in SU(2) the common centralizer is $\{1, -1\}$. The gauge is then the same central element on the blocks containing the hull base points, so it fixes the hull datum and the collar variable. Continuity in the real core data gives equality also at reducible data. Holomorphy in the presentation parameters then gives equality on the common parameter disc at this vertex. This use of continuity requires two admitted families over an open set. At an isolated reducible datum a stabilizer can rotate the collar variable.

The chart source of a link is fixed by the handed increment in the physical frame. If $\mathfrak{Q}_{s-1}$ is the accumulated frame map before the link, and the chart updates the average at c by $e^{ib_s(c)}$, frame covariance conjugates that factor by $\mathfrak{Q}_{s-1}(c_-)^{-1}$ in the physical average. To realize the prescribed increment $\beta_s(c)$ one therefore uses $b_s(c) = \mathrm{Ad}_{\mathfrak{Q}_{s-1}(c_-)}\,\beta_s(c)$. This is a recursive holomorphic assignment on the admitted tube, since the frame is known before the link. It preserves the size at real data, and the complex frame bound multiplies the size by at most $e^{2\cdot 1.07 K_u \varrho_\Pi}$. A row set to the previous object's own average has zero increment in both frames. For a kept Gaussian the increment may also enter its quadratic in the carrier frame, so its literal value must be kept in that quadratic.

For the zero-face check, the local fixed-point comparison uses switches on enlarged walk carriers. In top-level units give a switch cell Δ a halo $\mathcal{N}(\Delta)$ of width $3LM_1$. Multiply a walk and its transpose by the product of the switches whose halos meet its enlarged localization set, including switches of cells outside the enabled box. A shell row of level n depends on the box within $3s_n$ of the row, and $3s_n \le 3LM_1$. Thus it is the halo condition that removes walks whose rows could change when a cell is deleted.

If the walk has contour tree length $\widehat{d}$, the geometry floor places all its switch cells within $M/4$ of the tree. There are at most $C_d(1 + \widehat{d}/M)$ such cells by the covering count. For $|s(\Delta)| \le e^{\kappa_1}$ the product costs at most $e^{C_d\kappa_1} e^{\delta_0 \widehat{d}/2}$ under $\delta_0 M \ge 2C_d\kappa_1$. This leaves half of the original walk decay.

For one native response link with a fixed base, set a switch to zero and compare the two boxes. The surviving walk words have the same intermediate local stencils, levels and base values off the halo. The first kernel and its local output stencil kill the output on the halo. The last switched kernel reads only input stencils away from the halo. Where the prescribed data agree on those stencils, the two systems therefore have the same equations on the common part and the same weighted uniqueness ball for the response extended by zero. For the ordinary slot system this applies with the slot source on core rows and the prescribed current slot of the fixed base. For the sourced slot system the two extra terms are

$$-\mathcal{G}_0(1-\theta)Q^*\theta_1 H^\dagger_{\mathbf{\Omega}_1(W)} J_1, \qquad -\mathcal{G}_0(\theta J_{1,2}),$$

where W is the box of the link. Switch the cut-geometry operator $H^\dagger$ and the outer kernel $\mathcal{G}_0$ by the same rule. The two J sources are fixed in the core, and the operators between the switched kernels read only local stencils. This makes the sourced terms obey the same zero-face restriction. Rim data read from a fixed configuration agree on the common stencils as well. Uniqueness gives equality of the two outputs on the common bonds and the base on the halo. To apply this check to the Gaussian family, we must verify those walk and row identities for the boxes generated by the unit's switch subsets, including the junction data, and identify the reconstructed bonds in the fixed physical frame on the full padded read.

A.8.0.20. The exterior sum of the Gaussian units. At healing, form the core K_e of a unit by padding its hull by one layer of level-m cells and adjoining the whole protected blocks it touches. For a set of enabled exterior cells J, read in the component $G_e(J)$ of this core after adding J and the protected

blocks joined to it. A unit is far if its padded hull avoids the enlarged operated region. For a far unit subtract the value at the root before taking the alternating sum. This makes the vertex value zero when the box sees no operated component. For a deep unit use the full value, with its hull inside the collar of one treated component. The other units are shallow. The coefficient of a set B of cells is the alternating sum of the values for $J \subset B$. The sum over B recovers the full vertex value, with the root subtraction for a far unit. If a cell of B is outside $G_e(B)$, pairing subsets which differ at that cell gives zero. Thus each connected part of B must attach to the core, counting cells sharing a protected block as adjacent.

At an admitted far read let b_e bound the displacement of the hull datum from its root value at every vertex and let r_e be the local chart radius on the hull. To estimate b_e, compare the exact average of the last field with that of the root, restoring both endpoint frames. The frame corrections are products of the factors for the intervening layers. Their logarithms are bounded by the sum of the layer increments. The two averages can be compared on the disc of the same real centre, where Cauchy's estimate gives the corresponding Lipschitz bound for their logarithms. If the increments at the switch vertices decay away from the enlarged operated blocks $C^\sharp$, uniformly on the admitted tube of hull data, this gives

$$b_e \le C\alpha_{0,m} \sum_C e^{-\delta_P d^\wedge(X_e^+, C^\sharp)}.$$

Here $\alpha_{0,m}$ is the step amplitude and $d^\wedge$ is distance measured along paths in the local scale units. On the complex polydisc it suffices that the total size of the increments is bounded by the chart radius. Both estimates are on the same switch family.

For a function of that family bounded by V on the vertices and by H on the polydisc of radius ρ_1, the alternating coefficient for B is bounded by

$$\Big(\frac{4}{\rho_1 - 1}\Big)^{|B|/2} (VH)^{1/2}.$$

Indeed the vertex sum gives $2^{|B|}V$. Face agreement lets one replace the vertex value in the alternating sum by its integrated mixed derivative in all the switches of B: the terms on a zero face cancel in pairs. Cauchy's estimate gives $(2/(\rho_1 - 1))^{|B|}H$. Switches outside B stay at one. Take the geometric mean of these two bounds.

Write ν_e for the majorant of the unit and $\nu_e^\times$ for that of its common-datum difference. With the fixed tube constants absorbed, the one-run difference from the root has vertex bound $C\nu_e b_e$ and contour bound $C\nu_e r_e$. The change of the common-datum part has the same pair of bounds with ν_e replaced by $\nu_e^\times L^{-\theta j_e/4}$, where j_e is the level of the arrest. For the reading part of the two-run difference from the root, use the better of the separate one-run vertex estimates and the direct vertex comparison. With n_{X_e} the lowest zone on the hull this gives a vertex bound

$$C\nu_e \min\{b_e,\ r_e \vartheta_2^{n_{X_e}/2}\} \le C\nu_e (b_e r_e)^{1/2} \vartheta_2^{n_{X_e}/4}.$$

Its contour bound is $C\nu_e r_e$. Thus in addition to the common switch factor the reading coefficient has size at most $C\nu_e r_e^{3/4} b_e^{1/4} \vartheta_2^{n_{X_e}/8}$. The other two coefficients have the factor $(b_e r_e)^{1/2}$. The quarter-power loss in the reading part therefore affects the spatial and coupling gain as well as the zone rate. The comparison uses the zone rate bound $\vartheta_2^{n/8} \le \vartheta_f^{n/2} \le C\Delta_n^c$ for the reading class $n \le n_{X_e}$, with ϑ_f the decay rate at the later reading sites. Keep the common-datum part in its own class, at j_e or at the level of its filing cell.

For the sum at an exterior cell Q, file the piece for (e, B) on the union of the core, the cells of B, the protected blocks they touch and their attached treated components. Weight it by $e^{a d_{m,Z}}$, where $a = 31\kappa/20$ and $d_{m,Z}$ is its tree length outside the large-field region. If the coefficient is nonzero, this label connects K_e to Q. The length is at most $C(N_e + |B|)$, where N_e is two plus the number of collar cells of the unit. Its ordinary length is at least $\mathrm{dist}_m(Q, K_e) - 1$. Bound the relative length

by the ordinary one and use an extra unit of ordinary length weight to factor out $e^{1-\operatorname{dist}_m(Q,K_e)}$, with distance in level-m units. If c_l is the length allowance per switch cell, take the coefficient rate $\kappa_1^\natural$ so that $\kappa_1^\natural-(a+1)c_l$ is at least the rate required to sum connected families at the boundary of the core. This sum costs at most e^{CN_e}, since the number of core cells is $O(N_e)$ and the adjacency has bounded degree. The unit weights have a corresponding reserve in N_e. What remains to sum is the unit weight times its spatial profile and the factor $e^{-\operatorname{dist}_m(Q,K_e)}$.

For each C in the far profile, use one fraction of its spatial decay to continue that last distance to $C^\sharp$. Use a second fraction to move the decay from the hull to the filing cell of e. The hull has $O(N_e)$ touching cells, so this uses another fixed exponential in N_e. The remaining weight at each filing cell is summable over all live arrests at once. The distance sum over filing cells is bounded by a constant times the number of exterior boundary cells of $C^\sharp$. For this step the distance rate times the width of a cell in its own units must be large enough to pay for subdivision across levels. Finally the separated blocks satisfy $\sum_C e^{-\operatorname{dist}_m(Q,C^\sharp)}\le C$, by counting them in shells around Q. The boundary count costs at most a fixed power of the separation scale.

The unit weight contains a polynomial in the logarithm of the inverse squared coupling at j_e. For the common-datum comparison it is absorbed in the classical load. For the one-run estimate and the weaker reading estimate use a further fraction of the spatial decay: the path from the hull to the boundary crosses the intermediate zones, giving exponential decay in $(m-j_e-2)_+$ after the hull-size cost. The flow bounds the logarithm at j_e by its value at m plus $C\log(2+m-j_e)$. Thus the cost after summation is polynomial in the logarithm at m. Denote that cost by P_m and the common upper bound on the boundary-cell counts by $N_{\partial,m}$. In the exterior norm (the sum of the weighted suprema over the labels containing Q, followed by a supremum over exterior Q), the far one-run bound is $CN_{\partial,m}P_m\alpha_{0,m}^{1/2}$. The two-run bound for class n is

$$CN_{\partial,m}(\alpha_{0,m}^{1/2}+P_m\alpha_{0,m}^{1/4})\Delta_n^c.$$

There are enough spatial fractions in the weakest rate $\delta_P/4$: the cell-summation rate may be chosen at most $\delta_P/16$ in the scaled distance.

For the deep units, use a fixed vertex as the reference. The reference has zero alternating coefficient for nonempty B. Only those B enter the exterior norm because the core is inside the operated region. On a deep hull use the admitted contour bound on the datum increment from this vertex. The preceding comparison then uses the full contour gain $C\alpha_{0,m}e^{-\delta_P d^\wedge(X_e^+,\mathsf{C}_C^c)}$ in place of b_e, where C_C is the collar of C. Cauchy's bound for one run and the vertex/contour bound for the reading difference retain, respectively, $\alpha_{0,m}$ and $\alpha_{0,m}^{1/2}$. Sum at the exterior boundary of the collar in its own level units.

The shallow units use the tube majorant even when their hulls meet the boundary. If the arrest is inside a treated collar but its hull reaches outside, the collar-cell carrier reaches across the collar margin. If the arrest is outside all treated components but its hull meets an enlarged one, the carrier spans the separation from that arrest to the enlargement. Either way, $N_e\ge c\check R_m-C$, where $\check R_m$ is the separation scale. Spend the spare exponential in N_e to get $Ce^{-c'\check R_m}$; in the one-run sum reserve part of it for the polylogarithm at the arrest level, since the carrier has a cell for each intervening level. The same boundary sum now applies with this carrier gain in place of the small spatial amplitude.

All three estimates are small after the boundary and logarithmic costs. For the two-run direction, the dial radius cancels the classical load against the full load. These are the exterior Gaussian contributions to the terminal comparison.

A.8.0.21. Box pieces for a term at its own healing. Consider an interior unit v at the healing site **L**. By the pocket-extinction rule, each of its pockets dies inside the integration region at this step. Use its full fat core K_v in every box of the four links, along with the mandatory hubs $H_C^{(t)}$ of link t. The eligible cells at link t are the cells of its partition that meet neither the interior of any

$H_C^{(t)}$ nor K_v°. Thus a switch never cuts the core. At zero switch on Δ, the one-machine locality identity identifies the restricted response and averaging operators on K_v° for boxes differing by Δ. The moved point reads the operators through a function supported in K_v°, so it agrees for the two boxes. This applies to a shallow interior term as well as a deep one. A kept term reading a foreign live strip still uses the strip parameters above.

For a tuple of finite eligible switch sets $\vec{B} = (B_1, \dots, B_4)$, fix nested regions Y_t before varying the vertices. Take Y_t to be the union of the level-m cube cover of K_v and of the cells of $B_1, \dots, B_t$, enlarged by the components of Z it meets. Thus Y_t depends on the full sets B_s, $s \le t$. If $J_t \subset B_t$ is the enabled set, the box in Y_t consists of the fixed core and hubs there together with the cells of J_t. Hubs outside Y_t are separate wall components and are unread. Build the chain from link 4 to link 1, using at each new chart the parent readings on its layer and the prescribed data at the original sites.

For the analytic handoff to the next link, let c be a young site in that chart, with padded read $P^+(c)$. In a common frame write $b_t^{\mathrm{off}}(c)$ for the parent layer increment before the move and $b_t^{\mathrm{nat}}(c)$ for its increment after the move. Use the handed increment

$$b_t^{\mathrm{off}}(c) + \prod_{\Delta:\ \mathcal{N}(\Delta)\cap P^+(c)\neq\varnothing} s_t(\Delta)\big(b_t^{\mathrm{nat}}(c) - b_t^{\mathrm{off}}(c)\big),$$

where the product uses the link's switch cells and $\mathcal{N}(\Delta)$ is the switch halo. Compose its exponential, after frame transport, with the baseline group datum. At original sites the prescribed increment is zero. If a zero switch meets the padded read, the layer datum is the parent datum on both faces. If its halo misses the read, the natural increment is unchanged by the local response identity. At all ones the handoff is the native layer datum. In particular, the row 2 continuation uses the switched datum even off its box. Keeping the old exterior field without that switch would give two different layer data on a zero face when the toggled cube contains that read. On the admitted reference tube the number of halo factors per young site is bounded and the layer estimate keeps the new datum in its chart.

On the admitted switch discs the responses, layer averages and chart maps are holomorphic. Their composition at a fixed $\vec{B}$ has the same zero-face agreement: the regions are fixed, the parent of the toggled link is fixed, and the remaining links read its output only. For the invariant unit evaluation $F_{\vec{B}}$ on this family let $T_v(\vec{B})$ be its alternating sum over $J_t \subset B_t$ at unit switch values. For $\vec{B} \neq \vec{\varnothing}$ the mixed Cauchy estimate at radius $\rho > 1$ gives

$$|T_v(\vec{B})| \le \left(\frac{2}{\rho - 1}\right)^{\sum_t |B_t|} \inf_{c_0} \sup |F_{\vec{B}} - c_0|.$$

This estimate needs only the family for the given full tuple.

To recover the endpoint, take $D = C$ or $C^\sharp$, and sum over switch sets contained in D. Each Y_t is contained in D because D contains K_v and contains every component of Z it meets. In the sum over B_4, the regions Y_1, Y_2, Y_3 are fixed. The link 4 value for J_4 depends only on J_4 and the hubs reached by the reads from the fixed smaller regions or connected to their wall components. Extra hubs included only by $B_4 \setminus J_4$ are separate summands. At the full enabled set every cube of D outside the fixed core and hubs is enabled. Any hub in D belongs to a component of Z that meets the core or those enabled cells, so the enlargement includes it. Since D is wall connected and the other hubs are separated from it, Möbius inversion on its eligible cells gives the all-enabled link 4 on D.

The chart at Y_3 is now the restriction of that natural vertex. Indeed its block set is the induced one, its layer data are the readings of that vertex, and original sites of Y_3 are original sites of D with the same datum. The restriction rule and uniqueness of the regular critical orbit identify the two charts, up to the complex gauge in the chart. The same identification at complex data follows on the admitted connected seed discs by holomorphy. At fixed J_3, the next links use this restriction

only on the enabled box and on the reads passed to Y_2. The native vertex depends on the parent on its box, and its output off the box is the parent. These reads are independent of any extra part of Y_3 included through $B_3 \setminus J_3$; the box determining set is the label restricted and eroded at the enabled box itself. Thus the sum over B_3 gives the all-enabled link 3 on D. For link 2, use the natural vertex with the prescribed data on the two sides. Its tilted naturality gives the critical chart with the original datum passed to link 1. The same restriction and inversion first at link 2 and then at link 1 give

$$\sum_{\vec{B}:\bigcup B_t\subset D\ \forall t} T_v(\vec{B}) = F_v(X_v;(q^D,J(q^D))|_{X_v}).$$

Here q^D is the field of the four natural links on the full box D. Restriction to the hull followed by its invariant read gives the last expression. This proves the endpoint identity with the tuple-dependent regions, using the native chart restriction and locality on the admitted one-run tubes.

A.8.0.22. Counting the four successive box reads. For a kept term whose construction uses four successive links on boxes with a fixed core K, count the switched cells in their order of dependence, starting with the link read by the term. Let B_t be the switched cells of link t. Start with $\mathcal{R}_0 = K^+$, the core and its touching cells. At link t adjoin B_t and the protected blocks to K. Keep the wall components that meet $\mathcal{R}_{t-1}$, and add those components and their touching cells to obtain $\mathcal{R}_t$. These sets contain the possible reads of the first t links at any vertex with smaller switch sets.

The alternating coefficient is zero if a switch cell lies outside the retained wall components of its link. Removing it leaves every read unchanged at each vertex paired with that removal. For a nonempty tuple the coefficient is also zero if none of the retained components meets a protected block. In that case every link is at its base on the required reads. A connected part of B_t may attach to the already reached region without carrying a source of its own. Count such parts by their first cell touching the reached region, directly or through a protected block. Following a wall path to $\mathcal{R}_{t-1}$ gives such an attachment: as long as the path uses switched cells and their shared protected blocks it stays in one connected part, and the first passage into the core already meets K^+.

On this geometry the cells at the core wall are level-m cubes. Together with the bounded size of a protected block and the bounded adjacency between cells, this gives $C(1 + d_m(K) + \sum_{s<t} |B_s|)$ choices of an attachment cell. Here d_m is ordinary tree length in level-m units. The filing label is built by joining each part at its attachment and including the parents of its cells and its touched protected blocks. This costs at most $c_l|B_t|$ additional tree length at link t. This construction uses the same filing rule for membership in each box. The coefficient bound is used on this larger set of allowable families.

At the chosen connected-family decay rate, the sum for a single attachment cell is bounded by the convergent geometric series for connected cell sets through that cell. With the rate margin for the cell geometry, the product over possible attachments is at most $\exp\{(d_m(K)+1)/4+1+\sum_{s<t}|B_s|\}$. Sum the four links in reverse order, starting with link four. Each summation spends at most one unit of switch decay at each earlier link. After allowing for the tree weight e^{rd_m}, a margin of three units above the connected-family rate suffices. The four sums together cost $e^5 e^{(r+1)d_m(K)}$.

In the exterior estimate the label of a nonzero piece reaches a protected block inside the operated region and also the exterior anchor Q. Its ordinary length is at least $9\check{R}_m + m_\sharp - 2$ and at least the distance from Q to the enlarged component containing K. Here $m_\sharp$ is the width of the exterior enlargement in level-m units. Spend one unit of length decay on each lower bound. The preceding count with $r = a + 2$ leaves the weight $e^{(a+3)d_m(K)}$ for the ordinary unit size sum. The remaining distance to Q is summable over separated components. The factor $e^{-(9\check{R}_m+m_\sharp-2)}$ pays the strip and shallow-cell counts. This uses the four-link filing and its stated locality at the vertices.

A.8.0.23. Old kept terms at a later healing step. For a kept term of Y outside the region Z being treated at step k, take the four-link expansion on its admitted native family. The empty tuple reads

no response: its boxes are the hubs of Z, separated from the padded kept hull. The remaining pieces are split by the first link with a nonempty switch set. The oscillation on the admitted tube bounds the piece for $\vec{B}$ by $\mathfrak{O}(v)e^{-\kappa_1^{(1)}\sum_t |B_t|}$. The wall path from the padded hull to a source leaves the strip's collar. The depth and the number of selected cells are therefore at least $5\check{R}_m/2-1$ for a strip born at m, as needed for the kept-anchor pile. Its label connects $Q_Y(k)$ outside Z to a source cell in Z, so the native separation bound gives length at least $\check{R}_k-2$. Spend one unit of the length decay on this separation, starting the remaining pile at rate $a+1$.

For the rest of the sum use the native weighted piles $\mathsf{Q}_r[\mathfrak{L}^t]$, with t the number of links and r the rate of the label weight. The reading sets give the distance condition at each link. Summing the last link bounds the pile by $(1+C_\Sigma^{\mathrm{sum}}C_e)\mathsf{Q}_{r+2}[\mathfrak{L}^{t-1}]$ for $t\geq 2$. At the first link the kept anchor contributes $4C_\Sigma^{\mathrm{sum}}\mathsf{T}^*_{r+2}$, where T^*_r is the kept-anchor pile and the four counts come from the first nonempty link. The rate floor $\kappa_1^{(1)}\geq c_l(a+9)+\lambda_*$ permits the four sums and the one unit already spent. Since the anchor pile is at most $\mathfrak{n}^{\mathrm{kept,U}}$, the exterior norm at rate a costs

$$e^{-(\check{R}_k-2)}(1+C_\Sigma^{\mathrm{sum}}C_e)^3\,4C_\Sigma^{\mathrm{sum}}\mathfrak{n}^{\mathrm{kept,U}}.$$

If Y lies inside a treated component C, its padded hull lies in the never-integrated core C of C. On the admitted switch polydisc, compare with a fixed shape point over the same seed and retained datum in the same frame. The framed dilation radius is at least $e^{\delta_P D'/2}$, with $D'=d^\wedge((Y^\sharp)^+,\mathsf{C}^c)$. Schwarz's lemma bounds the difference by $\mathfrak{O}(v)e^{-\delta_P D'/2}$ throughout the switch polydisc. Subtracting the fixed value leaves every nonempty mixed coefficient unchanged. The switch Cauchy estimate then retains the same switch-count decay, with the improved oscillation weight. For any exterior piece at least one selected family leaves C: if all families stay inside, so do their corridors and hubs, which lie in the smallest boxes containing their endpoints. Assign Y a cell of C containing a hull point nearest to C^c. The distance of that cell to C^c is at most D', and at most 2^d regions use a given cell. Since $D'\geq w(\check{R}_m-1)/2$ for a region born at m, one quarter of the exponent absorbs the polynomial oscillation at that birth level. The other quarter sums by the boundary cell estimate for C. Thus the deep kept contribution is bounded by the boundary cell count times $C\mathfrak{n}^{\mathrm{kept,U}}$. Both bounds use the native kept tube, the locality of its pieces and the one-run geometry at healing.

A.8.0.24. The exponent of a nested history. At an admitted root read, separate the exponent of each node into its own list and quadratic form, the kept members of its immediate children, and the Gaussians of its live arrests. A child's kept member is read as its empty-switch value plus its nonempty pieces at the parent. For each such member write the two-run difference as the family difference evaluated at a common datum plus the change of read in one family. At the evaluation of a treated root the two runs use the same seed, so the choice of seed introduces no reading mark. Retain the reading marks of the individual stored terms, including the read of a child at its parent's vertex. In the child's family difference, recurse only on the empty-switch value, at the child's datum furnished by the parent's empty-switch evaluation. Keep the nonempty pieces at the parent. The levels decrease along branches and the recursion is an identity at every node. In the resulting sum each own unit is charged once, with the original class for each family mark, reading mark, form and Gaussian.

Write $N(Y)$ for the count of determining sites by stratum in the padded region of Y at its own step, and $K_{\mathrm{cell}}(m_Y)$ for the one-run per-cell bound at that node's step m_Y. The tree totals are

$$N_{\mathrm{tree}}=\sum_Y N(Y),\qquad V_{\mathrm{tree}}=\sum_Y K_{\mathrm{cell}}(m_Y)N(Y).$$

The children inject into the parent's stage cells. The live arrest collars at a node also charge those cells, with disjoint arrest regions. Hence the sum of the child count and the arrest collar-cell count is at most $2N(Y)$. At a real root the retained Gaussian value is nonpositive, and the one-run oscillation bounds its increase on the admitted tube. The node's own quadratic form has bounded

real part and costs a fixed amount at its node. The screened nonempty pieces of a child cost a fixed amount per child: subtract its empty-switch value and apply the depth estimate at fixed collar variable before the switch sum. Summing by generation gives the real-part bound $V_{\mathrm{tree}} + CN_{\mathrm{tree}}$ in either run.

For the comparison on a class dial, the per-cell family bounds give a contribution proportional to N_{tree} after cancelling the load. In the child-family contribution of a nonempty switch set, subtract the family mark at the empty-switch datum before taking the alternating sum. The comparison at fixed collar variable gives the depth factor for this difference on the contour. It pays the polynomial size of the child's family pile. For a child the change-of-read estimate at its parent's vertex has factor ϑ_f^n. For the nonempty pieces take the geometric mean of the vertex and screened contour bounds, leaving $\vartheta_f^{n/2}$ and enough depth decay to pay the child sum. The dial radius is at most $C\vartheta_f^{-n/4}$, by the lower bound on the full load. The absolute contributions from reads are therefore bounded by fixed multiples of V_{tree} and N_{tree}. The family part of the node's own form is charged at its determining rows. To bound the reading part, use the mixed-datum line from the common datum at zero to the second run's datum at one. At the node's step m_Y it lies in the tube for $|s| < R$, with $R = (8C_{\mathrm{read}}\vartheta_Y^\sharp)^{-1} \geq 2$. Here $\vartheta_Y^\sharp \leq \vartheta_f^{m_Y}$ is the relative reading rate and C_{read} includes the frame allowance. Along the line the imaginary part of the form is bounded by its small one-run majorant Σ_Y. For $\Sigma_Y > 0$, mapping the strip $|\operatorname{Im} w| < \Sigma_Y$ to the disc by $w \mapsto \tanh(\pi w/(4\Sigma_Y))$ and using Schwarz–Pick bounds the change by

$$\frac{2\Sigma_Y}{\pi} \log \frac{R+1}{R-1} \leq \frac{2\Sigma_Y}{R}.$$

Use a slightly larger strip and then its limit if needed. This also gives zero when $\Sigma_Y = 0$. The dial bound $C\vartheta_f^{-m_Y/4}$ makes the cost at most one per node for the class m_Y, by the smallness of Σ_Y. For the Gaussians use the dial bound per arrest collar cell. The preceding count charges these costs to N_{tree}. Thus the real-part estimate on the interpolated exponent has the same two tree totals, with the prescribed enlargements of the coefficients.

For a first-class component C reached from a larger residual domain, take the average of the larger root over the determining set of $(C^\sharp)^+$, including its boundary rows. Use the same real inner variables Φ_C and construct the slice on $C^\sharp$ from this averaged datum. On a finer separated box the real restriction is critical. Indeed, extend a competitor on the smaller fibre by the original root outside the box. The finer constraints preserve the larger averages. Any plaquette meeting the cut has its inside bonds on the frozen fine boundary rows, so its action is unchanged. The action difference is exactly the difference of the two smaller-box actions. This also identifies the restricted current on the bonds whose six plaquettes are retained. The inherited layer bounds and regularity of the induced datum give the real orbit identification when their bounds lie in the box radii.

On complete carriers protected by the padding, the restriction of the shell hierarchy preserves the levels of the rows. Indeed, the shell at a given level is obtained by intersecting its ambient member with the box eroded at that level, so it is unchanged on blocks away from both cut collars. The cut can still create new boundary rows. On each complete double block the exact average is holomorphic about an admitted real reference, with both endpoint node factors and the bounded averaged logarithm. The datum on the collar must be computed by this read. Even on a matched real collar the aligned datum can be $e^{iB_1}V^W$, where V^W is the native box datum and B_1 is the small collar correction.

To use this restriction in the residual production, we must match the finer separated sequence with the native padded determining set of C, including the boundary rows where the averaging contours change. The slice with the assigned current must land in the half tube of the kept-factor bound. For the paired and mixed reads we must also fit the quarter-tube and eighth-tube reserves

and the allowance for the frame change. Real restriction on the matched rows gives the real endpoint of this test. The second-class kept-member read uses its own admitted box.

A.8.0.25. Arguments of the production formula. For an aligned label use the recorded direct units, the read terms from earlier productions, and the operator and normalizing entries. The direct entries include the coupling and source coefficients and the constants in the fifth load. At a fluctuation step the operator entries are the covariance, the walk kernel and its composed quadratic form. The remaining entries include the localized potentials, Jacobians and the normalizer with its stored boundary share. At a healing step use the corresponding chain and kernel entries.

For the large-field integral, on its native history tree the exponent consists of the raw Wilson term, the inner integrals' quadratic forms and source weights, and the normalization constants at each node, together with the kept exponent of the output. The latter is the fresh form and kept potential, with the child terms and arrested Gaussians inserted as in the nested sum. Haar factors, tree constraints, the tests and the inner integral kernels are part of the production too. When a source is held fixed, some of these factors still depend on the cutoff through the coupling, density or chart. In particular the old inner quadratics have their own cutoff differences even when independent of the later background. The histories of an inner integral also act on the outer potential terms whose domains contain that integral's component.

Use the localized remainder after the Wilson and quadratic cancellation. In the resulting array its terms take the place of the raw brackets they represent. The kept factors of a pocket are separate entries until they are read into a later exponent. For a live arrest use the Gaussian piece, its shifted value minus the base, its grain piece, or its retained weight, according to the reading site. Each is taken at the site and in the variables in which it occurs. The new integral's determinant is a separate normalizing entry.

On a common chart for the integrated and retained variables, the measures, constraints, tests and reference factors must either be identified by the alignment or entered with their actual changes. With these identifications, substitution of the two arrays into the same integral formula gives the two productions. The componentwise family and reading identities then give $x^{\mathsf{B}} - x^{\mathsf{A}} = \sum_z W^z$ in the entries of that formula. This check uses the full list of native factors at the production, including the terms carried by its inner histories.

A.8.0.26. Bounds for the production on the class discs. At a fluctuation half-step the class derivative splits into an operator direction and a marked potential direction. The Gaussian units enter the latter through their weighted pile. The marked expansion at the convex base is linear in the marked potential, and bounds its derivative by the pile times the native output decay. The one-cell pile and the fluctuation weight therefore add at most $C\theta_i \Pi_G^+(x_i)\Delta_n^{\mathsf{c}}$ to the class-n input. Here θ_i bounds the inverse fluctuation weight. Every filed Gaussian unit holds a retained collar cube, so it enters the large-field activity. The list of outputs wholly in the clean region does not read it. The operator direction keeps its own bound.

For a live arrest W outside the components being treated, evaluate the retained quadratic at the new root on the top storey. Write D_W^z for the sum of its marks of class $z = (n, k')$ and $N(W)$ for the number of filing cells holding its collar. The vertex bound gives $|D_W^z| \le K_G N(W) \Delta_n^{\mathsf{c}}$. For $0 \le \lambda \le 1$ and $|\varepsilon| \le \Lambda_z$, convexity of the real part gives

$$\left|\exp\left((1-\lambda) q_W^{\mathsf{A}} + \lambda q_W^{\mathsf{B}} + \varepsilon D_W^z\right)\right| \le \max_{\mathsf{m}} |e^{q_W^{\mathsf{m}}}|\, e^{K_G E_1^z N(W)}.$$

The collar cells of distinct live arrests are charged on their disjoint regions. Keep the maximum separately for each arrest. The exterior difference from the root to the healed field is filed in the potential and uses the exterior sum above. At the last lattice the weight is read at the root without intervening links. For an arrest nested in a treated component C, use the collar-cell bound inside the exponent of the healer. Its retained variable is integrated there. For a class n present in that arrest the birth index satisfies $j(C) \le n + 1$, giving age at least $m - n - 1$ in the estimate for the healed term.

Before applying the strip estimate, take the convex bound on the one-run potentials and add the class direction. The exterior remainder and the exterior Gaussian each contribute a one-run norm and a two-run norm multiplied by the dial radius. The class direction is bounded by using $\Lambda_z \Delta_n^c \le E_1^z$. The four coefficients tend to zero under the same coupling ceiling, so each may be bounded by one before multiplying by the native strip factor. In the rim direction the two exterior marks enter the linear potential with their original classical load Δ_n^c. At a preparatory stage let ν_ζ be the array of positive unit bounds for the response direction ζ, and μ the moment bound which controls the stage holomorphy. The stage disc has radius $1/(4\mu[\nu_\zeta])$ for a nonzero moment bound. Convexity gives the one-run majorant on the base, and the block estimate gives the additive majorant on the disc. The staged leaf estimate reads this direction bound on the common chart. The Gaussian collar coordinate stays fixed there.

The exterior bracket of the fifth comparison row uses the one-run outer cell estimate in the coefficient of its own unknown. It therefore multiplies the fifth load in that row.

These modulus bounds are for the unnormalized activities. In the activity and age estimates the new costs are the nested exponent, the collar cells of the untreated arrests, and the bounded remainder per treated component. Charge them in the entropy constant and use the age bound at each generation. For the residual output with filing domain X', the same production map $\mathcal{P}_{X'}$ is used at the two arrays of slot values. Apply the modulus bounds to its values on the disc $x^\lambda + \varepsilon W^z$, where x^λ is the convex array and W^z is the class direction. Cauchy's estimate can then bound the corresponding first variation by the supremum on that disc divided by Λ_z. The own classes use their healed exponent bound. This is the passage from the component estimates to the class directions used in the terminal sum.

A.8.0.27. Accumulation of the stored boundary loads. Fix the birth zone n. Let u_j be the partial sum of the class-n loads of stored boundary terms after the first j productions that create such a term. The next production reads at most $a_n + u_j$, where a_n is the class input before this feedback. A fluctuation step adds its store with the crossing weight $w_{\ell,n}$ of its output. A healing step adds its residual store with its residual comparison coefficient. Thus the two estimates take the form

$$u_{j+1} \le (1+\mu_j)u_j + \mu_j a_n + b_j, \qquad u_0 = 0.$$

The b_j are the weighted classical inhomogeneous bounds at the fluctuation steps. The first two crossing weights are one. For $\ell \ge n+2$, let t be the depth of level $\ell - 1$ from the terminal level. The weight is bounded by a multiple of $\exp[-(2/L)(\log(x_* - 2c_2 + \lambda_{\text{flow}} t))^{r_{\text{pr}}}]$, where x_* is the lower bound on the inverse squared coupling and $\lambda_{\text{flow}} > 0$ is the flow lower bound. The depths for different ℓ are distinct. Since $r_{\text{pr}} > 1$, the terms are bounded by a summable tail uniformly for x_* above a fixed lower bound. The tail tends to zero as x_* increases. This gives $\sum_\ell w_{\ell,n} \le 3$ at small coupling.

The fluctuation coefficients are bounded by their uniform bound times $w_{\ell,n}$, and the residual coefficients already have a summable bound. With the enlarged smallness budget of the class estimates these give $\sum_j \mu_j \le 1/40$. Iterating the inequality and bounding the products of $1+\mu_j$ gives

$$u_j \le e^{1/40}\left(a_n \sum_{i<j} \mu_i + \sum_{i<j} b_i\right) \le a_n/38 + e^{1/40} \sum_{i<j} b_i.$$

The new classical marks are bounded by the existing class load and so fit in its right member. The fifth-row term stays in its own coefficient. Only these crossing-weighted stores and the residual stores enter the accumulated load.

The zone of a slot is assigned before its load is formed. A resolved slot inherits an anchor in the zone of its formation. An ordinary zone-b anchor is in Ω_{b+1}^c, and a prepared zone uses the quiet window to give the same birth bound. Trace the anchor through the later reads of that slot. As long as the containing component survives, its successors retain that birth and meet the read domain.

A second-class or arrested successor retains its record. If the containing component is healed, the interactions reading its inner history are summed in the healing bracket. A slot whose zone occurs only in the summed sequence is no longer a resolved read of that zone. Its old age factor is spent in the own-output estimate at production. File the resulting whole slot, with its norm, at the later of its stored level and the block zone. At subsequent reads use the live-incidence condition of the storage rule for that new class. For $b \le k-2$, the terminal comparison requires each sensitive label in class b to have a live component born by $b+1$. This is checked using the resolved interpolation on the actual reads and the block incidence for the own slots. The birth of an erased component gives no terminal age.

A.8.0.28. The envelope for the full zone load. The preceding recurrence sums the stores resolved in one birth zone. The boundary terms produced in healing and filed at their own level also enter the load. Let ℓ_j be the full load in zone j, including the regular and remainder reads, both boundary loads, the shift and increment reads, and the classical index terms. Put $s = K-j$, $e_s = \rho^{K-s} + \Pi_K$, and $\mathsf{l}_s = (\log \theta_{[s]})^{c_1}$, with the exponent covering the logarithmic weights of the comparison. For a lag m use

$$e_{s+m} \le \rho^{-m} e_s, \qquad \mathsf{l}_{s+m} \le \widehat{\mathsf{l}}_m \mathsf{l}_s,$$

where $\widehat{\mathsf{l}}_m$ grows at most as a power of $1+\log(1+m)$. Use the constituent response envelopes on the actual common slot reads. On a live second-class strip we must verify the relative-format version of those bounds on its stored reads, as well as the ordinary version on the other slots. In the weighted term norms S_i^+, at $i = j-m$ they give

$$S_i^+[E] \le C \mathsf{l}_{s+m} e_{s+m}, \qquad S_i^+[R] \le C \theta_{[s+m]}^{-1} \widehat{r}_{s+m} e_{s+m}.$$

The first bound adds the anchored, quadratic and source-defect entries in their respective reading units. The weight for the E terms is bounded by $C(m+1)^3 q^m$. Since $q/\rho < 1$, its sum is $O(\mathsf{l}_s e_s)$. The R weight instead contains $\theta_{[s+m]}/\theta_{[s]}$. It cancels the inverse coupling in the R reading unit. The unweighted remainder tail $\sum_{r>s} \widehat{r}_r e_r \le 2\Pi_K$ then gives $O(e_s)$ for the R load.

The gauge load convolves the shifts $O((1+s+m)e_{s+m})$ with L^{-m}, and the increments $O(e_{s+m})$ with $L^{-m/2}$. The prefactor is bounded by $C\theta_{[s]}^{-1}(\log \theta_{[s]})^{2q_\flat}$. Both convolutions are summable relative to e_s. The ratio $(1+s)/\theta_{[s]}$ is bounded by the flow. Thus this load is $O(\mathsf{l}_s^2 e_s)$. For the classical E and boundary entries the kernels are $C(m+1)^3 q^m$ and $L^{-m/2}$, respectively, times the class rate at i, bounded by $C\rho^i$. The classical R entry with $g_i^{\kappa_0}$ has instead the coupling weight of the R row. After its cancellation the sum contains $\theta_{[r]}^{1-\kappa_0/2} \rho^{K-r}$ at depth r. The one-run comparison of remainder coefficients bounds its sum by $C\Pi_K$. The last classical entry costs $C\mathsf{l}_s e_s$ by the index rate and the logarithmic weight. Together these give $O(\mathsf{l}_s^2 e_s)$ before the two boundary loads are added.

At healing level r, the own output bound uses the load in each zone $i \le r$ with its terminal age weight. Reading that output in zone j costs $L^{-(j-r)/2}$. Interchanging the sums over $r \le j$ and $i \le r$, and adding the resolved boundary estimate above, gives

$$\ell_j \le a_j^0 + \sum_{i \le j} \mathcal{K}(j,i) \ell_i, \qquad \mathcal{K}(j,i) = \frac{4(1+\epsilon_0)}{E_0} \sum_{i \le r \le j} L^{-(j-r)/2} c_1^\flat(g_r)(r-i+1) q_a^{(r-i-1)_+}.$$

Here ϵ_0 is the resolved-load coefficient of the own contribution. The direct and classical bounds just proved enter a_j^0 with fixed constants. The additional own inhomogeneity at r is bounded by $C c_1^\flat(g_r)(q_a^{r-n_c} + \vartheta^r)$ before the $L^{-(j-r)/2}$ convolution, with $\vartheta \le \rho$. The factor $q_a^{-n_c}$ is bounded by a power of $\log(X + CK)$, where $X = \theta_{[0]}$. Split that logarithm at depth $K-r$: the factor that grows with $\theta_{[K-r]}$ is absorbed by $c_1^\flat(g_r) \le C\theta_{[K-r]}^{-\kappa_0/2}$, and the factor growing with r by $(q_a/\rho)^r$. The resulting inhomogeneity after convolution is $O(e_s)$. Hence $a_j^0 \le C\omega_j$, where $\omega_j = \mathsf{l}_{K-j}^2 e_{K-j}$.

For the weighted supremum norm with weight ω_j, write $\xi = j - r$ and $\eta = r - i$. The ratio ω_i/ω_j is at most $\widehat{\mathrm{l}}^2_{\xi+\eta}\rho^{-(\xi+\eta)}$. The two geometric factors $L^{-\xi/2}$ and $q_a^{(\eta-1)_+}$ make the resulting double sum finite, since $L^{-1/2} < \rho$ and $q_a < \rho$. The norm of $\mathcal{K}$ is therefore bounded by $C \sup_r c_1^\flat(g_r) < 1$ at weak coupling. The loads are finite by the a priori dial bound. Taking the weighted norm in the displayed inequality gives $\ell_j \le C\omega_j$. For the stop at depth $s_\circ = K - k$, the same lag comparison yields

$$\sum_{j\le k}(k-j+1)q_a^{(k-j-1)_+}\ell_j \le C\mathrm{l}^2_{s_\circ}e_{s_\circ}\sum_{m\ge 0}(m+1)q_a^{(m-1)_+}\widehat{\mathrm{l}}^2_m\rho^{-m} \le C'\mathrm{l}^2_{s_\circ}e_{s_\circ}.$$

This uses the two-run fluctuation and healing bounds on the admitted slots and the actual crossing weights.

A.8.0.29. Removing the old histories from a remainder. For a history-created second-group remainder $R'^{(k)}(X)$, retain in each operated component only the sequences whose first index exceeds $n < k$. Write $0 < q_{\mathrm{op}} \le 1/2$ for their geometric forgetting rate. Denote the resulting formula by $R'^{(k)}_{>n}(X)$. Make this restriction on the full component operation, including its last exponential, before forming the receiving cluster. The following estimate uses its admitted holomorphic formation chart, with absolute subfamily majorants and the doubled whole-component input allowed by the age-dial construction.

Put $a_0 = k - n$, $p_k = p_0(g_k)$, $P = p_0^\sharp(n) = \min_{j\le n} p_0(g_j)$, and $E_k = \exp[-2p_k/(1+\beta_0)]$. Here $0 \le \beta_0 < 1$ is the degree-comparison constant, and the age comparison gives $P \ge p_k/(1+\beta_0)$. An age-a sub-sum in the removed part, $a \ge a_0$, has absolute majorant at most $\mathrm{e}\, e^{-2P}q_{\mathrm{op}}^{a+1}\sup|F|$. Multiply all these old sub-sums, in every operated component, by the same variable μ. Use the disc

$$|\mu| \le R_\mu := q_{\mathrm{op}}^{-a_0}\exp\bigl[2P - 2p_k/(1+\beta_0)\bigr].$$

The whole old input on this disc is bounded by

$$\mathrm{e}E_k\sup|F|\sum_{a\ge a_0}q_{\mathrm{op}}^{a+1-a_0} \le \mathrm{e}E_k\sup|F|, \qquad q_{\mathrm{op}} \le \tfrac{1}{2}.$$

The younger input has the same bound without the dial. Thus their sum stays within the allowed $2\mathrm{e}E_k\sup|F|$ input. This sum is made at the level of the history-dependent absolute majorants, with the last exponential split separately in each history. No unchanged per-age bound is needed after the old part is enlarged. The receiving formation therefore remains holomorphic and has its bound $\mathfrak{B}_X = e^{-p_k}e^{-\kappa d_k(X)}$ on the disc. At $\mu = 1$ it is the original remainder and at $\mu = 0$ its younger part. Since $R_\mu \ge 2$, the one-variable Schwarz estimate gives

$$\begin{aligned}|R'^{(k)}(X) - R'^{(k)}_{>n}(X)| &\le 2\mathfrak{B}_X/R_\mu\\ &\le 2e^{-\kappa d_k(X)}e^{-(1-\beta_0)P}q_{\mathrm{op}}^{k-n}.\end{aligned}$$

The second inequality follows from $p_k \le (1+\beta_0)P$. Multiplication by the domain weight gives the same bound in the flat remainder norm.

The restriction also identifies which old uses can remain. A direct use of zone $n' < n$ requires an operated sequence with first index at most $n'+1 \le n$, so it has been removed. If every live witness of a leaf on this reader belongs to one of its operated components, a live witness of level $e \le n$ likewise requires first index at most e, and has been removed. Old zone copies can still occur inside an owned leaf formed at $e > n$. The carry bound gives them the factor

$$C_* q_{\mathrm{op}}^{e-n'-1} \le C_* q_{\mathrm{op}}^{n-n'}.$$

Such a copy can occur only when the containing operated sequence starts by e. Thus the younger remainder retains these controlled old-zone reads. In using the live-witness exclusion we must check the stated witness containment on the actual receiving carriers.

A.8.0.30. Aligning the nested stored terms. An aligned outer sequence can still read a stored term whose own healed histories start below n_c. Restrict those histories before using the comparison on zones at or above $n_c - 1$. For a first-group stored leaf formula ψ formed at level e, define ψ^{AL} recursively in its formation level. Restrict the sequence sum of each healed component in its cluster to first index at least n_c. Whenever a nested occurrence loses its witness under this restriction, replace it by its own aligned formula. The recursion terminates since nested formation levels decrease. This changes the formula on its original variables and preserves the full carriers used in its majorant.

First consider the branch with per-cell leaf piles $\epsilon_e^{\mathrm{all}}$ satisfying

$$\epsilon_{\mathrm{tot}}^{\mathrm{all}} := \sum_e \epsilon_e^{\mathrm{all}} \le \tfrac{1}{16}, \qquad C_{\mathrm{AL}} := (1 - 4\epsilon_{\mathrm{tot}}^{\mathrm{all}})^{-1} \le \tfrac{4}{3}.$$

Use the same admitted per-use domains and the two independent age and leaf dials as in the carry estimate, with the operation rate q_{op}. If $\mathfrak{B}_\psi$ is the original full-carrier majorant, then

$$|\psi - \psi^{\mathrm{AL}}| \le C_{\mathrm{AL}} \mathfrak{B}_\psi q_{\mathrm{op}}^{(e-n_c)_+}.$$

Indeed, removing its own unaligned histories costs at most $\mathfrak{B}_\psi q_{\mathrm{op}}^{(e-n_c)_+}$ by geometric forgetting. For nested occurrences formed at $r < e$, the induction hypothesis gives the per-cell dial size $C_{\mathrm{AL}} \epsilon_r^{\mathrm{all}} q_{\mathrm{op}}^{(r-n_c)_+}$. The age dial has radius $q_{\mathrm{op}}^{-(e-r)}$, and the leaf dial has the reciprocal of that size as its radius. The mixed difference estimate therefore bounds this level's contribution by

$$4 C_{\mathrm{AL}} \epsilon_r^{\mathrm{all}} \mathfrak{B}_\psi q_{\mathrm{op}}^{e-r+(r-n_c)_+} \le 4 C_{\mathrm{AL}} \epsilon_r^{\mathrm{all}} \mathfrak{B}_\psi q_{\mathrm{op}}^{(e-n_c)_+}.$$

Summing over r closes the induction because $1 + 4 C_{\mathrm{AL}} \epsilon_{\mathrm{tot}}^{\mathrm{all}} = C_{\mathrm{AL}}$. The constant is independent of the formation level. If only a uniform per-level pile bound is available, the strengthened carry estimate above remains available; the present constant specifically uses the summed small pile.

Run the affine comparison on these fully aligned formulas, including all their nested occurrences. Every retained use is then in the zones where the comparison input applies. The discarded nested differences enter the unmatched term of an operated component. A reader $\mathbf{T}'_k(X)F$ gives a level-e difference the additional factor q_{op}^{k-e}. Since

$$(k - e) + (e - n_c)_+ \ge k - n_c,$$

the transported difference has the same age power as the own unaligned histories. The reader production factors and full carriers are the same in these two estimates. Sum $C_{\mathrm{AL}} \epsilon_e^{\mathrm{all}}$ over the formation levels. The own unmatched bound is multiplied by

$$C_{\mathrm{align}} := 1 + C_{\mathrm{AL}} \epsilon_{\mathrm{tot}}^{\mathrm{all}} \le \tfrac{13}{12}.$$

Keep the terminal rate q_a fixed and choose the operation age reserve so that $q_{\mathrm{op}} \le \min\{q_a, 1/2\}$. Take the admitted dial and history bounds at this reserve before fixing the coupling ceiling. For $k \ge n_c$, the operation error is then bounded by a constant times $q_a^{k-n_c}$. This construction uses the common scaffold, admitted dial domains and zone comparison of the two runs; it does not supply those inputs on an unadmitted read. For a first-group term still stored at the terminal step, the slot argument is more direct. Let Ψ_u be the term of level e occupying such a slot, and set $H_u^{(e)} = \Psi_u - \Psi_u^{\mathrm{AL}}$. Count each outer stored slot once; its aligned formula already includes the nested replacements. On its admitted full reading domain the preceding bound gives the per-cell size

$$\rho_e = C_{\mathrm{AL}} \epsilon_e^{\mathrm{all}} q_{\mathrm{op}}^{(e-n_c)_+}.$$

For nonzero ρ_e, use the slot path $x_u(\nu_e) = \Psi_u^{\mathrm{AL}} + \nu_e H_u^{(e)}$, with the other level slots held at their current endpoints. Its values at zero and one are the aligned and original slots. Omit levels with zero pile. The stored-family value and activity budgets are linear in this pile. Thus a single level-e parameter multiplying $H_u^{(e)}$ has a disc of radius a fixed multiple of ρ_e^{-1} in the terminal slot. Reserve

the corresponding one-unit value and activity allowance, with the coupling ceiling making the radius at least two. Keep the ramps, tests and real geometry fixed. The terminal modulus proof uses these value and activity bounds and the same raw Wilson factors, so its bound on this disc is $CA^\sharp$.

A still-stored boundary term has an anchor in the enlargement of the level-e large-field region in the current label. Its sensitive terminal labels therefore have a live component of age at least $(k-e-1)_+$. Subtract the insensitive labels and use their age-weighted modulus bound on the leaf disc. The Schwarz estimate, with arbitrary labelwise Borel phases, bounds the sum of the resulting total variations by

$$CA^\sharp C_{\mathrm{AL}} \epsilon_e^{\mathrm{all}} q_{\mathrm{op}}^{(e-n_c)_+} q_a^{(k-e-1)_+}.$$

For $k \geq n_c$, summation over e gives $C(q_a) A^\sharp C_{\mathrm{AL}} \epsilon_{\mathrm{tot}}^{\mathrm{all}} q_a^{k-n_c}$. This argument uses the full leaf reading domain, including its configuration tube. We must check that the actual terminal read lies in that tube and that its slot has the reserved value and activity allowance.

When a leaf has been absorbed by a healing operation, its change can enter both a younger boundary term and a second-group regular remainder. For the former use the operation-reader estimate and then the surviving younger boundary slot. For the latter we must identify the recomputed list and terminal slots and verify their comparison bounds. Such absorption does not by itself supply an old live witness at the terminal step. After these terminal transport checks, write C_{term} for the fixed coefficient of the total unmatched bound.

A.8.0.31. Summing the changes of the aligned terminal terms. On the common terminal variables first compare the fully aligned labels with the ramps and the stop-level production slots of the ramp move fixed to those of run A. On a standing second-class component the common variable is V', with $V = V' V_\Lambda^{\mathsf{c}}$ in run c. On a removed component with stored shell variables use $V'' = V' M_{\mathbf{B}''}(U_0^{\mathsf{c}})$. Elsewhere keep the raw variables. In the order of the reference construction each multiplier is determined by the already fixed exterior. Conditional right translation thus preserves the free Haar factors, and the recorded tree constraints act on the common relative variables. Both physical charts push forward from the same reference space for this label and frame. The two physical tree slices can have different images. All total variations of aligned differences below are computed on the common chart. Write $\tau_h^{B|A}$ for the B term with these A ramps and production slots, and τ_h for a term along the interpolation to it. Test the family against arbitrary Borel φ_h with $|\varphi_h| \leq 1$. The first variation of $\sum_h \int \varphi_h \, d\tau_h$ is the sum of the directions indexed by a charged birth zone b and a read level $t \in [b, k]$, where k is the stop level. Use the slot comparison at the common endpoints, so the sum of these directions is the actual interpolated derivative.

Write ℓ_b for the load of a zone. Its direction has an analytic disc of radius E_1/ℓ_b in the aligned comparison, with zero loads omitted. Terms that read no slot of that direction are constant on the disc. Subtract the sum over those insensitive labels before applying Cauchy's inequality. Put $a = (k-b-1)_+$ and let $m_a(h)$ count the live components of age at least a. If $a > 0$, the incidence check gives $m_a(h) \geq 1$ on each remaining label. The age modulus bound on the disc allows multiplication of each term by $\mu^{m_a(h)}$, with $|\mu| = q_a^{-a}$. The age reserve pays this multiplier in the sum of the absolute masses, bounded by $A^\sharp$. The sum over the sensitive labels without the multiplier is therefore at most $A^\sharp q_a^a$. When $a = 0$ the ordinary modulus bound suffices. The common integrable majorant permits the holomorphic integration against the tests. Cauchy's inequality, integration along the interpolation and summation over t give

$$\left| \sum_h \int \varphi_h \, d(\tau_h^{B|A} - \tau_h^A) \right| \leq \frac{A^\sharp}{E_1} \sum_{b \leq k} (k-b+1) q_a^{(k-b-1)_+} \ell_b$$

at the fixed ramps. For each label take the conjugate polar phase of its difference measure as the test. The left side becomes the sum of its total variations, so the comparison holds before summing the label masses.

For the joint estimate of the ramp change and the recent unaligned labels, keep the objects of run B at its real center. On the aligned labels use the move that interpolates the ramps $t^{\mathsf{A}} + s(t^{\mathsf{B}} - t^{\mathsf{A}})$ and the small production slots that read only V_k. On the common slot chart, each such interpolated slot is bounded by $1 + 20C_\chi \vartheta_\chi^k |s|$ times the enlarged support indicator in run B. The indicator is fixed on the real integration space. There are at most N_w^4 slots on the last lattice. Their product is bounded by e times the enlarged support on the disc

$$|s| \le (20C_\chi N_w^4 \vartheta_\chi^k)^{-1}.$$

In using this disc, the admitted fillings and the labelwise modulus estimate must hold with doubled component majorants. The weight bound pays this doubling from the component exponent and sums the fillings. It permits the insertion of the same arbitrary bounded Borel phases as above. On the disc the integral with these phases is bounded by a fixed multiple of $A^\sharp$. Cauchy's inequality bounds its change from $s = 0$ to $s = 1$ by $CN_w^4 \vartheta_\chi^k A^\sharp$. Here the disc contains $|s| \le 2$ for sufficiently large k. The two endpoints have the B objects and, respectively, the A and B ramps and stop-level slots.

For each run separately, multiply the common unaligned labels born above n_c by μ. The admitted multiplier disc has radius $(4C_\chi^\sharp \vartheta_\chi^k)^{-1}$, with the same modulus bound. The sum for this class is linear in μ, so its coefficient has size at most $CC_\chi^\sharp \vartheta_\chi^k A^\sharp$. Taking the supremum over the labelwise phases gives the variation sum for these terms. This gives the joint bound $C_{\mathrm{test}} \vartheta_\chi^k A^\sharp$, using the common-slot, support and modulus bounds of the admitted ramp moves. Add it once to the fixed-ramp comparison. The labels born at or below the common-level threshold n_c which are left unpaired contribute at most $C_{\mathrm{term}} q_a^{k-n_c} A^\sharp$, including the nested remainders when the terminal marked-leaf check just described holds on the summed-pile branch. With no nested terms take $C_{\mathrm{term}} = 4$. Thus the total of the aligned differences and the unaligned masses is bounded by

$$A^\sharp \left[E_1^{-1} \sum_{b \le k} (k - b + 1) q_a^{(k-b-1)_+} \ell_b + C_{\mathrm{term}} q_a^{k-n_c} + C_{\mathrm{test}} \vartheta_\chi^k \right].$$

At a fixed stop depth $s_\circ = K - k$, the alignment level satisfies $n_c \le C + C \log\log(x_0 + C)$ on the admitted runs. Since $x_0 \le C_g(1 + K)$, the factor $q_a^{-n_c}$ grows at most as a fixed power of $\log(2+K)$. For $q_a < \rho < 1$ this power is absorbed by $(q_a/\rho)^k$. Thus the old-label term is $O(\rho^{K-s_\circ})$, as is the joint ramp term if $\vartheta_\chi \le \rho$. With the full load envelope, the three terms therefore cost $C_{s_\circ} A^\sharp (\rho^{K-s_\circ} + \Pi_K)$ at a fixed stop, at both the source and its real centre. This is the error for the scalar comparison below once the actual terminal labels have the stated slot interpolation, age incidence, marked-leaf transport and jointly controlled ramp.

A.8.0.32. The normalized integral at the stop. For the second line of eq. A.lxxiv, put $v = t + \sum_i z_i f_i$. Use v in run A and $\mathfrak{n}_K \circ v$ in run B. Take the real centers at $t_1 = \mathrm{Re}\, t$ and $\mathfrak{n}_K(t_1)$. The sources relative to the centers are $v - t_1$ and $\mathfrak{n}_K \circ v - \mathfrak{n}_K(t_1)$, respectively.

For the source-class comparison, let r_J be the parameter-disc radius and take $|t_1| \le r_J/4$. Choose the residual source $W = v - t_1$ in the class of radius $3r_J/8$. Its amplitude is at most $1.6(3r_J/8) = 0.6r_J$, and its Lipschitz bound is $3/8$ of the bound in the radius-r_J class. Thus the values of $t_1 + W$ lie in $\bar{D}(0, 0.85r_J)$. Write $\mathfrak{n}_K(z) = z + e(z)$, with $|e(z)| \le \Upsilon_K |z|$ on $D(0, r_J)$. Cauchy's estimate on the smaller disc gives $\sup |\mathfrak{n}_K'| \le 1 + (20/3)\Upsilon_K \le 8/3$ when $\Upsilon_K \le 1/4$. Integration along the segment joining $t_1 + W(x)$ and $t_1 + W(y)$ gives the Lipschitz bound of the radius-r_J class for the residual source of run B. Its amplitude is at most

$$\|W\|_\infty + \sup_x |e(t_1 + W(x))| + |e(t_1)| \le (0.6 + 0.85/4 + 0.25/4) r_J = 7r_J/8.$$

The matched real center satisfies $|\mathfrak{n}_K(t_1)| \le (5/4)|t_1|$. Choose the real center interval with room for this change and the source radius in both runs. These bounds admit the matched residual source on the local pair, including its spatial variation.

For one run, take w relative to its real center and let $Z(w)$ be the corresponding bare sourced partition function. At level j write $\mathsf{V}_j(X;w)$ for the sum of the regular anchored terms and the remainder produced at that level, evaluated at the trivial field, together with the one-point gauge terms extracted by the completed gauge steps. Group the latter on their single M-cubes and include each at the step at which it is extracted. The gauge term at a pin is $\log[\mathfrak{z}(a_j(y;w))/\mathfrak{z}(x_j)]$, with the reference coefficient x_j of that run at its real center. Set

$$e_j(X;w) = \mathsf{V}_j(X;w) - \mathsf{V}_j(X;0), \qquad E_u^{\mathrm{src}}(w) = \sum_X e_{K-u}(X;w).$$

The values of these energies are independent of where the run is stopped. For a stop at depth s put $k = K - s$ and define

$$I_k(w) = \exp\left(-E_{(k)} - \sum_{j=1}^{k}\sum_X e_j(X;w)\right)\int \rho_k^w.$$

Here $E_{(k)}$ is the source-independent vacuum constant and the integral includes the stored variables. Exact preservation of mass under the first k operations gives $\int \rho_k^w = Z(w)$.

In the native history representation, the boundary energy is extracted globally. A label $\mathcal{S}$ produces its regular share only on the carriers contained in its small-field regions $\Lambda_j(\mathcal{S})$. Thus its term in $I_k(w)$ contains the compensating exponent

$$-\sum_{j\le k}\sum_{X\not\subset\Lambda_j(\mathcal{S})} e_j(X;w).$$

This includes the negative copy of the centered gauge term on each omitted cube. The compensating exponent is the unit-field evaluation of stored boundary families at their respective levels, and their real-center vacuum constants are stored separately. A common multiplicative normalization in a run is chosen once at its real center and applies to every label and source value in the comparison.

Consequently the normalized stop factor is

$$\widetilde{Z}^{[s]}(w) = \frac{I_k(w)}{I_k(0)} = \exp\left(-\sum_{u=s}^{K-1} E_u^{\mathrm{src}}(w)\right)\frac{Z(w)}{Z(0)}.$$

Increasing the stop depth from s to $s+1$ therefore multiplies the stop factor by $e^{E_s^{\mathrm{src}}(w)}$. In the logarithms normalized at $w=0$ this adds exactly $E_s^{\mathrm{src}}(w)$. For a fixed stop depth, its cost in the bound for $|\widetilde{Z}|$ is at most $\exp(C\ell^4\sum_{u<s}L^{4u})$, using the connected-domain sum for each transferred energy. This cost is independent of the cutoff at a fixed s.

At a fixed stop depth $s_\circ$, the one-run positive lower bound and stability upper bound give $\widetilde{Z}(0)=1$ and $|\widetilde{Z}|\le Q_\ell$ on the source ball, with Q_ℓ fixed at fixed torus. If the radius is r, then on the ball of radius $r/(2(Q_\ell+1))$ the Schwarz lemma on each complex line gives $|\widetilde{Z}-1|\le 1/2$. The logarithm there is single-valued and Lipschitz on the range.

To apply the history estimate to the stop integral, choose one positive scalar a_{c} for each run and real center, in the one-run vacuum normalization. Let P, Q be the resulting stop integrals $a_{\mathsf{B}} I_k^{\mathsf{B}}$ and $a_{\mathsf{A}} I_k^{\mathsf{A}}$, at the matched residual sources. Use these same scalars at zero residual source. Let τ_h^{c} denote the normalized history measure in the chart of its label. Its total mass is unchanged by the chart substitution. With H_{al} the aligned labels, the difference of the scalar readouts is

$$P - Q = \sum_{h\in H_{\mathrm{al}}}(\tau_h^{\mathsf{B}} - \tau_h^{\mathsf{A}})(1) + \sum_{h\in H^{\mathsf{B}}\setminus H_{\mathrm{al}}}\tau_h^{\mathsf{B}}(1) - \sum_{h\in H^{\mathsf{A}}\setminus H_{\mathrm{al}}}\tau_h^{\mathsf{A}}(1).$$

Pair the first sum in the common label charts and bound each evaluation at 1 by the corresponding variation. The sum estimate above therefore gives both $|P-Q|\le A_\ell^\sharp\varepsilon$ and $|P_0-Q_0|\le A_\ell^\sharp\varepsilon$, where subscript 0 denotes the zero residual source at those same real centers. In terms of the original

two integrals the common comparison scalar is $a_{\mathsf{A}}/a_{\mathsf{B}}$. The one-run lower bound gives $P_0 \geq B_\ell^{-1}$ in this normalization. Subtracting the two ratios gives

$$\left|\frac{P}{P_0} - \frac{Q}{Q_0}\right| \leq B_\ell(|P-Q| + |Q/Q_0|\,|P_0 - Q_0|) \leq B_\ell A_\ell^\sharp(1+Q_\ell)\varepsilon.$$

The logarithms on the smaller ball have the same error up to a fixed factor. This uses the history estimate for the actual tests and stored variables at both arguments.

A.8.0.33. A uniform bound on the wider strip. The admitted interval I_K in eq. 5.lxv leaves the stated room for the source. Its terminal image contains $h \pm \varrho$, and the upper slope bound for x_K there is at most $5/3$. The preimages of these two values are each at least $3\varrho/5$ from $\beta_K^\natural$. Thus the one-run estimates apply at the real centers $|\operatorname{Re} t| < \varrho/2$. Let $r_\ell > 0$ be the radius of the smaller source ball just obtained from the Schwarz bound. For $|\operatorname{Im} t| < r_\ell/2$, take a product disc in the z_i on which $\sum_i |z_i|\|f_i\|_\sharp < r_\ell/2$. The residual source $w = \mathrm{i}\operatorname{Im} t + \sum_i z_i f_i$ lies in the smaller ball, with real center $\operatorname{Re} t$. There the stop factor is nonzero and its logarithm has a uniform bound. The local energy factors in the exact partition-function identity are exponentials. Thus the original partition function is nonzero on this disc and the mixed derivative of its logarithm includes a uniformly bounded stop term by Cauchy's inequality.

In each individual local energy the single-point frozen share depends on at most one z_i at a plaquette. For $n \geq 2$ it disappears from the mixed derivative. The remaining terms contributing at depth s have enlarged carriers meeting every support. The individual energy bound and the separation of the supports then give the summable majorant $C(\ell L^s)^4 e^{-c\mathsf{d}L^s/M}$ after the connected-domain count. Cauchy's inequality on the same fixed product disc bounds their mixed derivatives uniformly in K. Together with the stop term this bounds $F_{K,n}$ on the wider strip. At each finite cutoff the bare integral is jointly entire in the bare coefficient and the finitely many source parameters. At nonzero values its mixed logarithmic derivative is independent of the local logarithm branch and is holomorphic in t. This gives holomorphy across the real-center slices used to obtain the bound.

A.8.0.34. Mixed derivatives and the separation of supports. At a plaquette barycenter at most one f_i is nonzero. Every mixed derivative in distinct z_i of the pointwise change $\mathfrak{n}_K \circ v$ thus vanishes from order two on. The mixed derivative of the full logarithm for run B is $\mathfrak{n}_K'(t)^n F_{K+1,n}(\mathfrak{n}_K(t))$. The same argument kills the sitewise frozen pieces of the local energies for $n \geq 2$. In the other local terms the derivative selects only enlarged carriers $X^\sim$ meeting every support. If the separation is at least $\mathsf{d} > 0$, this forces $d(X) \geq \mathsf{d}L^s/M - C$ at depth s, where $d(X)$ is the size used in the connected-domain sum.

On a shared carrier at depth s, decompose the trivial-field evaluation $\mathsf{V}_{K-s}(X;w)$ into the sum of the frozen regular terms at their separate base points and the evaluation of the defect, remainder and gauge terms. For the frozen term at a base point y the source enters only through $w(p_y)$. The full mixed derivative kills this share in each run separately. Represent the difference of the remaining sums at the matched sources by a local family $G_s(X;v)$ on the common scaffold. Its sum gives the difference by the total identities of the comparison families. The centered difference uses $G_s(X;v) - G_s(X;t_1)$, with the same real centers as above.

The one-point part of G_s on a single M-cube is the sum over its pins y of the paired log normalizer differences. On the common scaffold these are

$$\log \mathfrak{z}(\theta_{[s]} - \zeta_{(s)}^{\mathrm{B}}(p_y)) - \log \mathfrak{z}(\theta_{[s]} - \zeta_{(s)}^{\mathrm{A}}(p_y)),$$

up to constants independent of the source. Here $\zeta_{(s)}$ is the running shift at the gauge step being compared. For the common gauge cutoff write $\mathfrak{z}(a) = \int \chi e^{-aQ}\, dH$, where dH is Haar measure and $0 \leq Q \leq \epsilon_s^2$ on the cutoff support. On the strip $|\operatorname{Im} a|\epsilon_s^2 \leq 1$ its real part is at least $\cos(1)\mathfrak{z}(\operatorname{Re} a)$, and differentiating under the integral gives $|(\log \mathfrak{z})'(a)| \leq \epsilon_s^2/\cos(1)$. Apply this on the segment joining the admitted weights. The pointwise shift bound gives $C(1+s)(\rho^{K-s} + \Pi_K)$ for the difference

at a pin, and the fixed number of pins per cube preserves this rate. On the plateau this is the pointwise bound for the local pair. On a common transition layer the two shift fields interpolate their consecutive-depth values with the same coefficient $\lambda(p_y) \in [0,1]$. Their difference is thus the interpolation of the two paired differences. If the two adjacent depths are $s, s+1$, write $e_s = \rho^{K-s} + \Pi_K$. Then $e_{s+1} \le \rho^{-1} e_s$ and $s+2 \le 2(1+s)$, so the layer has the same $C(1+s)e_s$ bound. The consecutive reads in this argument are those of the actual paired residual sources. At each pin we must check the common profile and admission of both reads. For different interpolation coefficients the additional term is their difference times the change of one run's shift between the two depths.

For the compensating gauge copy in the terminal integral, the standing aligned label supplies the same regions and cell partition in the two runs. The fixed profile is a product over rounded complement cells. At a pin only cells within one quarter of their side length contribute a factor different from one. Thus the common pin and the matching cells of the standing label give identical profile values. In a restoration step the sequence in force can differ from the retained label. A gauge read there requires this check for the sequence that actually supplies it.

The argument of the normalizer on an omitted cube is the stored gauge-weight entry at its own level j, read at the terminal step. The mark of this entry is charged in the running-weight load. Write $\mathfrak{g}_j = g_j^2 (\log x_j)^{2q_\flat}$ for the load weight and E_1 for the bound on the product of this weight and the moved slot along the dial. The change of the gauge exponent on a cube is at most $CE_1 \epsilon_j^2 / \mathfrak{g}_j$, by the strong logarithmic derivative bound above. Since $\epsilon_j^2 \le C g_j^2 (\log x_j)^{2\mathfrak{p}_0}$ and $q_\flat \ge \mathfrak{p}_0$, this is CE_1 per cube on the admitted dial. The negative sign of this copy is retained in the exponent. The global gauge term uses the local energy comparison.

An older-layer read also has a summable bound when the pointing measures match, even if the active depths at the pin are far from the nominal gauge depth. At each shared depth u, the pointing measure is the sum of the tents at the pin times the profile value, with atoms at their source sampling points. Its mass is at most one. Use the two real centers $t_1, \mathfrak{n}_K(t_1)$ and put $W_A = v - t_1$, $W_B = \mathfrak{n}_K(v) - \mathfrak{n}_K(t_1)$. By the exact shift formula, the difference of the residual shifts is $W_B - W_A$ plus the sum of the paired centered increments integrated against the common pointing measures, and the extra finest increment of the longer run. At an atom with source value v_*, the shared increment difference obeys

$$|\delta b_u(v_*) - \delta b_u(t_1)| \le C \min\{a_{[u]}, e_u/\varrho\}\, |v_* - t_1|.$$

The two bounds follow from the one-run slopes and Cauchy's estimate on the smaller disc, respectively. The extra increment costs $C a_{[K]} \|W_A\|_\infty$. Since $\mathfrak{n}_K' - 1 = O(\Upsilon_K)$, integration along the source segment bounds $W_B - W_A$ by $C\Upsilon_K \|W_A\|_\infty$. The same sum as in eq. A.lxxviii then bounds the residual shift difference by $C\Upsilon_K \|W_A\|_\infty$. If the pointing measures differ, their difference acts on a one-run centered increment and requires a separate comparison.

For the centered logarithm, the full gauge arguments also contain the real-center inverse couplings. Denote their difference at the pin by d_s. The two logarithm differences, at the source and at its center, are bounded together by $C\epsilon_s^2 (2d_s + \Upsilon_K \|W_A\|_\infty)$ on the same admitted gauge strip. When the centers are the scalar centers, their difference uses the paired scalar estimate.

The shift reads the source within two depth-s spacings of the pin. The gauge term therefore uses the enlarged carrier test for mixed derivatives. Since its carrier is a single cube, once $CML^{-s} < \mathsf{d}$ it cannot meet two of the separated supports and its mixed derivative vanishes. The older-layer estimate thus adds only $C_{n,\ell,\mathbf{f}} \Upsilon_K$ to the mixed-derivative comparison when used on gauge pins with the indicated locality and compared real centers.

For a sharper comparison, consider a pin p in a common native zone of actual depth $m < K$. Its profiles are zero for $u < m$, possibly partial at m, and one for $u > m$ among the available inputs, including the extra finest input of the longer run. Use this calculation where that pattern and the common tents apply to the full gauge read, and the re-centered shift formula uses the

same increment functions as the frozen matching, as in eq. 5.lxxiii. Let $D_u(z) = \delta b_u(z) - \delta b_u(t_1)$ for the shared increments, and let D_K denote the centered extra increment at the matched offset. Terminal matching at $v(p)$ and at t_1 gives

$$W_B(p) - W_A(p) + \sum_{u=0}^{K} D_u(v(p)) = 0.$$

Replace each tent sample by its value at the pin in the residual shift difference. The identity cancels the full sum, leaving the omitted increments for $u < m$ and the omitted fraction at m. On the smaller source disc their total is at most $C(1+m)e_m\|W_A\|_\infty$, since $e_u \le e_m$ for $u \le m$. For the error of this replacement, the sample distance is $O(L^{-u})$ and the increment difference has derivative bounded by Ce_u/ϱ on the shared depths. Hence the error is at most

$$C\,\mathrm{Lip}(v)\left(\sum_{u=m}^{K-1} e_u L^{-u} + a_{[K]}L^{-K}\right) \le C\,\mathrm{Lip}(v)e_m L^{-m},$$

using $L^{-1} < \rho$ and bounded $a_{[K]}$. The real-center coefficient is compared separately as above. If the extra input is not fully present, the omitted fraction of $D_K(v(p))$ must also be included.

The logarithm on a cube is a sum over individual pins. At one pin the source halo has radius $O(L^{-m})$. Once this is below a fixed fraction of d, the halo misses at least one support and the mixed derivative at that pin vanishes. On the remaining pins with $s \le m$, both depths are bounded in terms of the separation. The bound $(1+m)e_m = O_{\mathsf{d}}(\rho^K + \Pi_K)$ then gives the sharper mixed-derivative rate after the finite cube count and Cauchy's estimate. The identification of the actual zone and the profile pattern is needed for this use of the rate.

For the remaining two parts use the total identities at the unit field, where the regular background is the unit field and the current is zero. The source defect D contributes the sum over base points of its comparison representative with weight $E_0\mathsf{l}_s$. The remainder contributes one representative per carrier with weight $(C_t\theta_{[s]})^{-1}$. These are the weights of the native comparison units, with $\mathsf{l}_s \le C(1+s)$ and $\theta_{[s]} \ge h$. On the admitted source polydisc the A and R envelopes therefore bound these two parts together by $C(1+s)(1+d(X))(\rho^{K-s}+\Pi_K)e^{-\kappa^c d(X)}$. Here κ^c is the decay rate in the comparison norm, and the factor $1+d(X)$ counts the base points in the defect. Absorb that factor by taking $\kappa_e < \kappa^c$. This gives the following bound for the regular parts, and for the complete family at depths where the gauge pins satisfy the nominal-depth estimate. Use it on the shared depths through $K/2$:

$$|G_s(X;v)| \le C(1+s)(\rho^{K-s}+\Pi_K)e^{-\kappa_e d(X)}.$$

We must verify the comparison envelopes and the pin estimates for the actual paired trajectories on this polydisc. Summing by an anchor cube and reserving exponential decay after the connected-domain count costs at most $C(\ell L^s)^4 e^{-c\mathsf{d}L^s/M}$. This cost times $(1+s)\rho^{-s}$ is summable. Thus Cauchy's estimate gives $C_{n,\ell,\mathbf{f}}(\rho^K + \Pi_K)$ for the mixed derivative from these depths. For deeper shared depths, and for the one extra depth of run B, use the two individual local energy bounds. The same carrier count gives $C_{n,\ell,\mathbf{f}}e^{-c'\mathsf{d}L^{K/2}/M}$. For the stop logarithms use Cauchy's estimate on the smaller polydisc, with the fixed-torus radius above. In particular the second line of eq. A.lxxiv follows if the stop error ε has a summable bound and the shared-depth estimate holds. At $t=0$ the identity for N_K cancels the derivative factor in the comparison of $N_K^{-n}F_{K,n}(0)$, with no additional error from the matching derivative.

For summability one can stop the shared-depth comparison earlier. For any $q > 1$ take s_K with $c\mathsf{d}L^{s_K}/M \ge 2q\log K$ and $s_K = O(\log_L \log K)$. The individual local bounds give a summable tail above s_K, including the carrier count. This leaves the comparison of the terminal normalized integral at the fixed stop and the shared-depth estimate through s_K. One can also transfer the shallower totals into the stop factor at depth s_K using the exact identity above. In that form the stop factor must be compared at the moving depth. For sources near their real centers, the Schwarz

estimate for each local energy and the connected-domain sum give $|\sum_{u<s} E_u^{\mathrm{src}}(w)| \le C_\ell L^{4s}\|w\|_\sharp$. The stop factor at depth zero is close to one on a fixed source ball. The exponential of the transferred energies is also close to one on the ball of radius $c_\ell L^{-4s}$. At $s = s_K$ the resulting mixed Cauchy estimate costs only a fixed power of $\log K$, provided the comparison of the two moving-stop factors is established on that ball.

Proposition A.15 (The conditional terminal-coupling limit)**.** These inputs imply uniform convergence $F_{K,n} \to S^{[t]}_{\ell,n}$ on the smaller strip and $\Xi_K \to \Xi_\infty$. The latter is a real bi-Lipschitz homeomorphism from J onto $I \supset [h - \varrho/6, h + \varrho/6]$. Set

$$S^{(\ell,x)} = S^{[\Xi_\infty^{-1}(x)]}_\ell, \qquad x \in I.$$

If $t_K \in \mathsf{J}$ and $\Xi_K(t_K) \to x$, then $F_{K,n}(t_K) \to S_n^{(\ell,x)}$, without a subsequence. ■

Proof. Cauchy's estimate on the wider strip bounds $F'_{K,n}$ uniformly. Thus replacing $\mathfrak{n}_K(t)$ by t in eq. A.lxxiv, and its derivative factor by one, costs $C\eta_K$. The resulting increments are summable, uniformly on the smaller strip. Their limit is holomorphic and continuous on J. The coordinate increments are summable too. Its real Lipschitz bounds pass to the limit; the endpoint bounds give the asserted interval. Uniform coordinate convergence gives $\Xi_\infty(t_K) \to x$; the lower Lipschitz bound forces $t_K \to \Xi_\infty^{-1}(x)$. Uniform convergence of F_K and continuity of its limit finish the proof. □

This gives the terminal-coupling limit in part (d) of Thm. A under the stated comparison premises; infinite-volume uniqueness requires a separate argument. The depth coordinate $\Xi_{\infty,s}(t) = \lim_K x^\natural_{K-s}(\beta^\natural_K - t)$ requires the corresponding fixed-depth comparison. If its envelope is

$$\lambda s - C \le \Xi_{\infty,s}(t) - \Xi_{\infty,0}(t) \le \Lambda s + C,$$

then $\Xi_{\infty,s}(t)^{-1/2}$ decreases in order as $s^{-1/2}$; at length L^{-s} this is logarithmic running. The reference value $g_{[s]} = \theta_{[s]}^{-1/2}$ is a calibration, not this arbitrary member's running coupling. Common-prefix matching must also control $\hat{t}_{K,s} = \beta^\natural_{K-s}(g_{[s]}) - \beta^\natural_K(g)$. If it converges to $\hat{t}_s$, exact finite dilation passes to $S^{[t]}_\ell[g] = S^{[t+\hat{t}_s]}_{L^s\ell}[g_{[s]}](\mathbf{f}^{[s]})$, wherever both offsets are in their windows. For the first-passage application let K' be the stopping index of the run whose choices follow the coupling, at bare inverse coupling β. The scaffold comparison in E4 must give a live frozen run of length K' from the same bare value, in the admitted real tuning class. Write y for its terminal inverse coupling. Write $\omega(g) \le 1$ for the terminal cost in eq. 5.lv. The first-passage window then gives

$$h - \omega(g) \le y \le h + B_\sharp + \omega(g).$$

Use the increasing inverse of the frozen terminal coupling as a function of the bare value in this class. Its value at h is $\beta^\natural_{K'}$. The inverse tuning estimate has Lipschitz constant at most $3/2$, so

$$-\tfrac{3}{2}\omega(g) \le \beta - \beta^\natural_{K'} \le \tfrac{3}{2}(B_\sharp + \omega(g)).$$

For $\varrho \ge 6(B_\sharp + 1)$ this puts the offset $\beta^\natural_{K'} - \beta$ in J. The identification uses uniqueness of the admitted real frozen run at terminal value y.

Conversely, for sufficiently large K and $\beta = \beta^\natural_K - t$ with $t \in \mathsf{J}$, the forward comparison at its first-passage index K' gives $|\beta^\natural_{K'} - \beta^\natural_K| \le \varrho/2$. The matched-depth estimates below give a lower spacing bound between the tuned bare centres. To see this, compare their couplings at depth $\min(K, K')$ by telescoping in the run length. The geometric error and the summed floor give a fixed bound there. The remaining depth interval of the longer run then contributes at least $\lambda|K - K'| - C$ by the flow bound. This gives $|K - K'| \le C(\varrho)$. The comparison between the ordinary and the frozen bookkeeping, including admission of the frozen run, is the input to this argument. Exact lattice dilation uses $f^{[b]}(y) = f(L^{-b}y)$, without an observable prefactor, and $T_\ell \mapsto T_{L^b\ell}$. Conditional

offset limits and depth shifts pass through that identity only when the offsets converge and both torus floors hold. The change-of-reference claims retain these matching premises. The tuned bare increments must also satisfy:

$$\beta^{\natural}_{K+1}(g)-\beta^{\natural}_{K}(g)\longrightarrow c_0,\qquad \beta^{\natural}_{K+b}(g)-\beta^{\natural}_{K}(g)\longrightarrow bc_0\quad (b\in\mathbb{Z}\text{ fixed}). \tag{A.lxxx}$$

The second assertion follows by finite telescoping from the first. The following proof uses the stronger comparison hypotheses. Write $x^{[i]}_{[s]}$ for the tuned depth-s coupling in the run of length i, with $x^{[i]}_{[0]}=h$ and $x^{[i]}_{[i]}=\beta^{\natural}_i$. Require $x^{[i]}_{[v]}-x^{[i]}_{[u]}$, for $u<v$, to lie in $[\lambda(v-u)-C,\Lambda(v-u)+C]$, and

$$|x^{[i+1]}_{[s]}-x^{[i]}_{[s]}|\le C(L^{-c(i-s)}+s\Pi_i),\qquad \sup_{s\ge1}s\sum_{i\ge s}\Pi_i<\infty.$$

These constants and the last bound are fixed before ϱ. Comparing two bare centers at the same depth K', then telescoping in the run length, bounds their extra discrepancy by $C\sum_{i\ge K'}L^{-c(i-K')}+CK'\sum_{i\ge K'}\Pi_i\le C'$. The spacing bounds therefore give a uniform bound A on $\alpha_K=\beta^{\natural}_{K+1}-\beta^{\natural}_{K}$. Choose $\varrho>20A$.

Each cluster value α of α_K gives $S^{[t]}_{\ell}=S^{[t-\alpha]}_{L\ell}(\mathbf{f}^{[1]})$ by exact finite dilation and uniform moving-offset convergence. Two cluster values $\alpha^-<\alpha^+$ give an offset period $\omega=\alpha^+-\alpha^-$ on an open interval. Holomorphy in the offset extends that identity throughout the overlapping strips. Repeated blocking can then restore every offset modulo ω into $[0,\omega)$; all intermediate offsets stay in J by the choice of ϱ. Require, additionally, one fixed positive shape Ψ, a floor ℓ_0, and $r_0>0$, such that

$$0<\mathfrak{m}(r)\le S^{[t]}_{\ell,2}(\Psi_r)\le\mathfrak{M}(r),\quad \mathfrak{M}(r)\longrightarrow0,\qquad t\in\mathsf{J},\ \ell\ge\ell_0,\ 0<r\le r_0.$$

Normalization by the two fixed supremum norms is understood. The required uniformity in offset, shape placement and arbitrarily large tori is part of the stated tuned two-point comparison. For $r_m=L^{-m}r_0$, blocking gives $\mathfrak{m}(r_0)\le\mathfrak{M}(r_m)\to0$, a contradiction. Thus α_K has one cluster value and converges. Finally eq. A.lxvii–eq. A.lxviii, backward drift and $x^{\natural}_K=h$ make the average nonlinear increment error tend to zero, so $\beta^{\natural}_K/K\to c_0$. Cesaro averaging identifies the unique cluster value with c_0. Without these two-run and uniform-envelope premises, eq. A.lxxx requires a separate comparison estimate. With eq. A.lxxx, exact finite dilation and the moving-offset limit give

$$S^{[t]}_{\ell}(\mathbf{f})=S^{[t-bc_0]}_{L^b\ell}(\mathbf{f}^{[b]})\qquad (b\ge1),$$

when both offsets lie in their windows and the torus floors hold. Indeed the same bare coupling has the second offset $t-[\beta^{\natural}_{K+b}-\beta^{\natural}_{K}]$, which converges to $t-bc_0$. Thus the original blocking target is preserved without claiming it follows from one-step potential estimates.

Comparison of distinct offsets requires the following additional two-point assumption. Fix a nonempty class of nonnegative C^2 pairs: each test is supported in a radius-r ball, the two supports have distance in $[r,6r]$, and each test satisfies $\int f\ge\vartheta r^4\|f\|_\infty$ and $\mathrm{Lip}\,f\le\|f\|_\infty/(\vartheta r)$. Define $\sigma\approx_2\sigma'$ by an error $Cr^2\|f\|_\infty\|h\|_\infty$, uniformly on this class at all sufficiently small r. Set $(D_\mu\sigma)_2(f,h)=\sigma_2(f(\cdot/\mu),h(\cdot/\mu))$. Require $\sigma_t\approx_2 D_\mu\sigma_{t'}$, with $\mu=\exp((t-t')\log L/c_0)$, and uniform two-point upper and lower envelopes of order $(\log(1/r))^{-2}$. A germ cannot be fixed by D_μ, $\mu\ne1$. For $\mu>1$, apply its error bound to one fixed rescaled shape, with normalized value $Q(r)$, at radii $r\mu^{-a}$. The upper envelope gives $Q(r\mu^{-a})\to0$, so

$$Q(r)\le C\sum_{a\ge1}(r\mu^{-a})^2=\frac{Cr^2}{\mu^2-1}.$$

This contradicts the logarithmic lower envelope for arbitrarily small r. For $\mu<1$, invert the dilation. Thus equality of two different-offset limits would contradict rigidity. The comparison retains its

shape, placement, offset and torus-floor quantifiers; it is an additional premise, not a consequence of matching alone.

Why a geometric relabelling needs another construction. Take three test tuples of the same fixed correlation order, for example three pairs, with observable values

$$F_K(t) = (1,\, 1+t,\, 1+\Pi_K) = \alpha + \beta t + \gamma \Pi_K, \qquad \Pi_K = K^{-q}, \quad q > 1.$$

Here $\alpha = (1,1,1)$, $\beta = (0,1,0)$, $\gamma = (0,0,1)$, with determinant one. On $|t| \le 1/4$ the values are positive and uniformly bounded. With $\Xi_K(t) = h - t$ and $\mathfrak{n}_K = \mathrm{id}$, all summable matching inequalities hold; their increments are $O(K^{-q-1})$. Suppose a reparametrization $t \mapsto \tau_K(t)$ and one common normalization $a_K(t)$, bounded above and away from zero, made their increments geometrically small. At a fixed t, geometric summability forces a_K, the first component, to converge geometrically to a nonzero limit. The third component minus the first is $a_K \Pi_K$, tends to zero, and would also be geometrically small. This contradicts its polynomial lower bound. The same argument allows arbitrary reparametrizations: their value does not enter either the first component or the third-minus-first. Only a common, nonvanishing field normalization is required. This is a counterexample to the proposed implication from numerical inequalities, not an assertion that these three numbers already form a physical Yang–Mills state. Thus those inequalities alone do not supply the stronger second-coordinate claim. The construction with filed remainders uses its own running coordinate. At the filing step add the vacuum-subtracted pointed shares to E. Extract their Wilson coefficient on the filing lattice and subtract the corresponding counterterm. The vacuum values go into the scalar normalization and the shares still in the filing band remain in the unfiled part. The shifted Wilson coefficient and the gauge-fixing coefficient both use the new running shift. The filing identity is applied within the same admitted production. If x_K is the coupling before this transfer, the two zero-source coordinates at the same bare datum satisfy

$$\hat{x}_K = x_K - \sum_{i:\, i'' \le K} \mathrm{coeff}_{A,i''}\big(\mathsf{RF}[R^{(i)}]\big).$$

Here i'' is the actual filing level and $\mathrm{coeff}_{A,i''}$ denotes the coefficient of the vacuum-subtracted total at that level. On a common admitted complex offset disc, denote this sum by $T_K(t)$. The filing norm and coefficient estimate bound each summand by

$$C\theta_{i''} w_{i''-1,i} \|R^{(i)}\| \le C\theta_i^{1-\kappa_0/2}.$$

The inequality uses the comparison of radii at the filing depth and the one-run remainder bound. Summing over the depths of the input remainders, where the inverse coupling grows at least linearly, gives

$$\sup_t |T_K(t)| \le C h^{2-\kappa_0/2} \qquad (\kappa_0 > 4).$$

Cauchy's estimate gives the same small bound for the derivative on a fixed smaller disc. Thus the coordinate $\Xi_K(t) - T_K(t)$ of this presentation keeps a lower real Lipschitz bound when Ξ_K has one and the coupling is small. The ordinary pin at h is then at $h - T_K(0)$ in the filed coordinate at that bare datum.

For the two-cutoff estimate align the remainders by birth depth s from the terminal lattice. If the two runs use the same scaffold, the filing delay a_s at that depth is fixed by the scaffold. The remainder is included precisely if $a_s \le s$, so the inclusion test is common on shared depths. Terms at an extra bare depth can be bounded by their one-run size. If the schedules differ, their inclusion tests must be compared as well.

On the admitted paired paths write χ_s for the termwise difference norm of the two remainders at birth depth s, and ι_s for the relative datum error of their filed read. The termwise filing estimate

and the Wilson coefficient bound give

$$|\delta T| \le C \sum_{\substack{s \text{ shared} \\ a_s \le s}} (\theta_{[s]}\chi_s + \iota_s \theta_{[s]}^{1-\kappa_0/2}) + C\theta_{[K+1]}^{1-\kappa_0/2}.$$

Here the coefficient estimate at the filing level uses the crossing weight to return to the unit at birth. Each filed remainder occurs once in the sum. The termwise norm uses the actual filed slices of the runs.

In the comparison pinned in the filed coordinate, the filed response rows bound $\theta_{[s]}\chi_s$ by $C\widehat{r}_s\rho^{K-s}$. The datum term has the same bound on the admitted paths. Using $\widehat{r}_s \le C\rho^{-(K-s)/2}\widehat{r}_K$ and summing the geometric factor gives an $O(\widehat{r}_K)$ bound for δT, including the bare end. Thus a geometric comparison at each fixed depth may still yield a polynomial error for the sum of the transferred coefficients. If the paired reads are available only through depth $K/2$, their contribution is bounded by a geometric factor $\rho^{K/2}$ times the summable one-run weights. The other depths are bounded separately by the one-run coefficient sum, which on that depth interval is $O_g(K^{2-\kappa_0/2})$. With $\widehat{r}_K$ of order $\theta_{[K]}^{2-\kappa_0/2}$ times a power of its logarithm, the bound is summable for $\kappa_0 > 6$.

On a common admitted terminal interval for the filed runs, let u be the filed terminal coupling and write $\mathcal{T}_K(u)$ for the sum T_K at its corresponding bare datum. The pre-transfer coordinate of this same presentation is $X_K(u) = u + \mathcal{T}_K(u)$. On a smaller interval it has a uniform positive lower Lipschitz bound by the one-run derivative estimate and the admitted inverse for u. For a pre-transfer target x, put $u_K = X_K^{-1}(x)$. Comparing $X_{K+1}(u_K)$ with x gives

$$|u_{K+1} - u_K| \le C \sup_u |\mathcal{T}_{K+1}(u) - \mathcal{T}_K(u)|.$$

This transfers the summable bound to the change of pin within the same presentations. Its use for the separately constructed ordinary run requires the matching of its production and source normalization to that presentation.

The optional Ward target on arbitrary defining sequences. In this section $S_{j,n}$ and S_n, $n \ge 2$, are *connected* forms. Require convergence on every smooth compact separated tuple on $\mathbb{R}^4$, along the specified defining sequence. On every fixed collection of separated compact support neighborhoods require uniform local multilinear C^1 bounds. Mollification inside slightly enlarged separated neighborhoods then extends the forms and their convergence to compact C^1 tuples: first approximate each entry, use the uniform telescoping bound, and then pass to the limit for the smooth approximants. Assume full signed-permutation symmetry W_4 of the limit. The specified lattice probability laws realize these connected forms; the mixed cumulants below use those laws. For torus approximants a fixed R must fit in one common chart for all sufficiently large j. For $\omega \in \mathfrak{so}(4)$, set $\delta_\omega f = -(\omega x)\cdot\nabla f$ and

$$D_{j,\omega}^s f(x) = \sum_\rho (\omega x)_\rho \frac{f(x + a_j e_\rho) - f(x - a_j e_\rho)}{2a_j}.$$

Here are actual additional Ward inputs, independent of the angular route. Choose smooth $\chi_R = 1$ on B_R, zero outside B_{2R}, with derivatives bounded by $C_r R^{-r}$. For every j, ω, R, supply fixed annular local functions

$$\mathfrak{B}_{j,\omega,R} = \sum_{\Delta \in \mathcal{A}_{j,R}} \mathfrak{B}_{j,\omega,R}^{\Delta}.$$

There are at most CR^4 physical unit boxes; each summand is a specified gauge-invariant Borel function of links in a fixed enlargement of its box, linear in ω, supported near $R - Ca_j \le |x| \le 2R + Ca_j$. The functions may contain the divergent Wilson weight. They are supplied by the actual

change of variables, independently of the tests, not defined as their desired rotation defect. Require the exact finite identity

$$\sum_i S_{j,n}(f_1,\dots,D^s_{j,\omega}f_i,\dots,f_n) = \mathfrak{U}_{j,\omega,R}(\mathbf{f}) + \langle \mathfrak{B}_{j,\omega,R}; \mathcal{O}_j(f_1);\dots;\mathcal{O}_j(f_n)\rangle^T. \tag{A.lxxxi}$$

In eq. A.lxxxi, $\mathcal{O}_j(\mathbf{f})$ denotes the separate list of cumulant arguments, not their coincident product. The bulk functional $\mathfrak{U}$ must also be the specified correlation from that same Ward construction; it is not an arbitrary error chosen after the boundary functions. For every fixed sufficiently large R, require $\mathfrak{U}_{j,\omega,R} \to 0$ and the analogous sum with $D^s_{j,\omega}f_i + \delta_\omega f_i$ to tend to zero. These include the actual typed anisotropy and volume-transfer estimates where needed, and are not proved by scalar source bounds.

Multilinear telescoping and local C^1 continuity differentiate the limit's rotation orbit on smooth tuples. Applying the assumed convergence at the fixed derivative tests in eq. A.lxxxi, without differentiating a cutoff limit, gives

$$\lim_j \langle \mathfrak{B}_{j,\omega,R}; \mathcal{O}_j(\mathbf{f})\rangle^T = -\delta_\omega S_n(\mathbf{f}). \tag{A.lxxxii}$$

It is independent of R. Consequently the condition in part (e) of Thm. A

$$\liminf_{R\to\infty} \limsup_{j\to\infty} \left| \langle \mathfrak{B}_{j,\omega,R}; \mathcal{O}_j(\mathbf{f})\rangle^T \right| = 0 \tag{A.lxxxiii}$$

is equivalent to vanishing of this derivative. The inner limit always has R fixed.

For completeness, one nonzero generator suffices. Assume also the invariant one-point convention $c\int f$ and zeroth moment one, or use the centered functional. Let G be the closed subgroup of orthogonal transformations preserving the connected forms. Closedness follows from C^1 continuity on separated tuples. Equivalently, define G from the centered moment forms obtained by the finite sum over partitions of these cumulants; the inverse partition formula gives the same group. The invariant one-point function $c\int f$ makes the uncentered moment group the same. Let $\mathcal{A}$ consist of skew matrices whose entire one-parameter group lies in G. It is closed under real scalar multiplication and addition: the finite-matrix product formula

$$e^{t(A+B)} = \lim_{r\to\infty} (e^{tA/r}e^{tB/r})^r$$

follows by expanding each factor to second order and telescoping the product error, which is $O(r^{-1})$. Closedness of G then applies. It is also stable under conjugation by W_4. For $a < b$, sign matrices $D_\epsilon = \mathrm{diag}(\epsilon)$ give the projection

$$2^{-4} \sum_{\epsilon\in\{\pm1\}^4} \epsilon_a\epsilon_b D_\epsilon A D_\epsilon = A_{ab}E_{ab}.$$

Thus any nonzero element of $\mathcal{A}$ supplies a coordinate-plane generator; permutations supply all of them. Successive plane rotations reduce any determinant-one orthogonal matrix to the identity column by column. Hence G contains SO(4), and its coordinate reflections give all O(4). The condition in eq. A.lxxxiii for a nonzero ω, on every smooth tuple, gives its whole one-parameter group by applying the zero derivative also at each rotated tuple. Conversely full invariance makes eq. A.lxxxii zero for every ω. No Lie-subgroup theorem is needed. Indeed an infinite closed G has nonidentity $g_r \to I$; the normalized skew logarithms have a nonzero subsequential limit A. Integer powers $g_r^{\lfloor t/\|\log g_r\|\rfloor} \to e^{tA}$ supply the required one-parameter group. Therefore such a W_4-invariant group is finite or all of O(4).

Infrared meaning and the Hilbert-space consequence. A uniform mixed-insertion estimate $|\langle \mathfrak{B}^{\Delta}; \mathcal{O}_j(\mathbf{f})\rangle^T| \le CD^{-4-\delta}$, $\delta > 0$, at distance D from the fixed supports, implies eq. A.lxxxiii: its shell sum is at most $CR^4R^{-4-\delta}$. Decay D^{-4} alone yields only a bounded sum. It also suffices that the sum of absolute mixed insertions tend to zero along one sequence $R_l \to \infty$, after $\limsup_j$. Ordinary per-ball density bounds do not give either estimate for these different, weight-bearing insertions. If an older survival argument is used, its event $\mathcal{L}_{\mathfrak{c},k,a,K}$ means that cell $\mathfrak{c}$ is live at level k, its component lineage starts at $k-a$, and it remains live at every level $k,\dots,K$. Its weighted law is an additional history input.

Assume the relevant centered or recentered moment functional also satisfies the HB quotient hypotheses. Once full scalar rotation invariance is supplied, spatial $R \in \mathrm{O}(3)$ acts on the HB quotient by $V_R[F] = [(R \oplus 1)F]$. It preserves the positive form and null space, has inverse $V_{R^{-1}}$, fixes Ω, commutes with time evolution and conjugates a spatial translation by x to one by Rx. Local C^1 continuity proves strong continuity on dense test vectors, and unitarity extends it to the completion. The joint spectral measure is consequently covariant under $(E,p) \mapsto (E,Rp)$. For limits for which HB's cube inequalities have been established, they give $E \ge |p|$: use a countable dense set of rotations, remove their common null set, and approximate a rotation carrying any given p to $|p|e_1$. Centering is the map C_m proved in § 6.16 and changes none of these conclusions. In the alternative notation, $\mathsf{sh}_\xi = C_{-m_\xi}$, $m_\xi(f) = c_\xi \int f$, so its inverse is C_{m_ξ}. No operator for a general time-mixing Euclidean rotation is asserted. External OS reconstruction, F4 identification of the full theory and any mass-gap estimate remain separate. The periodic-state angular proof retains its own mirror, cone and ultraviolet interface; the optional Ward premises above do not silently enlarge that state class.

A.9. **Weighted derivatives and matched presentations.** This section formulates weighted derivative estimates and comparisons of matched presentations on their specified domains. These stronger estimates are separate from the ordinary scalar source argument and its angular continuation. We prove the analytic, convolution and normalization steps. The remaining input is the corresponding extension of the actual formation and history maps, with the weights and reserves specified here. No survival probability is used as an enlarged input radius.

A direction is a list, including its own coefficient. Fix a real frame and all its reference operations. A direction at old level j contains a pointed regular family $\dot{E}^{(j)}$, any awaiting remainder $\dot{R}^{(j)}$, and the specified weight or vertex amplitude. Its regular family has the actual gauge covariance and the covariance of its pointed total required by the chosen channel. Its own coefficient is differentiated with that family.

For the scalar channel let T be the fixed physical Hessian readout. If E^λ is an admitted holomorphic family, put $b^\lambda = T[E^\lambda]$. With the frame fixed the map T is linear and independent of λ, so

$$\dot{b} = T[\dot{E}], \qquad \frac{d}{d\lambda}[E^\lambda - b^\lambda h_z A]\big|_0 = \dot{E} - \dot{b}\, h_z A. \tag{A.lxxxiv}$$

The tent h_z and background convention are the assigned frozen ones. If the readout itself changes between two frames, its difference is an additional term; it is not covered by eq. A.lxxxiv. For a tensor channel the scalar coefficient is replaced by the full assigned vector of counter-insertions. Its variation is taken at the same time as that of its own family.

This rule has analytic content at a single old base. Marginal cancellation is applied to the whole covariant member, including its own counterterm, before the bracket interpolation. A noncovariant defect is a separate input with its own scale-small norm. Cauchy differentiation of a partition function cannot give that defect the cancellation of another member.

The norms below are norms at the birth level, on the actual hereditary cores. Write $\mathsf{e}_j, \mathsf{r}_j$ for the regular and remainder norms. Let τ_j be the amplitude and k its fixed generating test. The norms also cover the associated frozen families at every admitted constant source ζ and every constant

generator h_0 in the channel with $|h_0| \le \|\mathsf{k}\|_\infty$. The amplitude norms below are the corresponding suprema over ζ. This frozen coverage is part of the weighted input class; it is not inferred from a norm of only the varying test. Put

$$\mathsf{z}_j = \|\tau_j\|_\infty \|\mathsf{k}\|_\infty, \quad \mathsf{b}_j = \|\tau_j - \tau_{j-1}\|_\infty \|\mathsf{k}\|_\infty, \quad \mathsf{z}_n^\sharp = \sum_{j \le n} L^{-(n-j)}(\mathsf{z}_j + \mathsf{z}_{j-1}). \tag{A.lxxxv}$$

Use $\mathsf{z}_{-1} = 0$ and the actual first-entry convention. The symbols here measure this direction, not the deviations of the running coupling.

Let ς_ν be the actual forgetting weights and let $w_{n,j} = (\alpha_n/\alpha_j)^2$ be the squared radius ratios. If a remainder born at j is refiled at j'', define

$$\begin{aligned} \mathcal{L}_n = &\sum_{j \le n} \varsigma_{n+1-j} \mathsf{e}_j + \sum_{j \le n \le j''} w_{n,j} \mathsf{r}_j \\ &+ \mathfrak{g}_n \left[\mathsf{z}_n^\sharp + \sum_{j \le n} L^{-c(n-j)} \mathsf{b}_j \right]. \end{aligned} \tag{A.lxxxvi}$$

The second sum includes precisely the remainders still awaiting refiling. A bare stored insertion contributes its stated additional size $C\mathfrak{g}_0 N_{\mathrm{bare}} \|\mathsf{k}\|_\infty$ at level zero. The size N_{bare} is counted from that insertion and is not silently set to one.

The vertex response factor is of order $\mathfrak{g}_n = x_n^{-1}(\log x_n)^C$ on the coupling-independent analytic route. For a member analytic only on a running field radius the corresponding gain is generally the square of the fluctuation-to-radius ratio. These two factors are different. The parity calculation below explains the distinction.

Weighted extension and the derivative rows. Attach one dial $\lambda_{n,k'}$ to the entry when it is used in zone n at step k'. A useful actual class requires a joint extension with axis radii

$$|\lambda_{n,k'}| < c/\mathcal{L}_n. \tag{A.lxxxvii}$$

When a load is zero its direction has no contribution and that axis can be omitted. The class also specifies the joint multi-axis budget; individual axis discs alone do not give their Cartesian product.

The required analytic assertion has two parts. In the small-field map the differentiated potential norm must retain $C\varkappa_k \mathcal{L}_k$, where $\varkappa_k$ is the actual fluctuation-to-radius ratio. For a large-field output, setting one dial to zero must change its assigned term by a bound proportional to the share of histories retaining that zone, on the same radius in eq. A.lxxxvii. The small factor and the age bound are bounds of the extension, rather than consequences of its holomorphy.

Here are the exact implications once that class has been proved. The inserted finite-map theorem applied to the potential derivative gives its regular potential row. In addition the actual refile operation must carry a remainder born at j with norm at most $Cw_{k,j}\mathsf{r}_j$, and the new birth has norm σ_{k+1}. These primitive refile bounds give the complete regular row below. For the amplitude row one must also use the actual channel update and its normalization:

$$\mathcal{T}_{k+1}[\dot{E}^{(k+1),\mathrm{fr}}_{\zeta,h_0}] = [\tau_{k+1}(\zeta) - \tau_k(\zeta)]h_0. \tag{A.lxxxviii}$$

Here $\mathcal{T}_{k+1}$ is the own scalar or tensor coefficient readout in the fixed chosen channel. Its field-radius bound is $|\mathcal{T}_{k+1}F| \le C\alpha_{k+1}^{-2}\|F\|$. Apply it to every frozen constant generator; taking $|h_0| = \|\mathsf{k}\|_\infty$, or the supremum over its unit directions for a linear amplitude map, proves the displayed amplitude-increment bound. If $\|\mathsf{k}\|_\infty = 0$ that bound is immediate. Without this actual update and frozen coverage the argument bounds only the own coefficient $\mathcal{T}_{k+1}[\dot{E}]$, not the separately defined amplitude increment. A coefficient readout costs the inverse square of its physical field radius:

$$\mathsf{e}_{k+1} \le C\varkappa_k \mathcal{L}_k + C \sum_{j \text{ refiled at } k} w_{k,j}\mathsf{r}_j + \sigma_{k+1}, \qquad \mathsf{b}_{k+1} \le C\alpha_{k+1}^{-2}\mathsf{e}_{k+1}. \tag{A.lxxxix}$$

If a different normalized coefficient convention is used, its explicit conversion replaces the last factor. In Gaussian coordinates that conversion includes the square of the coupling. It cannot be charged once in $w_{k,j}$ and a second time as another old-radius loss:

$$\alpha_n^{-2} w_{n,j} = \alpha_j^{-2}. \tag{A.xc}$$

Suppose a single zone dial has holomorphic output difference $F(\lambda) - F(0)$ bounded on eq. A.lxxxvii by $C\epsilon_k q_a^{(k-n-1)_+}$, with $0 < q_a < 1$. Cauchy's formula gives

$$|F'(0)| \le C'\epsilon_k q_a^{(k-n-1)_+} \mathcal{L}_n. \tag{A.xci}$$

There are $k - n + 1$ possible uses of this zone by step k. Summing its actual dial derivatives gives the aged load

$$\mathcal{A}_k = \sum_{n \le k} (k - n + 1) q_a^{(k-n-1)_+} \mathcal{L}_n. \tag{A.xcii}$$

This derivation uses an already contracted direction at each use, with its own radius. It does not apply Cauchy again on a radius chosen at the original birth.

The own part of a new boundary term can have this age-weighted bound. Dependence on an inner stored layer in a live component is different: its boundary exponent can carry order-one coefficients counted at each later use. Its small factor belongs to the component's mass integral. That inner part must be paid under that mass where the component enters. Placing the same age factor in an exponent norm would claim a stronger estimate than eq. A.xci.

The exact convolution requirements. Assume the actual forgetting kernel satisfies $\varsigma_\nu \le C\nu^4 L^{-c(\nu-1)}$. For a fixed θ with $L^{-c} < \theta < 1$ put

$$S_\theta = \sum_{\nu \ge 1} \varsigma_\nu \theta^{-\nu} < \infty. \tag{A.xciii}$$

The convergence is geometric after a polynomial factor. If the shifts agree, the unmarked row $u_{k+1} \le \varkappa_k \sum_{j \le k} \varsigma_{k+1-j} u_j$ propagates $u_j \le A\theta^j$ whenever $\sup_k \varkappa_k S_\theta \le 1$. Substitute the induction bound, factor $A\theta^{k+1}$, and the remaining sum is at most S_θ. Thus θ is chosen first and the weak-coupling floor after it. The weight itself is not generated by this induction.

For the age kernel define $a_\nu = (\nu + 1) q_a^{(\nu-1)_+}$. On sequences decaying as θ^n its norm is

$$A_\theta = \sum_{\nu \ge 0} a_\nu \theta^{-\nu} < \infty \quad \Longleftrightarrow \quad \theta > q_a. \tag{A.xciv}$$

For $\nu \ge 1$ the ratio in the geometric series is q_a/θ, with the extra factor $\nu + 1$. At equality the terms do not even tend to zero. Consequently $\mathcal{L}_n \le B\theta^n$ implies $\mathcal{A}_k \le BA_\theta \theta^k$ under this strict inequality. The first finitely many ages are included in the same finite constant. They are not discarded by an asymptotic argument.

Squared radius weights often grow polynomially in age under the admitted frame. If $w_{n,j} \le C(n - j + 2)^A$ and a refiled remainder has $\mathsf{r}_j \le B\theta^j \eta^{n-j}$ for its actual allowed range, then

$$\sum_{j \le n} w_{n,j} \mathsf{r}_j \le CB\theta^n \sum_{a \ge 0} (a + 2)^A (\eta/\theta)^a. \tag{A.xcv}$$

This is finite for $\eta < \theta$. A remainder merely bounded by $B\theta^j$ has no such conclusion for growing weights. The recent-window remainders must instead be treated by their own recursive small factor and finite window length. These are distinct origin classes.

More generally if a nonnegative sequence satisfies $e_{n+1} \le \epsilon \sum_{\nu \ge 1} K_\nu e_{n+1-\nu} + s_{n+1}$, with $e_j = 0$ at negative indices, the weighted supremum norm gives

$$\sup_{n \ge 0} \theta^{-n} e_n \le \frac{e_0 + \sup_{n \ge 1} \theta^{-n} s_n}{1 - \epsilon \sum_{\nu \ge 1} K_\nu \theta^{-\nu}} \tag{A.xcvi}$$

when the denominator is positive. Prove it first up to a finite horizon, take the maximum, and move its coefficient to the left. The same bound is independent of that horizon. This is the discrete contraction used after the actual weighted rows are obtained; it does not establish those rows.

A single-zone incidence budget on its original mass. A zone parameter can occur in several copied potentials, counterterms and scalar anchors. To exhibit its true domain, list these occurrences before estimating a complex exponential. Let $B_p(Y) \geq 0$ be the specified reserve quantities of a component, including any size reserve, and let $a_{pt} \geq 0$ be the charge of occurrence t against reserve p. Suppose the actual exponent increment satisfies

$$|\Psi(\lambda, Y, e) - \Psi(0, Y, e)| \leq \sum_p B_p(Y) \sum_t a_{pt} |\lambda_t| \tag{A.xcvii}$$

on its admitted parameter domain. All occurrences and their scalar constants are included. An oscillation norm alone does not bound a scalar anchor.

The needed unsourced reserve is the weighted mass

$$\int^* \sup_{e \in \mathcal{E}_\omega(Y)} |w^0_\omega(Y, e)| \exp\left\{ \sum_p r_p B_p(Y) \right\} dY \leq M_\omega. \tag{A.xcviii}$$

The set $\mathcal{E}_\omega(Y)$ is the actual admissible external fibre at the stored variable Y. The upper integral is the infimum of integrals of measurable majorants; one may equivalently assume the displayed common integrable envelope as part of the premise. The parameter-dependent integrands are measurable in Y and pointwise holomorphic on their joint source domain. Fixed integration sets and this common envelope justify the dominated Cauchy argument below. The original inner Wilson factor is part of w^0_ω with its prescribed original weight. This assertion does not replace it by a freely reduced coupling. The positive reserve must have been established in the original mass estimate with its exact allocation.

On the joint domain

$$\sum_t a_{pt} |\lambda_t| < r_p \quad \text{for every } p, \tag{A.xcix}$$

equations in eq. A.xcvii–eq. A.xcviii bound the perturbed component mass by M_ω. The proof multiplies the absolute value of the original integrand by the exponential majorant and integrates. The exterior supremum stays inside the stored-variable integral. For fixed integration sets, this same domination on smaller parameter domains justifies holomorphy of the integral by the Cauchy formula.

For polydisc radii R_t it suffices to prove $\sum_t a_{pt} R_t \leq (1 - \epsilon) r_p$ simultaneously. Single-axis bounds $a_{pt} R_t \leq r_p$ do not imply this sum-budget condition. This is the no-reuse incidence test: every copy is charged once, and all copies sharing a reserve are summed.

For one dial with load $\mathcal{L}_n$, an incidence estimate $\sum_t a_{pt} \leq C_p \mathcal{L}_n$ gives radius $c/\mathcal{L}_n$, with c chosen from the unused r_p/C_p. Its radius does not increase as the zone ages. Age rarity is a bound on M_ω or its sum, and yields the factor in eq. A.xci. The zone-reserve test section proves why placing its reciprocal into the input radius fails. The application uses eq. A.xcvii–eq. A.xcviii for the complete one-zone list and its assigned mass, including the original inner Wilson factor and dropout fibres.

For m source directions sharing one potential allowance, radii proportional to $c/(m\mathcal{L}_i)$ give a valid sum-budget disc. Its mixed derivative costs at most $M(m/c)^m \prod_i \mathcal{L}_i$. Since $m^m \leq e^m m!$, this has a factorial majorant. It is incorrect to use the two-direction spare-slot radii for arbitrary m without summing the shared charge.

The even-coupling vertex gain. There is an exact analytic gain for a vertex admitted on coupling-independent field radii. Let q be an auxiliary coupling, distinct from any constraint derivative. Suppose the actual finite integral and localized formation are holomorphic for $|q| < R_q$ and $|u| < u_0$. The parameter u multiplies the specified vertex. Assume the Gaussian and cutoffs are fixed and

even, the potentials are unchanged by $(q, Y) \mapsto (-q, -Y)$, and at $q = 0$ the output is independent of u. Write its normed output as $\Phi(q, u)$ and suppose $\|\Phi\| \le M$.

Cauchy in u bounds $F(q) = \partial_u \Phi(q, 0)$ by $2M/u_0$. Changing the integration variable $Y \mapsto -Y$ proves $F(-q) = F(q)$, term by term only when the actual localization rule respects that change of variables. Independence at zero gives $F(0) = 0$. Therefore

$$\|F(g)\| \le \frac{2M}{u_0}|g/R_q|^2, \qquad \|F(g) - g^2 L\| \le C\frac{M}{u_0}|g/R_q|^4, \quad L = \tfrac{1}{2}F''(0), \quad |g| \le R_q/2. \tag{A.c}$$

For a proof expand $F(q) = \sum_{j\ge 1} a_{2j} q^{2j}$. Cauchy bounds $\|a_{2j}\| \le (2M/u_0)R_q^{-2j}$. Alternatively the even function defines a holomorphic function of q^2 and Schwarz proves the first bound. The geometric tail starting with $j = 2$ proves the second.

The radius R_q is determined by the actual potential and field cutoff. If the cut field has size $b_k \asymp (\log x_k)^{p_0}$, a cubic intrinsic remainder $q^{-2}V_{\ge 3}(qY)$ has removable value zero and size $O(|q|b_k^3)$. With the other potential and core estimates admitting this whole disc, one may take $R_q = cb_k^{-3}$. Further proved polynomial logarithmic losses replace the exponent three by their total exponent. Then $(g/R_q)^2$ has the form $x_k^{-1}(\log x_k)^C$. A mere upper bound on a possible radius would not prove this gain. If the admitted disc is instead only $R_q = c\alpha_k/b_k$ on a running field radius, the ratio squared is $c^{-2}(\delta_k/\alpha_k)^2$, where $\delta_k = gb_k$. Parity alone does not replace that smaller radius by a coupling-independent one.

The one-loop coefficient has a direct normalized formula. Suppose the inserted vertex and other potentials have $S = qS_1 + q^2 S_2 + \cdots$ and $V = qV_1 + \cdots$. Differentiate $\log \mathbb{E}_0 e^{V+uS}$ in u and expand at zero. Parity makes $\mathbb{E}_0 S_1 = \mathbb{E}_0 V_1 = 0$. The coefficient of q^2 is consequently

$$\mathbb{E}_0 S_2 + \mathbb{E}_0(S_1 V_1) - \mathbb{E}_0 S_1\, \mathbb{E}_0 V_1 = \mathbb{E}_0 S_2 + \mathrm{Cov}_0(S_1, V_1). \tag{A.ci}$$

The expectation includes the actual cutoff and its normalizer. Replacing it by an uncut Gaussian requires the separate cutoff-tail estimate. The formula in eq. A.ci does not compute its tensor eigenvalue or its sign.

Matched reference measures on a common domain. Two local coefficient lists can be compared by differentiating a common finite integral only after their variables, sharp sets and numerators have been pulled to the same reference domain. Let

$$Z_t(z) = \int_D e^{V_t(y,z)}\, d\mu_{A_t}(y), \qquad d\mu_{A_t} = (2\pi)^{-N/2} \det(A_t)^{1/2} e^{-y^{\mathsf{T}} A_t y/2}\, dy. \tag{A.cii}$$

Assume the determinant branch, matrices and integrands are holomorphic on a common neighbourhood of the interpolation $0 \le t \le 1$, with fixed D and uniform domination there. Assume the generating function has a common nonzero neighbourhood of $z = 0$. Differentiation gives exactly

$$\frac{d}{dt}\log Z_t(z) = \tfrac{1}{2}\,\mathrm{Tr}(A_t^{-1}\dot{A}_t) + \left\langle \dot{V}_t - \tfrac{1}{2} y^{\mathsf{T}} \dot{A}_t y \right\rangle_{t,z}. \tag{A.ciii}$$

This follows by differentiating the determinant and the quadratic exponent. A change-of-variables Jacobian belongs in V_t with its own derivative. If the cutoff moves, eq. A.ciii is not the complete derivative unless the induced boundary term or an exact fixed-domain pullback has been supplied.

For the normalized moment generator $\log Z_t(z) - \log Z_t(0)$, the trace cancels if A_t has no source dependence. With $L_t = \dot{V}_t - \frac{1}{2} y^{\mathsf{T}} \dot{A}_t y$ the derivative is

$$\langle L_t(z)\rangle_{t,z} - \langle L_t(0)\rangle_{t,0}. \tag{A.civ}$$

A subtracted vacuum energy has its derivative as well; it cancels between two presentations only when it is the genuinely common energy. If V_t includes a transported observable, $\dot{V}_t$ includes that observable's coordinate derivative. It is not just the difference of old interaction coefficients.

Suppose the right side of eq. A.civ, including every required scalar energy term, has holomorphic supremum at most ϵ_t on a common polydisc of source radii r_i. Integrating in t and using coordinate Cauchy gives for a mixed cumulant derivative

$$|\Delta\kappa_{i_1,\dots,i_m}| \le \gamma! \prod_i r_i^{-\gamma_i} \int_0^1 \epsilon_t \, dt, \tag{A.cv}$$

where γ_i is the number of repetitions of coordinate i. For distinct coordinates there is no $m!$. A common source radius with repeated derivatives has the indicated factorial. This is a cumulant bound because it differentiates a logarithm. For raw moments use the actual normalized generator $M_t(z) = Z_t(z)/Z_t(0)$. If $|M_t(z)| \le Q$ on the same polydisc and $G_t = \partial_t \log M_t$ is bounded by ϵ_t, then $M_1 - M_0 = \int_0^1 M_t G_t \, dt$. Coordinate Cauchy gives the raw-moment version of eq. A.cv with the additional factor Q. Scalar energy subtractions must be restored or included in the identified target generator before it is called a physical moment. Thus a coefficient comparison gives a matched moment estimate only after the actual common domain, scalar normalization, source generators and expectation bound have been proved.

For adjacent cutoff estimates the resulting error sequence has to be summable in the telescoping theorem. A direct two-cutoff bound by $\epsilon_{\min(K,K')}$ with $\epsilon_K \to 0$ is another sufficient route. Bounded derivatives at each cutoff, with no comparison of the generators across cutoffs, supply neither. The comparison-capsule section gives the resulting fixed-torus Cauchy limit in its exact scope.

A.9.0.1. Transfer between the two bare lattices. At a common physical depth transfer a regional pair (U, J) by blocking U one step and taking the cell mean of the current J. On common rows the composition of the straightened constraints identifies the retained block field. The local Jacobian and the block gauge factors agree when formed from this same field by the same rule. The other quantities to compare are the regional propagators and kernels, the localized Wilson response, the localized Gaussian normalizer, and the fields used to evaluate earlier activities. Define these on the two cutoffs by the same regional rule before taking differences. A walk term indexed by a finite set S of cubes is obtained from the alternating sum of the regional fluctuation operators of $Y \subset S$, each compressed to the interior of Y. The switched precision is linear in those walk terms. The normalizer uses the logarithm of an operator built on the recursive tower of each region. On the full torus the sequences are constant and the two regional rules use the same uncut fluctuation operator for their respective totals.

A.9.0.2. The analytic line on ordinary carriers. Take the sharp ordinary data $U, A', \mathbf{J}$ with radii a_0, a_1, c_0, where $a_1^2 \le C a_0$. Let $h = \eta/L$ be the sharp spacing in the common units. Use the line

$$A_z = A_{\mathrm{R}} + z A_{\mathrm{I}}, \qquad \mathbf{U}_z = e^{ihA_z} U, \qquad \mathbf{J}_z = J_{\mathrm{R}} + z J_{\mathrm{I}}, \qquad |z| \le R,$$

where the real and imaginary parts are in the real Lie algebra and $R > 1 + \sqrt{2}$ is fixed. The target is at $z = i$. The line has a fixed real base U.

For a plaquette p, let $d_U A'(p)$ be the sum of its four signed increments transported to the base of p in U. The first-order expansion of $\partial(e^{ihA'}U)(p)(\partial U(p))^{-1}$ is $1 + ih d_U A'(p)$, with error $Ch^2 a_1^2$. Both endpoint curvatures are bounded by $a_0 h^2$, so $|d_U A'| \le Ch(a_0 + a_1^2)$. The transports in U preserve the real Lie algebra. Applying the same expansion to A_z therefore bounds the curvature along the line by $C_R h^2 (a_0 + a_1^2)$.

The complete double blocks of a flat gauge cube and their neighboring translates lie in its 4η halo. Use the one-layer sharp collar when this halo is contained there. A cube whose halo fits within the sharp chart size can use the given gauge on the halo. Otherwise start from the sharp gauge on the cube, rounding inward by at most a fixed number of fine layers. Work on the lattice lift of the cube, using the covering charts on a short torus.

For the axial continuation add one whole face layer at a time. In the signed outward direction d, let $W(x)$ be the last gauged normal link from $x - hd$ to the face point x. With g the gauge already

defined, set

$$g(x+hd) = W(x)^{-1} g(x) U_d(x).$$

The new gauged normal link is then $W(x)$. For a tangential direction μ, the plaquette identity for the gauged links V gives

$$V_\mu(x+hd) = W(x)^{-1} (\partial U^g)_{d\mu}(x) V_\mu(x) W(x+he_\mu).$$

The plaquette error and the tangential change of W are both $O(h^2 a_0)$. Commuting W past V_μ costs $O(h^2 a_0^2)$, since both links differ from one by $O(ha_0)$. Thus each new tangential link differs from its old face value by $O(h^2 a_0)$. For tangential first differences compare the two corresponding old links and add these two errors. Normal links inherit their tangential differences and agree on successive links of each extended ray. The small logarithm divided by h therefore preserves the field and first-difference bounds, with a fixed constant at each added layer. Extend successive faces of the enlarged rectangle to include the corners. The halo takes $O(L)$ fine layers in each direction, so the total constant is independent of the cutoff.

In the resulting sharp chart write $U = e^{iha}$. The fixed one-step logarithm map has bounded first and second derivatives on a small chart and is the same function on translated stencils. Applying it to the real base gives a coarse gauge potential and first difference bounded by Ca_0. For the complex factor use

$$F(a,B) = \frac{1}{i\eta} \log\Big(\mathcal{M}(e^{ihB} e^{iha}) \mathcal{M}(e^{iha})^{-1} \Big).$$

It vanishes when $B = 0$. The derivative in B is bounded by C_L, and the mixed derivative bound gives $|D_a F| \le C_L h \sup |B|$. Comparing the complete neighboring stencils therefore bounds $F(a, A_z)$ and its first covariant difference by $C_R a_1$. The coarse plaquette estimate uses exchanges of adjacent steps in the averaging paths: the $O(L^2)$ resulting sharp plaquette errors are transported by products of bounded length. This bounds the two coarse curvatures by $C_{L,R}\eta^2(a_0 + a_1^2)$. The finite transport in the cell mean bounds the independent current by $C_{L,R} c_0$.

These are the single-scale clauses on any ordinary domain covered by these charts. In either tower rule, at an address of depth p below level j, put $\lambda = L^{-(j-p)}$. If a_0', a_1' bound the resulting curvature and complex factor, the tower theorem gives the bound $K_{\mathrm{red}}(\lambda a_0' + \lambda^2 (a_1')^2)$ at that address. In its tower subcall the independent current is set to zero. The current slot of the evaluation pair keeps its own radius. Taking the sharp radii smaller than the paired running radii by one fixed factor gives, on both lines, $a_i' \le b_i$ for the corresponding field radii, $a_0' + a_1' \le a^\sharp$, and $K_{\mathrm{red}}(a_0' + (a_1')^2) \le b_0$. Thus the line and its transfer lie in their cores at every tower address. On the real diameter the line gives real pairs in a fixed small radius, with real chart bound $C_{L,R}(a_0 + a_1)$. This is enough for the real regional estimates stated at a fixed small radius. For a shifted or graded read the same argument requires its own complete collar and bounds.

A.9.0.3. The regional row form. Write $\sharp$ for the finer bare lattice and $\flat$ for the other lattice. For the switched kernel use scale sequences on a fixed region Y. At physical spacing ξ_n the direct rule keeps precisely the cubes of side $LM_1\xi_n$ in Y whose distance from Y^c is at least $\mathsf{r}_t \xi_n$. The tests defining a member at a common physical scale therefore agree cube by cube: $\Omega_{n+1}^\sharp(Y) = \Omega_n^\flat(Y)$ for $n \ge 1$. At the lower cut include the full double blocks and the neighboring stencils of the first rows retained. Use real pairs of small radius whose transfers are also in the small-radius class. Extend flat row data by zero off the common interior and outward rows. Let F be the fluctuation form before the row penalty, Q the row map, and set

$$\mathsf{G} = (\mathsf{F} + Q^{\mathsf{T}} \xi_c^{-2} Q)^{-1}, \qquad \mathsf{M} = Q \mathsf{G} Q^{\mathsf{T}}, \qquad \mathsf{H} = \mathsf{G} Q^{\mathsf{T}} \mathsf{M}^{-1}.$$

Here ξ_c denotes the local row scale in the diagonal penalty. Let $\mathbb{P}$ be the cell mean and q_1 the straightened linearized bond average for one step. For $f = \mathsf{H}^\flat B_1$ and $h = \mathsf{H}^\sharp B_2^\uparrow$, write $\lambda_i = (\mathsf{M}^{-1} - a_{\mathrm{row}}) B_i$ for the row multiplier, with $a_{\mathrm{row}} = \mathrm{diag}(\xi_c^{-2})$ in that run. Then $\mathsf{F}\mathsf{H} B_i = Q^{\mathsf{T}} \lambda_i$. Set

$\mathsf{d} = Q^\sharp \mathbb{P}^\mathsf{T} f - B_1^\uparrow$. Use $\mathbb{P}^\mathsf{T} f$ in the sharp equation and $q_1 h$ in the flat one. The row penalties agree on the shared rows. If $Q^\flat q_1 h = B_2$, the identity is

$$\begin{aligned}(B_1^\uparrow, (\mathsf{M}^\sharp)^{-1} B_2^\uparrow)_\sharp - (B_1, (\mathsf{M}^\flat)^{-1} B_2)_\flat \\ = \mathfrak{D}(f,h) - (\mathsf{d}, \lambda_2), \qquad \mathfrak{D}(f,a) = (\mathbb{P}^\mathsf{T} f, \mathsf{F}^\sharp a)_\sharp - (f, \mathsf{F}^\flat q_1 a)_\flat.\end{aligned} \tag{A.cvi}$$

On common rows $Q^\flat q_1 h = B_2$ by composition of the straightened averages. For an unmatched bottom row use the complete double block in the sharp bare rim. Its fine links are rows of the sharp determining set with zero prescribed values, so its average is zero. If a regional cut changes this relation, keep the extra term $(Q^\flat q_1 h - B_2, \lambda_1^\flat)$ on the right of eq. A.cvi. The prolongation defect pairs with the sharp row multiplier. Its size is $O(\eta \nabla f)$ on the common interior, where η is the coarser of the two bare meshes.

The consistency estimate for $\mathfrak{D}$ uses the fields cut off at the unmatched rim. In scaled local first-order norms $n_1(y), n_2(y)$, the second of which includes the Hölder quotient of the gradient, its bound is

$$C(1+u_0) \sum_y (\eta/\xi_y)^\beta n_1(y) n_2(y), \qquad 0 < \beta < 1.$$

The row currents must satisfy $\xi_c^3 |\mathsf{j}^\sharp(c)| \le 1$ and $\xi_c^3 |\mathsf{j}^\sharp(c) - \mathsf{j}^\flat(c)| \le u_0 (\eta/\xi_c)^\beta$ on the common rows. The term linear in the prescribed current uses the exact transpose pairing $(\mathbb{P}^\mathsf{T} f, J)_\sharp = (f, \mathbb{P} J)_\flat$. In the Landau projection use the straightened site and field transfers q_0, q_1, for which $q_1 D_U = D_W q_0$ on the complete carriers, with $W = \mathcal{M} U$. Write $\mathbb{P}^\mathrm{f}$ for the covariant face mean. On the full stencils the site Laplacian commutator is

$$(\Delta^{\circ\flat} q_0 - q_0 \Delta^{\circ\sharp}) \lambda = D_W^\mathsf{T} (q_1 - \mathbb{P}^\mathrm{f}) D_U \lambda - (q_0 D_U^\mathsf{T} - D_W^\mathsf{T} \mathbb{P}^\mathrm{f}) D_U \lambda.$$

This adds and subtracts $D_W^\mathsf{T} \mathbb{P}^\mathrm{f} D_U \lambda$ after intertwining. The last term is bounded by $C \eta^{-1} \varpi \sup |D_U \lambda|$ on its box, with ϖ the plaquette defect there. The unit-scale curvature bound gives $\varpi \le C\eta^2$. The first term is the divergence of the small face-mean difference. After summation by parts the divergence term is paired with a controlled first difference. The resulting site resolvent term is controlled in cell L^2 and is used in the final pairing. A second application of a propagator to that term would need a different bound.

In screening the rim, crossing one layer pays for the growth of the number of tops by at most L^4 and for the growth of the consistency weight by L^β. The resulting sum is

$$\sum_y (\eta/\xi_y)^\beta e^{-\delta_0 d(y,y')} \le C (\eta/\xi_{y'})^\beta.$$

First work with the forms at prescribed row current zero. For the bond force $J^\sharp$, put

$$a_* = (1 - \mathsf{H}^\sharp Q^\sharp) \mathsf{G}^\sharp J^\sharp, \qquad \mathsf{j}_*^\sharp = (\mathsf{H}^\sharp)^\mathsf{T} J^\sharp.$$

Then $Q^\sharp a_* = 0$, and multiplying out the inverse equations gives $\mathsf{F}^\sharp a_* = J^\sharp - Q^{\sharp\mathsf{T}} \mathsf{j}_*^\sharp$. The exact transpose pairing for $J^\flat = \mathbb{P} J^\sharp$ therefore gives

$$(B_1, \mathsf{j}_*^\flat) - (B_1^\uparrow, \mathsf{j}_*^\sharp) = \mathfrak{D}(f, a_*) + (\mathsf{d}, \mathsf{j}_*^\sharp) + (Q^\flat q_1 a_*, \lambda_1^\flat).$$

The last term vanishes on the matched constraint carriers by the same common-row and bare-rim calculation. The weak form estimate with the weighted fields f, a_* and the screening sum then give the induced current difference. Insert these currents in eq. A.cvi. At unit rows the entrywise rate is $CL^{-\beta k}$ when the step has k finer levels. The consistency estimate supplies the power of the mesh and the propagation bound screens the bottom layers.

For the switched kernel use the common regional alternating sums with switches held at one on the prescribed collar. The alternating sums have a real smallness bound with a cost exponential in the number of cubes and an independent analytic bound with exponential decay. To combine the two, write the complex pair on the line through its real and imaginary parts whose real arguments

give real pairs. This line and its transfer must be admitted on a disc of radius $R > 1 + \sqrt{2}$, with the target at i. The two-constants estimate uses the bound on the real diameter and the analytic bound on the disc. Retain a sufficiently small positive power of the real smallness so the remaining localization absorbs the growth of the alternating sums. With the summable spatial decay this gives a bound $CL^{-\alpha_K k}$ on the differences of the inverse covariance and the auxiliary Gaussian kernel, for some $\alpha_K > 0$.

A.9.0.4. The normalization on the regional towers. The tower for the determinant is defined by the recursive regional rule. To compare its operators, let $\mathbb{E}^\sharp, \mathbb{E}^\flat$ be the inverses of the two first-order systems with bilinear forms $\mathfrak{K}^\sharp$ and $\mathfrak{K}^\flat$. For right-hand sides $G^\sharp, G^\flat$, put $\Phi^\sharp = \mathbb{E}^{\sharp\mathsf{T}} G^\sharp$ and $\Psi^\flat = \mathbb{E}^\flat G^\flat$. If $\mathfrak{i}$ prolongs the flat variables and $\mathfrak{a}$ averages the sharp variables, the inverse identities give

$$(G^\sharp, \mathfrak{i}\Psi^\flat)_\sharp - (\mathfrak{a}\Phi^\sharp, G^\flat)_\flat = \mathfrak{K}^\sharp(\Phi^\sharp, \mathfrak{i}\Psi^\flat) - \mathfrak{K}^\flat(\mathfrak{a}\Phi^\sharp, \Psi^\flat).$$

Use multilinear prolongation $\mathfrak{i}_0$ and straightened averaging $\mathfrak{a}_0$. Compare real pairs of small radius with transfers of small radius. The flat test field Ψ vanishes below a fixed margin above the first common layer. Require $\xi_c^3 |\mathfrak{j}^\sharp(c)| \le 1$ and $\xi_c^3 |\mathfrak{j}^\flat(c)| \le 1$ on every row of the two systems, respectively.

For a common bond row the chain rule gives $Q^\sharp = Q^\flat q_1$, and for a common top it gives $Q'^\sharp = Q'^\flat q_0$. This cancels the terms with the averaged fine field. For the reversed pairing with a prolonged coarse field B, the bond-row error is $Q^\flat(q_1\mathfrak{i}_0 - 1)B$. On a complete carrier the flat means reproduce constants. The local comb and the first difference of B bound the L^2 norm of the expression before the row map by $C\eta\|\nabla B\|_2 + C_L\varpi\|B\|_2$. The raw bond-row coefficients give $|\xi_c Q^\flat(c)F| \le C\xi_c^{-1}\|F\|_2$ on its full cells. This gives the mesh factor in the pairing with the raw multiplier. The reversed top pairing uses the estimate for $q_0\mathfrak{i}_0 - 1$ in its site scale.

For the top mass use $a'(y) = \kappa_n \xi_y^{-2}$, where $\kappa_0 = \kappa_1 = 1$ and $\kappa_{n+1}^{-1} = 1 + L^{-2}\kappa_n^{-1}$ for $n \ge 1$. The insertion of a fine level changes n to $n+1$ on a common top, so

$$|a'^\sharp(y) - a'^\flat(y)| \le \xi_y^{-2}(\eta/\xi_y)^2.$$

The local site row bound makes this a weak error of the same order in the scaled cell norms.

For the site slot p the site equation gives a first-difference bound. With $g_0, D^\mathsf{T} x$ the two parts of its source, test on a complete collar against $\chi^2 p$, where $\chi = 1$ on the cell and $|D\chi| \le C/\xi_y$. Covariant summation by parts and the local bound on Q' give

$$\xi_y \|Dp\|_{2,y} \le C(\|p\|_2 + \xi_y^2 \|g_0 - Q'^\mathsf{T} r\|_2 + \xi_y \|x\|_2),$$

with the norms on the right taken on the collar. The current in x is used in norm. The row-current term in x is $-\Delta^{(2)}[\mathfrak{j}](A - Dv)$. Its one-cell bound uses the raw amplitude $\xi_c^3|\mathfrak{j}(c)|$, with no difference of the multiplier. For the Laplacian pairing with p, apply the difference of the two gradient means to the other slot. In flat coordinates the derivative of the multilinear prolongation is the prolongation of each directional derivative, constant along its coarse segment and multilinear transversely. This map and its volume transpose reproduce constants on complete incidences. Together with $D_W q_0 = q_1 D_U$ this moves the difference of means onto the gradient of the other slot, costing one mesh times its extra L^2 difference. In the local comb the covariant corrections cost $C_L\varpi/\eta$ on site values and $C_L\varpi$ on gradient means. Thus p requires only its first-difference bound. The site equations for v, w, q have L^2 sources controlled by the cell norms and first differences of the bond field. In their admitted regular gauge, localizing to a cell and using the flat identity $\sum_{\mu,\nu} \|\partial_\mu \partial_\nu f\|_2^2 = \|\Delta_0 f\|_2^2$ gives their interior second-difference bounds. The cutoff terms and the difference from the covariant site Laplacian cost a bounded first difference and value in cell units. In the scaled cell norms of the first-order systems this gives

$$|\mathfrak{K}^\sharp[\mathfrak{j}^\sharp](\Phi, \mathfrak{i}_0\Psi) - \mathfrak{K}^\flat[\mathfrak{j}^\flat](\mathfrak{a}_0\Phi, \Psi)| \le C \sum_y \left(\frac{\eta}{\xi_y} + \mathfrak{u}(y)\right) [\![\Phi]\!]^\vee_{(y)} [\![\Psi]\!]_{(y)},$$

where $\mathsf{u}(y) = \max_{c \text{ at } y} \xi_c^3 |\mathsf{j}^\sharp(c) - \mathsf{j}^\flat(c)|$ on the common rows. The unmatched layers are screened by the cutoff and the exponential propagation bound. First use the estimate with zero row currents. The screening sum with exponent one then gives $\xi_c^3 |\mathsf{j}_*^\sharp(c) - \mathsf{j}_*^\flat(c)| \le Ca\,\eta/\xi_c$ on common rows, where a is the pair radius and $\mathsf{j}_* = \mathsf{H}^\mathsf{T} J$. Using these induced currents in the consistency estimate gives the real entrywise rate CL^{-k} on the common interior bonds. The exponential kernel estimate on the larger complex domain and the two-constants estimate give a Schur norm bound $CL^{-k/2}$ on the smaller domain.

A.9.0.5. Common layers of a recursive tower. Suppose the two calls use the same physical first member Y, with aligned grids, and the same recursive rule. At the next grid of side s, assume that Y is a union of its cells. If the previous member was obtained by removing k layers of side s/L from Y, a new cell at distance ts from Y^c has clearance $ts - ks/L$ when it is contained in that member. The distance index t is an integer. This follows by thickening the union of excluded closed cells in the sup metric, so the same rule applies at faces and corners.

The rule that requires clearance at least s therefore removes $1 + \lceil k/L \rceil$ new layers. Starting from $k = 0$ its counts are $1, 2, 2, \ldots$. Since the finer call has one more erosion before the first common scale, the two members agree at the second common erosion. This is the rule of the minimal determining tower with M_1-cubes.

For the rule with $\mathfrak{M}$-cubes and strict clearance $> R_1 s/L$, the new count is $1 + \lfloor (R_1 + k)/L \rfloor$. If $R_1 = L^a$, the count after n erosions for $1 \le n \le a$ is $1 + \sum_{b=1}^{n} L^{a-b}$. The count at $n = a$ is a fixed point of the recursion. Hence the members agree after a common erosions for this rule. The full torus and empty regions agree directly.

These calculations require alignment of Y through the indicated first common grids. Once a member agrees, the same recursive rule at the same physical grids gives agreement thereafter. The common determining rows and tops are obtained from the coincident members above this fixed bottom margin. A row at level n uses its predecessor member for the complete double block and its successor member for the row type. In the M_1 tower take $n \ge 3$ before allowing for the fixed stencil margin. Use the same rule one level above synchronization in the strict-clearance tower. Cut below the complete carriers and include the full stencils in the unit-error halo before the form comparison.

The fine tower is one erosion ahead at the first common grid, so its member there is contained in Y. Monotonicity preserves this inclusion at each common physical scale. Consequently the local fine spacing is at most the local coarse spacing. The one-run kernel bounds can use the coarser weighted distance, with a fixed reduction in the exponential rate. Indeed, away from layer boundaries the length weights are ordered pointwise. On a boundary, use the smaller of the two adjacent spacings as the weight convention, which is equivalent up to a factor of two to the length counting both adjacent layers: a boundary segment of length t contributes $t \max(\xi_1^{-1}, \xi_2^{-1})$ under the first convention and $t(\xi_1^{-1} + \xi_2^{-1})$ under the second. A coarse cell in the omitted layers contains only a bounded number of finer cells, since these layers span a fixed number of meshes. Thus the same shell count applies to the one-run terms in the unit-error halo.

For the inner window $\square_0 = \square^{\sim 5}$, the raw determining tower uses the strict-clearance rule. In units of the output level the original π_k-cells have side M/L. The inequalities $M \ge L^4 M_1$ and $M_1 \ge R_1 \mathfrak{M}$ give alignment throughout this tower when the two calls use the same physical window. The inner and removed-window reads lie in $\square^{\sim 2}$, and $\square^{\sim 3}$ lies in the protected interior of $\square_0$. The native pillar bound puts its $4L^n$-halo in the free level-n pillars in bare units. This includes the full plaquette and bond-current stencils for the inner reads. The inverse solves use the whole tower, with its unmatched lower data screened as above. If the depth is shorter than the fixed margin needed for synchronization, the individual bounds suffice with a larger constant at those bounded depths.

For the inner transfer at old level $1 \le j \le k$, use $X^\dagger$, the enlargement of X by one layer of π_{j-1}, as the read collar. In level-k units its width is $ML^{-(k-j+1)}$, at most M/L and at least ML^{-k}. It contains the one-step stencils and keeps $X^\dagger$ strictly inside $\square^{\sim 3}$ for $X \subset \square^{\sim 2}$. This places the transfer in the ordinary field and current bounds on the protected collar. For the inner input of Prop. 3.135, the same proof gives the old analytic core on the collar itself. Its complete bare stencils reach at most two bare steps from $X^\dagger$ and remain in $\square^{\sim 3}$, where the flat representative has the bounds eq. 3.mcx. For a tower address (p, Z) of $X^\dagger$, $Z \subset \square^{\sim 3} \subset \square_{(j)}$, so the exact change of gauge eq. 3.mcxvi applies to the restriction of the native response to Z. Its conjugation norm is less than $6/5$. For a truncation at depth $n' \le p$, the curvature and current bounds after this change are

$$\frac{6}{5}\frac{a_0}{8}L^{-2j}, \qquad \frac{6}{5}\frac{a_0}{16}L^{-3(j-n')}.$$

These are below $(a_0/4)L^{-(j-p)}L^{-2p}$ and $(a_0/4)L^{-(j-p)}L^{2(n'-p)}$, respectively, since $n' \le p \le j$. This gives both hereditary rules for the triple on $X^\dagger$, with core radii $(a_0/4, a_1/2, a_0/4)$, for the admitted native substitution. The pair-orbit evaluation is still on the activity domain X. Use the distance with the thinner read collar and a single sharp-to-flat radius loss for the one bare transfer. The frame and shifted inputs in the paired comparison must still be identified on that collar.

On a common row the plain relative datum has an exact transfer. First transfer the shifted sharp field and its sharp base separately. Their relative logarithm on a flat bond is $\mathsf{Q}_1^\sharp(\mathbf{U}; \mathsf{a})$. On the common small logarithm branches the semigroup identity gives

$$\mathsf{Q}_{q+1}^\sharp(\mathbf{U}; \mathsf{a}) = \mathsf{Q}_q^\flat(\mathcal{M}\mathbf{U}; \mathsf{Q}_1^\sharp(\mathbf{U}; \mathsf{a})).$$

Compare this input to the actual flat shifted input in the common frame on the complete carrier. At fixed base the row estimate eq. 3.mcxv bounds the datum difference by CL^q times the supremum difference of the dimensionless input logs. For the conjugation of the input potential, only the frame value at the initial site enters this bound. The change of base and the node factors of the straightened chart must also be matched. The baseline inner datum uses the output radius $a_{0,k+1}$. Its ratio to the old radius is at most $C(n+1)^{1/2}$, without a scale gain for that baseline.

The Gaussian compression uses the calculation for its specified tower. For any other response at a vertex, the same physical subregion and cutoff must be used at both depths, and the sequence of its core must be identified before applying the tower calculation. If the cutoff ζ is applied after the solve, the extra term in a common averaging row is

$$[q_1, \zeta]A(c) = \sum_b q_1(c, b)(\zeta(b_-) - \zeta(c_-))A(b).$$

Here the cutoff is evaluated at the initial endpoints of the bonds. This term vanishes on a plateau containing the whole carrier. For a smooth cutoff it costs at most $C\eta\|\nabla\zeta\|_\infty \sup_{\mathrm{supp}\, q_1(c,\cdot)} |A|$ for the complete one-step stencil of mesh η, by its bounded row sum. One must check the cutoff on the actual vertex read, including any derivative of this commutator needed in its transfer estimate. A characteristic cutoff on a straddling carrier gives only the individual row bound.

For the raw switched response a protected case is available. The field on an active wall component is its own restricted solve, with support in $\mathbb{Y}^1$, and its reduced current has support in $\mathbb{Y}^2$. The margins of $\mathbb{Y}^3$ keep the full row, plaquette and first-difference stencils that meet either support inside that component. Its indicator therefore adds no commutator on these native reads, by Prop. 3.175. In the specified raw sequence, if every partition cube meeting a cell hull has parameter one, the field, projected field and reduced current equal the all-one fields on that sequence. Indeed, every term of their operator series uses only these cubes, and the local structures agree throughout the sequence. This is the all-one identification in Prop. 3.175. When it holds on both actual regional sequences, use their undecoupled comparison with their own determining data.

For other switch assignments, the raw operator at a vertex keeps the walk terms of the ambient sequence supported on the active cubes. The Möbius sum defining a named vertex selects the

undecoupled response of its designated region. To identify the two, one must first identify their linear lifts on the specified row data. At the all-one vertex $QH_1 = 1$ on the rows. For the proper mask the linearized constraint is $QH_1(s)B'$, by Prop. 3.175. The support property alone therefore supplies no lift identity for a different designated regional solve.

For a named vertex using the direct region rule one can test the required top inset on its full read carrier K. If the required inset has width $r_{\mathrm{in}}\xi_{\mathrm{top}}$, it suffices that

$$\mathrm{dist}_\infty(K, Y^c) \geq (\mathsf{r}_{\mathrm{t}} + LM_1 + r_{\mathrm{in}})\xi_{\mathrm{top}}.$$

Every cube of the top grid meeting this neighborhood of K then passes the direct clearance condition. For an outer vertex the region and the reads used in this check must be those of its own supply.

Write A_Y^- for the interior compression of the tower operator and $T_Y = 1 - c_N^{-1}\mathsf{A}_Y^-$, with $\|T_Y\| \leq q < 1$ on the matched domain. At a free bond b the root of the logarithm is

$$f_b(Y) = 3\log c_N - \sum_{m\geq 1} m^{-1}\,\mathrm{tr}(T_Y^m)_{bb}.$$

Use the same alternating sum over regions $Y \subset X$ containing the determining cubes of b. Subtract the value of each sum at the trivial pair, weight by the tents of the base points, and multiply by $-1/2$. The alternating sum and partition of unity restore the normalized log determinant. The local pivot terms agree on the common retained rows because their coefficients are functions of the same retained field.

The difference of the roots is bounded by the operator norm difference times $C\sum_{m\geq 1} q^{m-1}$, since telescoping T_Y^m produces m terms and the logarithm divides by m. The sum over regions thus costs at most $C2^{|X|}L^{-k/2}$, before localization. Independently, a chain missing a cube cancels by switching that cube in the alternating sum. Short chains meeting all cubes pay the distance of the carrier. Long chains are summed using q^m. The split at a small multiple of the carrier length in units of the regional mesh retains exponential decay of the localized sum. Interpolating the two summed bounds with a small power of the norm difference absorbs the factor $2^{|X|}$ and retains the required exponential decay together with a positive power of L^{-k}. This also applies to the vacuum subtraction.

A.9.0.6. The regional Wilson increment. For each action carrier X and each vertex subregion Z containing X, let H_Z be the response on the core of Z times the prescribed cutoff. The localized interaction uses the action increment $\mathrm{Br}_{X,Z} = a_X(e^{i\eta H_Z}U) - a_X(U)$. For $Y \supset X$ sum these increments over $Z = X \cup S$, $S \subset Y \setminus X$, with sign $(-1)^{|Y\setminus X|-|S|}$, and take the third-order Taylor remainder in the fluctuation. Inversion at the full vertex restores the Wilson increment with the same subtraction. The one-run bound with the decoupling parameters in their larger polydisc provides decay in the number of cubes of $Y \setminus X$.

For a matched real vertex write U' for the perturbed fine field, W' for the perturbed coarse field, and $W = \mathcal{M}U$. Put $D = A^\flat \circ \mathcal{M} - A^\sharp$. Subtract the increments in the two actions to get

$$\begin{aligned}(A^\sharp(U') - A^\sharp(U)) - (A^\flat(W') - A^\flat(W))\\ = -(D(U') - D(U)) + (A^\flat(\mathcal{M}U') - A^\flat(W')).\end{aligned} \tag{A.cvii}$$

The local version includes the plaquette shell of the carrier. The second term compares configurations on the coarse lattice. Use the response estimate on the matched real cores and the continuity of the action there. The first term uses consistency of the action under a regular perturbation of a possibly rough background.

For this consistency, the exterior derivative commutes with the linearized averaging of bond fields. In unscaled plaquette logarithms the induced average on two-forms is L^2 times a probability average of fine plaquettes. The difference of the flat quadratic actions is therefore $-L^4/2$ times the sum of the corresponding flux variances, plus the shell term. If the perturbation changes the curvature from F to $F + \gamma$, the change of variance on a block is $2\,\mathrm{Cov}(F, \gamma) + \mathrm{Var}(\gamma)$, where the

covariance uses the Lie algebra inner product. Subtract the mean of γ and use Cauchy–Schwarz. The rough F enters through its size, and the oscillation of γ supplies a positive power of the mesh from the Hölder bound on the covariant gradient of the perturbation. In the localized consistency estimate the shell and the nonlinear errors from multiplication of plaquettes are kept with this same carrier. This is an estimate of the variation $D(U') - D(U)$, since the variance of F itself need not be small.

The first variation of this quadratic defect in the chosen cell frame is

$$-L^4 \sum_P \mathrm{Cov}_P(F, \delta_A F) + d(\mathrm{shell})[A].$$

Subtract the block mean of $\delta_A F$ in the covariance. The Hölder bound on the covariant gradient of the test variation then gives the mesh gain while the rough curvature is used only in norm. Keep the differentiated nonlinear plaquette errors with the same full carrier.

For the nonlinear force itself, keep the transports in the plaquette chart fixed and separate the explicit background holonomy. Use h for the bare spacing in one run, and write $\Pi^0 = c_0\mathbf{1} + iH_0$ for the background plaquette. The perturbed plaquette has trace $\mathrm{tr}(\Pi^0 e^{i\theta})$, where $\theta = d\gamma + n$ and the four γ's are the increments transported to the plaquette base. Put $\sigma = \max_i |\gamma_i|$ and $w = |\Pi^0 - 1|$. The chart bounds n by $C\sigma^2$. In the differentiated expansion the terms of order zero and one are the background force and the Hessian. The remaining explicit dependence on Π^0 is in the two oriented remainders of the plaquette force. Replacing (c_0, H_0) by $(1, 0)$ in those remainders changes them by $C\sigma^2 w$. Indeed $H - H_0$ and $H' - H_0$ change by at most $Cw|\theta|$ and each is multiplied by an $O(\sigma)$ factor. The other changed terms have a factor n, a second-order exponential remainder, or $(\cos\sqrt{\langle\theta,\theta\rangle} - 1)H_0$. Each has the same $C\sigma^2 w$ bound, since $|c_0 - 1| = w^2/2$ and $|H_0| \le w$. The transport of the output to its bond base is kept in both terms. At the local scale ξ use $w \le a_0(h/\xi)^2$, $\sigma \le h \sup|A|$, and the factor h^{-3} in the bond force. The resulting scaled force error is at most

$$Ca_0(h/\xi)\,(\xi \sup|A|)^2.$$

Thus the two cutoffs can bound their explicit rough holonomy remainders separately in the weak pairing.

To compare the remaining force, put $N(A)_{\mu\nu} = i[A_\mu, A_\nu]$. The second-order term of $\log(e^{-i\gamma_3}e^{-i\gamma_4}e^{i\gamma_1}e^{i\gamma_2})/i$ at $\gamma_3 = \gamma_1,\ \gamma_2 = \gamma_4$ is $i[\gamma_1, \gamma_4]$. On the full stencil the opposite increments differ by $h^2\nabla_U A$. Consequently

$$h^{-2}\theta = D_U A + N(A) + O\big((h/\xi)\xi^{-2}(a^2 + a^3)\big), \qquad a = \xi \sup|A| + \xi^2 \sup|\nabla_U A|.$$

Differentiating the same finite expansion in a test $\widehat{A}$ replaces $a^2 + a^3$ in the error by $C(a + a^2)b$, where $b = \xi \sup|\widehat{A}| + \xi^2 \sup|\nabla_U \widehat{A}|$. For the plaquette with the explicit holonomy removed the action is $\frac{1}{2}\langle\theta,\theta\rangle + O(|\theta|^4)$. Subtract the derivative of its quadratic action. Dividing by the cell measure h^4, the leading nonlinear weak density is

$$\langle N(A), D_U\widehat{A}\rangle + \langle D_U A + N(A), N'_A\widehat{A}\rangle.$$

The omitted density is bounded by $C(h/\xi)\xi^{-4}a^2 b$ on a small first-order ball.

On complete common cells compare this density at $(U, A, \widehat{A})$ and $(W, q_1 A, q_1\widehat{A})$, with $W = \mathcal{M}U$. Now take h and $\eta = Lh$ to be the two meshes. For a coarse $\mu\nu$-plaquette the flat per-area mean Q_2^0 assigns weight L^{-6} to the L^2 fine plaquettes of each translate based at a site in its initial block of L^4 sites. Stokes on each translated square gives $D_\eta Q_1^0 = Q_2^0 D_h$. Each fine plaquette occurs L^2 times over the incident coarse plaquettes. The lattice volume ratio is L^4, so the volume transpose of Q_2^0 reproduces constants on complete incidences.

Use the transports of a local comb to carry the fine plaquette values to the coarse base and call this mean Q_2. In a common comb on the enlarged stencil the one-step row coefficients and these transports differ from their flat values by $C_L\varpi$, with ϖ the maximum fine plaquette defect there.

The coarse links in this frame are also within $C_L\varpi$ of one. Taking the difference of the two local operators therefore gives

$$|D_W q_1 B - Q_2 D_U B| \le C_L \eta^{-1} \varpi \sup |B|$$

on that stencil. The estimate compares the row coefficients at each of the neighboring rows using their sup bound. It requires no difference estimate on the plaquette defect.

Use this identity for $B = A, \widehat{A}$. In the first pairing move Q_2 onto the coarse $N(q_1 A)$ by the volume transpose. In the pairing with $D_U A$, move it onto $N'_{q_1 A}(q_1 \widehat{A})$. Constant reproduction and the first-difference bounds compare these adjoint means with the corresponding fine products at cost $C\eta$ times a product difference and $C_L\varpi$ times its size. The purely algebraic pairing uses the same volume quadrature. Since $\varpi \le C(\eta/\xi)^2$, all three errors are bounded by $C(\eta/\xi)\xi^{-4}a^2 b$ in density, hence by $C(\eta/\xi)a^2 b$ per cell. Only first differences of the test are used. If a common smooth cutoff multiplies the product, its difference enters in that same quadrature bound. At a cubical face with an incomplete incidence strip of width $O(\eta)$, the density bound $C\xi^{-4}a^2 b$ and the strip volume $O(\eta\xi^3)$ give the same cell estimate. Keep any wider transition or unmatched row in its native cutoff estimate. This comparison is for the physical Wilson remainder on its admitted common carriers.

For the scalar weight carried by a sourced step, let c_h, c_η be the two plaquette weights on an admitted common carrier. Use S_h for the fine Wilson increment density, with its background subtracted, or its first variation. Include the lattice volumes in the sums. On complete incidences one has the exact identity

$$\sum_p h^4 c_h(p) S_h(p) = \sum_P \eta^4 c_\eta(P)(Q_2^0 S_h)(P) + \sum_p h^4 \big[c_h(p) - ((Q_2^0)^* c_\eta)(p)\big] S_h(p).$$

The transpose is taken for these lattice volumes. Extend the coarse weight to the common physical stencil, using its tent formula for the actual source. Every coarse barycentre contributing to the transpose at p is within $C\eta$ of the barycentre of p. Constant reproduction therefore bounds the coefficient in brackets by the paired weight difference at that barycentre plus $C\eta\,\mathrm{Lip}(c_\eta)$. Compare the first sum to the coarse action increment with the same weight c_η. In the variance calculation each block difference is multiplied by $c_\eta(P)$. The oscillation of the curvature increment still gives the gain against the rough background. In the curl pairings one includes c_η in the coarse test product before transposition. Its first difference adds the same $C\eta\,\mathrm{Lip}(c_\eta)$ error, times the bound on the corresponding pairing density.

For a plaquette filed to a single cube, incomplete incidences lie in the strip along its faces. A plaquette filed to two or four cubes already lies in that strip, since it crosses a face. On a fixed admitted carrier its volume is $O_M(\eta\xi^3)$. The bound for the normalized increment or variation density then gives the shell cost $O_M(\eta/\xi)$ in cell units, multiplied by the size of the weight. The physical variation of the weight member is the sum of the plaquette variations with their individual $c(p)$. It is used inside this weak pairing. The current argument of the response remains independent.

In particular let U_* be an actual fine critical field on the uncut core, $W_* = \mathcal{M}U_*$, and $P_* = d\mathcal{M}$ in compatible tangent coordinates. Take A with its complete action and row stencils where the vertex cutoff equals one and away from all unmatched row readouts. The physical row differentials then obey $K^\sharp A = K^\flat P_* A$. Write J^a for the inner-action gradient at cutoff a, which is the Wilson current on full stencils. With the fine multiplier ω_*, stationarity gives

$$\big\langle J^\flat(W_*) - K^{\flat\mathsf{T}}\omega_*, P_* A\big\rangle_\flat = dD_{U_*}[A].$$

If the carrier reaches an unmatched row or the action shell, keep its term in the comparison. This identity tests the physical coarse residual on transferred variations. The transition shell of a cutoff response retains its own force. With a general fine field the fine residual $\langle J^\sharp - K^{\sharp\mathsf{T}}\omega, A\rangle_\sharp$ also enters. The full equation with an independent current still requires the weak source estimate.

Use the common real-to-complex interpolation disc for the vertex bounds and then three circles in the fluctuation amplitude. A sufficiently small positive power of the real bound retains the required carrier decay after the alternating sum. On the resulting admitted disc the cubic remainder is bounded in powers of the unscaled fluctuation $\mathsf{t}^{-1/2}B$. Its contribution to the interaction is multiplied by t, so the cubic bound is $C\mathsf{t}^{-1/2}\|B\|^3$ times the mesh gain and the carrier decay. On $\mathsf{t}^{-1/2}\|B\| \le C\delta(\mathsf{t})$ this is $C\delta(\mathsf{t})\|B\|^2$ times those same factors. Compare the two vertex constructions with the same reference weight t here. A difference of actual scalar action weights is paid on the coupling disc in the step comparison.

A.9.0.7. Transport of earlier activities. Use the same regional rule to construct the response and its reduced current at the two spacings. The row data are related by composition of the relative averages. At vertices of the decoupling parameters the response is the undecoupled response of the selected subregion, multiplied by its cutoff. Thus the comparison uses responses with specified determining sets. Insert the averaged fine response into the coarser response equation. Its error in the field equation is measured in a weak pairing with one controlled difference on the test field. The nonlinear constraint on a common row composes with the actual one-step transfer. Write η for the coarser bare spacing, $h = \eta/L$, and $\breve{q}(A) = \eta^{-1}\mathcal{Q}^1(U^\sharp, hA)$ for that transfer in the straightened chart. If the comparison uses its linearization $q_1 A$, the Taylor bound on the full carrier P_c gives

$$|\breve{q}(A)(c) - q_1 A(c)| \le C_L(h^2/\eta) \sup_{\mathsf{P}_c} |A|^2.$$

Thus in the row scale ξ_y the discrepancy is at most $C(\eta/\xi_y)(\xi_y \sup_{\mathsf{P}_c}|A|)^2$. Use either the exact transfer or this small value defect in the constraint comparison. The same row estimate in a variation $\widehat{A}$ gives

$$|(D\breve{q}(A) - q_1)\widehat{A}(c)| \le C_L(h^2/\eta) \sup_{\mathsf{P}_c} |A| \sup_{\mathsf{P}_c} |\widehat{A}|.$$

Indeed the derivative of the dimensionless one-step remainder is bounded by $C_L h \sup_{\mathsf{P}_c}|A|$, and the input and output changes of units give h/η. On common rows the actual constraint derivatives obey $K^\sharp(A) = K^\flat(\breve{q}(A))D\breve{q}(A)$. When a weak equation uses $q_1\widehat{A}$ in place of the exact tangent transfer, the constraint-multiplier error is

$$\langle \omega,\, K^\flat(\breve{q}(A))(D\breve{q}(A) - q_1)\widehat{A}\rangle.$$

This error uses the row estimate on the full carriers and the actual dual weights of the multiplier. The Wilson and prescribed-current terms of the field equation require their own comparisons. The noncommon rows are in the lowest layers. For the weighted contraction put $e(y) = \eta/\xi_y$ above the fixed bottom cut and $e(y) = 1$ below it. Define $\mathsf{E}(x) = \sup_y e^{-\mu' d(x,y)} e(y)$, where d is the regional distance and μ' is smaller than the propagation rate. The triangle inequality gives $\mathsf{E}(y)/\mathsf{E}(x) \le e^{\mu' d(x,y)}$. Thus a kernel decaying faster than this weight varies retains a summable bound in the norm with weight $\mathsf{E}^{-\gamma}$. A layer r spacings below the top can enlarge the bare-to-local mesh ratio by at most CL^r, and each intervening layer has the fixed distance floor. Choosing the floor so the exponential decay absorbs L^r bounds E at the top by CL^{-m} in a tower with m levels. The reduced current is estimated from the row multiplier, without applying two differences to a response known only in a first-order norm. The comparison of the reduced current is used well inside the top layer.

Here is the passage from the cell estimate to the field norm used at a vertex. In units of one common cell let f be the difference of the transferred fine field and the coarse field, written on the common mesh of spacing b. Let E bound its lattice L^1 norm on the cell and a fixed collar. An L^2 estimate there gives this input by Cauchy–Schwarz. Use the first-difference bound and the common β_H-Hölder bound for the gradients. Both bounds are on the same chart and cover the full neighboring stencils. At an interior site x, average f on a cube of side $r \ge 2b$ near x. The number of sites is comparable to $(r/b)^4$. Thus the value at x has norm at most $C(Er^{-4} + r)$. For a gradient, average the difference of f between this cube and its translate by a mesh multiple of

size comparable to r in the gradient direction, divided by that translation length. Telescoping the difference and using the Hölder bound on every intervening stencil compares this average to $\nabla f(x)$ with error Cr^{β_H}. The two cube sums are bounded by CEr^{-4}, so

$$|\nabla f(x)| \le C(Er^{-5} + r^{\beta_H}).$$

Take r comparable to $\max\{b, E^{1/(5+\beta_H)}\}$ for the gradient, and to $\max\{b, E^{1/5}\}$ for the value. When either choice exceeds the collar radius the original bounded field norm gives the result with a larger constant. The resulting bounds are $C(E^{1/5} + b)$ and $C(E^{\beta_H/(5+\beta_H)} + b^{\beta_H})$, respectively. The same bounds hold at the edge of an aligned cell when the cell supplies the weak input and all the one-sided stencils. Choose the averaging cube inward in every coordinate and translate it in the inward sign of the derivative direction. Telescoping then uses only the given Hölder bound in the cell. For a backward difference the base of the stencil is one mesh from the forward base, which is covered by the same error. The small radii can be chosen below a fixed fraction of the cell side, and larger radii are covered by the original first-order bound. Consequently a weak estimate with a power of the local mesh ratio gives a positive power in the first-order field norm on the common interior. At the unmatched bottom use its unit bound in the screened weight. The multiplier comparison used for the current is separate from this interpolation.

To obtain the weak input for that interpolation, write $\lambda_y = \eta/\xi_y$ and let $f^\sharp, f^\flat$ be the actual bond sources in the direct regional comparison. In the scaled cell norms the source condition is

$$\xi_y \|f^\flat\|_{L^2(\Delta_y)} \le N(y), \qquad |(f^\sharp, \widehat{A})_\sharp - (f^\flat, q_1 \widehat{A})_\flat| \le \sum_y \lambda_y^\gamma N(y) \|\widehat{A}\|_y.$$

Inject $f^\sharp, f^\flat$ into the bond slots. Take $\Phi^\sharp = \mathbb{E}^\sharp f^\sharp$ and $\Psi^\flat = (\mathbb{E}^\flat)^{\mathsf{T}} g$, where g tests the wanted flat output in its own slot. Write the bilinear form with its operator acting in the second argument. Then the inverse identity is

$$\begin{aligned}(g, \mathfrak{a}_0 \Phi^\sharp - \mathbb{E}^\flat f^\flat)_\flat = {} & \mathfrak{K}^\flat(\Psi^\flat, \mathfrak{a}_0 \Phi^\sharp) - \mathfrak{K}^\sharp(\mathfrak{i}_0 \Psi^\flat, \Phi^\sharp) \\ & + (\mathfrak{i}_0 \Psi^\flat, f^\sharp)_\sharp - (\Psi^\flat, f^\flat)_\flat.\end{aligned}$$

To use the form estimate in the first line, write S for the constant self-transpose map on the first-order slots given by

$$S(A; v, w, \sigma; p, q, r) = (A; p + w, q + v, r - \sigma; v, w, \sigma).$$

For the full system add the multiplier slot $\omega \mapsto -\omega$. The reduced system obeys $\mathbb{K}^{\mathsf{T}} S = S\mathbb{K}$. In the full system the extra pairings in $(S\Psi', \mathbb{K}\Psi)$ are $-(QA', \omega) - (\omega', QA)$, so the same identity holds. The common transfer and cut use the same site map on v, w, p, q and the same top map on σ, r. They commute with this slot change. Thus $\mathfrak{K}(\Psi, \Phi) = \mathfrak{K}(S\Phi, S^{-1}\Psi)$ puts the first line in the order of the form estimate, with the same support at the cut. The source condition in the second line is tested at the prolonged bond component $\mathfrak{i}_0 \Psi^\flat$. It leaves the quadrature error pairing $f^\flat$ with the difference of $q_1 \mathfrak{i}_0 \Psi^\flat$ and $\Psi^\flat$ on their bond slots. On complete common cells the flat averaging and prolongation reproduce constants, so the difference of the means costs one mesh times one difference. The common comb frame adds a term proportional to the plaquette radius. Use the local L^2 bound on the prolonged test and its differences in this pairing. At the fixed-margin cut use the weighted kernel decay for the lower unmatched contributions. This gives the cell-mean comparison for the fields and the separate row comparison for the multipliers under the stated source condition.

In the middle part of the projected inverse $G_1 D R D^{\mathsf{T}} G_1$, use the first-order system with the multiplier and its equation removed. Its inverse contains the block G_1. Put $u^a = R^a D^{a\mathsf{T}} G_1^a f^a$ for $a = \sharp, \flat$. For the actual force with its weighted supremum bound, the first-difference Hölder bound for $G_1 f$ and the smoothing part of R give a scaled site Hölder bound of some exponent $\beta > 0$ for u. On a unit cell the site mean error E then gives a supremum error at most $C(Er^{-4} + r^\beta)$ by

averaging on a cube of side r around the test site. Use r of order $E^{1/(4+\beta)}$ above the mesh floor. This retains a positive mesh power in the site supremum norm. Split the second solve as

$$q_1 G_1^\sharp D_U u^\sharp - G_1^\flat D_W u^\flat = q_1 G_1^\sharp D_U u^\sharp - G_1^\flat D_W q_0 u^\sharp + G_1^\flat D_W (q_0 u^\sharp - u^\flat).$$

The last term uses the single-run differentiated-source kernel on the improved site norm. The first line uses the weak comparison again, now with the actual gradient source. On complete common stencils $D_W q_0 u^\sharp = q_1 D_U u^\sharp$. For such sources the weak source defect is the pairing of $D_U u^\sharp$ with $(1 - q_1^\mathsf{T} q_1)\widehat{A}$.

At the flat pair the per-length bond average has row mass one. In the weighted transpose the mass is also one, since a fine link of a given direction occurs in L paths counted across the incident coarse rows and the measure ratio is L^4. Both means only read a fixed number of bare blocks. Thus $(1-q_1^\mathsf{T} q_1)\widehat{A}$ costs $C\eta \sup|\nabla \widehat{A}|$. In a common comb on the full union of incident double blocks the straightened row coefficients differ from the flat ones by $C_L \varpi$, where ϖ is the plaquette bound there. This adds at most $C_L \varpi \sup|\widehat{A}|$. Since $\varpi \le C(\eta/\xi_y)^2$, the cell pairing gains a mesh ratio using the scaled L^2 bound of the gradient source.

For that bound, use the bond-force entry of the reduced first-order inverse on the admitted undecoupled regional frame, including its independent current. For a force $f_{y'}$ supported at one source cell, put $A = G_1 f_{y'}$. The cell estimate for this entry is

$$\xi_y^{-1}\|A\|_{L^2(\Delta_y)} + \|\nabla A\|_{L^2(\Delta_y)} + \xi_y \|\nabla\nabla A\|_{L^2(\Delta_y)} \le C e^{-\delta d(y,y')} \xi_{y'} \|f_{y'}\|_{L^2(\Delta_{y'})}.$$

The stencils in this estimate carry the covariant differences of that frame. In $Du = DD^\mathsf{T} A - D(1-R)D^\mathsf{T} A$, the first term on full interior stencils is bounded by the covariant second differences on the neighboring cells, with the curvature times A if their order is exchanged. For the second term, with η_a the bare mesh in the run, the kernel from z to y is bounded by $C(\eta_a/\xi_z)^4 \xi_y^{-2} e^{-\delta d(y,z)}$. Cauchy–Schwarz on the source cell and the volume of the output cell give the L^2 contribution $Ce^{-\delta d(y,z)}\xi_z^{-2}\|A\|_{L^2(\Delta_z)}$. After multiplying by ξ_y, absorb ξ_y/ξ_z in the exponential by the scale-conversion bound. Summing the cell estimates yields the same scaled L^2 force bound for Du with a reduced decay rate. Thus the second gradient-source comparison uses an off-shell one-run estimate on complete common cells. To return its output to the first-order field norm, use the differentiated-source Hölder bound as well. On the complete stencils $D_\mu u = -\nabla_\mu^\mathsf{T} X_{\mu\mu}$, where $X_{\mu\mu}(x) = \mathrm{Ad}(U_\mu(x))u(x + he_\mu)$ on the lattice of mesh h. The bound for $\nabla G_1 \nabla^\mathsf{T}$ applies with an output Hölder exponent strictly below the Hölder exponent of this transported site input. Together with the mean comparison this gives the required first-order interpolation for the second solve. At the cut the cutoff-gradient and incomplete-row terms must be kept in the lower-layer estimate. This second solve uses the site estimate just interpolated. The terminal L^2 correction for the site Laplacian commutator is only paired in the first comparison.

The lift, inverse row map and induced current used by the nonlinear equation are compared at zero prescribed row current, with the actual independent bond current still present. Use $m(c) = \xi_c$ to convert from per-length rows to raw rows. If H, S are the per-length lift and inverse row map, the raw quantities are Hm^{-1} and $m^3 S m^{-1}$. The row mass converts by the same rule as S; on a common row it agrees at the two cutoffs. Hence the comparison of P uses the difference of the converted S's.

At a common source row c', inject $m^{-1}e_{c'}$ in the constraint slot of the full first-order system. Its bond component is the raw lift applied to $e_{c'}$. Its multiplier component, multiplied by m^3, is the raw inverse row map applied to $e_{c'}$. For an output row c, use $m^{-1}e_c$ in the dual row slot, so the pairing with its multiplier has exactly the factor $m(c)^3$. For the output field, test in one cell at y by a bond force g with $\xi_y\|g\|_2 \le 1$. The source-row terms agree in the two inverse identities because the common source row and its normalized injection are the same on the complete carrier.

The form difference then controls the inverse row entry and the scaled cell L^2 difference of the lift. This comparison uses both directions of the form pairing, with the quadrature errors above.

Before comparison the raw row and lift kernels are bounded by $C(\xi_y/\xi_{c'})e^{-\delta d(y,y(c'))}$ in their respective scaled norms. The scale conversion absorbs the displayed ratio in a smaller exponential. In the form estimate use the two localized solutions centered at $y(c')$ and y. Summing their product against the mesh weight gives $C\mathsf{E}(y)^{\beta}e^{-\delta' d(y,y(c'))}$ for some $\beta > 0$ and a smaller rate δ'. This follows by the triangle inequality for d and $\mathsf{E}(z)/\mathsf{E}(y) \le e^{\mu' d(y,z)}$, leaving a summable exponential in the intermediate cell z. For the lift apply the cell interpolation to the difference divided by its one-run exponential envelope. The one-run gradient Hölder bound and the scaled cell error give a positive power of $\mathsf{E}(y)$ in the first-order norm with a remaining exponential in $d(y, y(c'))$. Thus, after reducing the exponent and the rate,

$$\|(\Delta H)e_{c'}\|_{X_y} + |\Delta P(c, c')| \le C\mathsf{E}(y)^{\alpha}e^{-\delta' d(y,y(c'))}, \qquad y = y(c)$$

for the row entry, and for any output cell y in the lift term. Here X_y is the scaled first-order field norm. A uniformly bounded number of rows per top and the summable distance bound give the weighted operator comparisons. For a row input bounded by E^{γ} times its norm, the output is bounded by $\mathsf{E}^{\alpha+\gamma}$ times that norm. Take $\gamma\mu'$ below the remaining rate.

For the induced current use a bond-force input $\mathbf{J}$. Elimination gives the multiplier component $-H^{\mathsf{T}}\mathbf{J}$, so its negative, multiplied by m^3, is the raw ϕ. If the transferred current is $\mathbf{J}^{\flat} = \mathbb{P}\mathbf{J}^{\sharp}$, the source discrepancy in the same row test pairs $\mathbf{J}^{\sharp}$ with the difference between the prolongation and $\mathbb{P}^{\mathsf{T}}$ of the bond test. The two means reproduce constants in the flat frame. On their common carrier the error costs η times one difference and the small comb correction. This gives the mesh gain in ϕ without differentiating the independent current.

Enlarge the lower cut by the full stencils of the rows and their neighboring cells. For the admitted local-box cut the first-order commutator is supported on this enlarged transition and has a uniform local weak L^2 bound. The extra constraint and multiplier terms are bounded there by their own complete row coefficients times differences of the cutoff. Use $e = 1$ in the transition, and screen its terms by the localized kernels. In particular a source row c' in the cut gives only the one-run exponential there, which is paid since $\mathsf{E}(y) \ge e^{-\mu' d(y,y(c'))}$. This treats the admitted direct sequences on common complete upper carriers. A complex comparison uses a common admitted line and the two-constants bound with a reserve in the localization rate.

For the nonlinear field equation, compare the force on the undecoupled solves at $s = 1$ before multiplying by the vertex cutoff. The form of the force is eq. 3.cdxlv. For a test $\widehat{A}$ put $x = dX(T)[\widehat{A}]$, and use raw row pairings. Moving the transposes to the test gives the identity

$$\begin{aligned}(\mathsf{W}_s(T), \widehat{A}) = &-(x - d\mathcal{C}_2(T)[\widehat{A}], \phi) - (\widehat{Q}\widehat{A}, P_s X)\\ &-(x, P_s\widehat{Q}T) + (x, P_s X) + (\mathcal{V}(Y), \widehat{A} - H_s x).\end{aligned}$$

The first four terms are row pairings. The last uses the weak Wilson estimate on the same carriers, with the adjusted test $\widehat{A} - H_s x$.

On the common rows the exact nonlinear composition identifies $\mathcal{C}^{\sharp}(B) - \mathcal{C}^{\flat}(q_1 B)$ with the difference of the flat full row map at $\breve{q}(B)$ and $q_1 B$. The common linear part cancels. Use the value and derivative estimates for $\breve{q} - q_1$ above, together with the local Lipschitz estimate for the row derivative on the admitted ball. This gives the small weak row error and its derivative, in the full row norms. The quadratic part has the same estimate by extracting the degree-two term on a fluctuation disc.

In $X = \mathcal{C}(T - H_s X)$, transfer T by q_1. On any common row stock where the weighted lift comparison holds, the difference of the right sides is the row error, plus the effect of the lift difference on $X = O(\|T\|^2)$, plus a term bounded by $C\|T\|\|H_s\|$ times the difference of X. Absorb the last term by the contraction margin. The same comparison for dX follows from the differentiated equation, or from Cauchy's estimate in the fluctuation at the fixed admitted pair. In the first pairing

retain the cancellation $X(T) = \mathcal{C}_2(T) + O(T^3)$ at each cutoff. On a smaller complex fluctuation disc the difference of $x - d\mathcal{C}_2(T)[\widehat{A}]$ then has quadratic order in T and the same mesh gain. The other row terms have quadratic order by $X = O(\|T\|^2)$ and $x = O(\|T\|\|\widehat{A}\|)$. These estimates use the row comparison for P_s and for $\phi = H_s^{\mathsf{T}}\mathbf{J}$ at the actual rows. The latter is the induced current comparison, with the transferred independent current kept in the pair.

The lift comparison also controls the difference between the two Y's and between the two adjusted tests in the first-order field norm. Thus on the admitted direct regional charts the Wilson pairing and the three row-operator comparisons give the force defect in the norm of the one-difference test. The estimate for the vertex field uses the common smooth cutoff after the solves. For each native vertex mask we must check its row and stencil carriers against these estimates, or apply the corresponding comparison on the actual recursive tower. Keep the cutoff commutators and incomplete stencils in the estimate at the lower margin.

For the inner evaluation, anchor both frames at the same base point. The mixed transport of a quaternion from y to x is $P_{xy}v = E(x,y)v\mathbf{U}(x,y)^{-1}$. At real data it is an isometry. In the frame equation write $D_b = \nabla_b + C_bS_b$ at spacing b, with $C_b = (P-1)/b$ on positive edges and S_b the shift to their terminal sites. Thus $\mathcal{K}_b = D_b^*D_b$, and the forcing is $F_b = (\theta + \Delta_b\theta)w_{0,b}$, where $\Delta_b = \nabla_b^*\nabla_b$.

Here is the comparison on a fixed box whose Dirichlet faces are common nodal planes, with zero values at their nodes on both meshes. Use regular gauges for $E, \mathbf{U}$ on the box and all double blocks of the coarse path and energy reads. Work in these gauges with $\|C_b\|_\infty + \|\nabla_b C_b\|_\infty \le C\varepsilon_{\mathrm{g}}$. Let a_b be the unit anchor and take the cutoff to vanish near the boundary. The comb has bounded physical length, so $\|w_{0,b} - a_b\|_\infty \le C\varepsilon_{\mathrm{g}}$. For the one-run normalization use

$$(\mathcal{K}_b + 1)(w_b - \theta a_b) = (\theta + \Delta_b\theta)(w_{0,b} - a_b) - (\mathcal{K}_b - \Delta_b)(\theta a_b).$$

Pairing forward and backward edges bounds the last term by $C\varepsilon_{\mathrm{g}}$. In fact the sum of the two transport increments in a coordinate direction is a difference of the forward coefficients, times b, plus $O(b^2\varepsilon_{\mathrm{g}}^2)$. The remaining terms contain one difference of θ. The resolvent has supremum norm at most one by the equation at a site of maximal quaternion norm. It follows that $|w_b|$ is bounded below on each fixed positive plateau of θ when ε_{g} is small.

To compare the forcing, use the same comb order on the box lift. Put $\epsilon_E = \eta^{-1}\sup|E^\flat - \mathcal{M}E^\sharp|$ in the aligned gauges. Use the restriction of the fine gauge for the coarse $\mathbf{U}$, so $\mathbf{U}^\flat = \mathcal{M}\mathbf{U}^\sharp$ in these frames. Each coarse transport differs from its straight fine product by $O_L(h^2) + O(\eta\epsilon_E)$, where $h = \eta/L$, by the one-step path comparison. Telescope the products from the base to a coarse site. For a nearby fine site, append the short cell path and put it in the native comb order by interchanging neighboring steps. There are at most C_L/h such exchanges, each with curvature error $O(h^2)$. The path terms therefore differ by $C(\eta + \epsilon_E + |a_h - a_\eta|)$ on paired cells. Away from the cells at the breaks of the piecewise polynomial θ, the two second differences of the cutoff agree up to $C\eta$. They are bounded in the break cells, of total volume $O(\eta)$. The forcing discrepancy thus costs $C(\eta^{1/2} + \epsilon_E + |a_h - a_\eta|)$ in physical L^2.

For the mixed energy let R denote restriction to coarse sites and I multilinear prolongation of a coarse test g. The two forms are $\mathcal{A}_b(v,g) = (v,g)_b + (D_bv, D_bg)_b$ in the physical-volume pairings. The one-step path comparison and the first differences in the good gauges bound the discrepancy of the per-length coefficients on corresponding stencils by $C(\eta + \epsilon_E)$. The flat gradient of Ig is an interpolation of the parallel coarse gradients. Its volume transpose preserves constants on each complete incident stencil. In the flat gradient terms replace this mean of $\nabla_h w_h$ by the mean along the straight segment giving $\nabla_\eta R w_h$. Their difference costs $C\eta\|\nabla_h^2 w_h\|_2$ by telescoping over the fixed number of fine edges in the stencil. In terms with C_bS_b, move coefficient factors onto w_h or $\nabla_h w_h$ before this quadrature. Differences then cost one difference of the coefficient and one of the field, or the coefficient discrepancy above. The mass terms use the constant-preserving site transpose. On a common grid-aligned Dirichlet box, boundary sites are zero and the coarse edges

paired with a nonzero test gradient have their full transverse incidence. This yields

$$|\mathcal{A}_\eta(Rw_h, g) - \mathcal{A}_h(w_h, Ig)| \le C(\eta + \epsilon_E)\|w_h\|_{H^2_h}\|g\|_{H^1_\eta}.$$

The one-run H^2_h bound follows by writing $(\Delta_h + 1)w_h = F_h - (\mathcal{K}_h - \Delta_h)w_h$. The last term is bounded in L^2 by $C\varepsilon_{\mathrm{g}}(\|w_h\|_2 + \|\nabla_h w_h\|_2)$. Energy controls these first-order norms. Odd reflection across the Dirichlet faces and commutation of the flat differences bound the second differences by the flat Laplacian norm. Pair the frame equations with $g = Rw_h - w_\eta$, using Ig on the fine lattice. The source bound and the same site quadrature give

$$\|Rw_h - w_\eta\|_{H^1_\eta} \le C(\eta^{1/2} + \epsilon_E + |a_h - a_\eta|).$$

For the Dirichlet realization one can also remove a thin boundary strip before comparing coefficients. Taking the norm in the mixed equation gives $(\Delta_b + 1)|w_b| \le |F_b|$. In a coordinate of width D, a multiple of $s(D - s)$, with s the distance to one face in that coordinate, dominates the bounded forcing and is nonnegative on the boundary. Comparison in each coordinate bounds $|w_b|$ by C times the distance to the boundary. Setting zero boundary data on a common inset at distance at most $r + \eta$ changes the solution there by at most $C(r + \eta)$ in supremum norm, by the homogeneous mixed equation. The coefficient and forcing comparison can then be made on that inset.

On an interior read the first differences are uniformly bounded by the local bootstrap eq. 3.dcccxci. Its proof applies componentwise to these orthogonal transports: the flat principal part is the same, and in the regular gauge the first-order coefficient is $O(\varepsilon_{\mathrm{g}})$, while the zeroth coefficient and the forcing have bounded finite L^p norms. The energy estimate supplies its outer H^1 hypothesis. All cutoffs fit in the fixed read collar. A maximum of size s for the difference therefore gives an L^2 contribution at least cs^6 in dimension four. Below mesh radius use the single site with weight η^4 and $s \lesssim \eta$. The resulting supremum error has the power $1/3$ of the L^2 error. The plateau lower bound permits normalization in SU(2) with the same error. This supplies the frame value for conjugating the inner datum on the common carrier.

The native box has faces between sites and is a union of complete paired cells. For the realization with only inner edges, use its inner-edge scalar Laplacian for $\Delta_b\theta$ and take θ constant in the normal directions near the faces. In particular a cutoff vanishing in a boundary collar has the same forcing comparison as above. Use the mixed cell mean P_0 from the fine sites to a coarse centre. Its transports are those of the two averaged contours. Let Q_P average fine bond fields along the straight L-step paths from one cell to the neighboring cell, transported to the initial centre. The weight of each fine edge occurrence in the path sum is L^{-5}. Telescoping the path differences gives

$$D_\eta P_0 = Q_P D_h + \mathcal{R}, \qquad \|\mathcal{R}\|_{2\to 2} \le C(\eta + \epsilon_E).$$

Indeed the mismatch of the two end transports is $O_L(h^2) + O(\eta\epsilon_E)$ on each path, and the path difference is divided by η.

For coarse v, let $I_P v$ be the multilinear prolongation, transporting the coarse corner values by short paths to the centre of the cell containing the fine site and from there to that site. The mass defect $I_P v - P_0^* v$ costs $C\eta\|D_\eta v\|_2$. In a local comb gauge on a complete stencil the gradients of $I_P v$ and $Q_P^* D_\eta v$ average the neighboring parallel slopes, with total weight one in each case. In the latter average this follows by counting the paths through the fine bond in its own direction. Their difference is bounded by $C\eta$ times the second differences of v. Restoring the transports costs $C(\eta + \epsilon_E)\|v\|_2$, by the complete stencil curvature bound and the same link comparison. At a cell face reflect the field and the tangential links, with identity transport on the link to the mirror site. The straddling plaquettes are then flat and the outward coarse slope is zero. The reflected stencil therefore gives the same estimate at the inner boundary.

For the second-difference bound put $v = w_\eta$ and $\psi = D_\eta v$. If T_μ denotes an orthogonal transport followed by one translation, the difference $T_\mu T_\nu - T_\nu T_\mu$ is a two-step transport times the plaquette

holonomy minus the identity. Consequently $[D_\mu, D_\nu]$, and the corresponding forward-backward commutator, have bounded L^2 operator norm under the normalized curvature bound. Commuting one difference through $D^\sharp D$ gives, with the shifted carriers retained,

$$D_\mu D^\sharp_\nu D_\nu v = D^\sharp_\nu D_\nu D_\mu v + [D_\mu, D^\sharp_\nu] D_\nu v + D^\sharp_\nu [D_\mu, D_\nu] v.$$

Thus the equation for ψ has source $D_\eta F_\eta$, a divergence of a field with norm at most $C\|v\|_2$, and a term of norm at most $C\|\psi\|_2$. Pair with ψ. Summing the source pairing over components gives $(D_\eta F_\eta, D_\eta v)_\eta = (F_\eta, F_\eta - v)_\eta$. Move the divergence onto the differences of ψ and use Young's inequality to absorb half their square norm. The site energy estimate then yields $\|D_\eta \psi\|_2 \le C\|F_\eta\|_2$. For the inner-edge boundary convention, perform the calculation after the preceding even reflection of the site field and links. The added normal difference is zero and the straddling plaquette is flat, so restriction gives the same estimate on the original box without a boundary term.

The exact form difference is

$$\mathcal{A}_h(I_P v, f) - \mathcal{A}_\eta(v, P_0 f) = (I_P v - P_0^* v, f)_h \\ + (D_h I_P v - Q_P^* D_\eta v, D_h f)_h - (D_\eta v, \mathcal{R} f)_\eta.$$

With $f = w_h - I_P v$, the forcing difference and these defects give the same L^2 error as in the nodal-plane case. Use the regular gauges on the read collar for the first-difference bound and the supremum interpolation. In those gauges the covariant prolongation differs from the ordinary one by $O(\eta)$ there.

For the native real box, use the common good gauge of the input $\mathbf{U}$, normalized at y_0 and restricted from fine to coarse. Here a_0 bounds the actual real potential in that gauge, including any real increment. The box and its one-step carrier fit the ordinary gauge cube by the size hierarchy. The actual box datum in this gauge is formed by the full iterated averages of the gauged input. It is gauge equivalent to the native comb datum by a small node transformation. Indeed the difference of the two gauges, normalized at y_0, is the inverse comb transport in the good gauge, hence close to one by the potential bound. The small normalized-gauge and real-base change argument in the proof of Prop. 3.135, on these complete box reads and the common smaller logarithm ball, identifies the two representatives of the box orbit.

The ordinary datum in the common good gauge agrees on common rows by composition and covariance of the averages. On a row whose full preceding outward read is also common, the reduced data agree by Prop. 3.176 and eq. 3.cccxi. At the trivial base, Cor. 3.178 identifies the Landau potential of the box minimizer with $\mathbf{H}(\mathbf{1}; B_\natural)$ on the closed noninward row stock, for its actual ordinary logarithmic datum and reduced datum, on the fixed small ball of that result. On a row of spacing ξ_c, the averaging bound at the trivial base gives $|B(c)| \le C\xi_c a_0$ in the good gauge. The same profile for $B_\natural$ follows from the local change of data, since its row lengths are comparable. Integrating the screened derivative of Cor. 3.178 from zero bounds the potential by Ca_0 and its first difference at a cell y by Ca_0/ξ_y. In the sum one absorbs the ratio of the source and output row lengths in the exponential kernel. Thus on the protected upper reads the regional response estimate compares the two Landau potentials at these data.

The actual coarse average of the fine minimizer uses the one-step node factors as well as the straightened potential. In the trivial-base chart the one-step factor differs from one by $C_L h \sup|A|$. Comparing the same holomorphic map on two translated blocks bounds its change by $C_L h\eta \sup|\nabla_h A|$. In the normalized coarse link the two endpoint factors therefore cost at most $C_L h(\sup|\nabla_h A| + \sup|A|^2)$. Here the quadratic term comes from commuting the near-identity factor past the coarse link. Include also the nonlinear straightened transfer error. This supplies the actual E-coefficient estimate on the matched protected reads.

The anchor in a Landau representative uses its gauge at y_0. By Prop. 3.176, the inverse of that gauge factor there is $v_B(y_0)$. The native comb node factor is one at this site. For the accumulated factor, separate the fine one-step factor from the recursion. The remaining product is the flat factor

at the exactly straightened fine input. The one-step factor is $1 + O(h \sup |A|)$. On the complete common top pillar the flat factor has a bounded holomorphic chart by Cor. 3.178, and Cauchy's inequality bounds its change by the supremum input error there. Hence the protected response comparison also compares the Landau anchor factors, when the original anchors coincide in the common input frame.

For the inner-edge realization the matched interior comparison suffices, with a shrinking boundary strip. In fixed box units let $C\eta < r < 1$. The accumulated erosion of the native tower through scale ξ is at most $C\xi$, by summing the successive mesh widths. Thus stencils at distance at least r from the faces have local scale $\xi_y \geq cr$. The fixed unmatched lower layers lie in the strip. By eq. 3.cdliii, the ratio of two row spacings is at most a fixed factor times $\exp((\log L)d/\rho)$, where d is the regional distance. Taking a fixed power $\sigma \in (0, 1]$ small enough for the screening rate gives $\mathsf{E}(y) \leq C(\eta/\xi_y)^\sigma$. On the complete common rows outside the strip the response bound and the one-step node correction give the per-length box coefficient error

$$\epsilon_E(r) \leq C\big(\eta^\alpha r^{-1-\alpha} + \eta/r\big), \qquad \alpha > 0.$$

The one-run mixed coefficient is bounded throughout the box by the potential bound, and has first difference at most C/r outside the strip.

For this application one need not bound the normalized curvature throughout the strip. Write the mixed equation as

$$\begin{aligned}(\Delta_b + 1)w_b = F_b - \nabla_b^*(C_b S_b w_b) \\ - S_b^* C_b^* \nabla_b w_b - S_b^* C_b^* C_b S_b w_b.\end{aligned}$$

Reflect the scalar site functions evenly at each cell face. In the divergence term reflect an edge component oddly across the faces normal to its direction, with zero flux across those faces, and evenly across the transverse faces. Then the extended flat equation uses the usual lattice differences. Integrating the heat kernel bound eq. 3.dcxlv with the mass factor e^{-t} gives a uniform L^∞ bound for the first derivative of the flat resolvent. Its derivative followed by a divergence costs at most $C(1 + |\log b|)$, since the second derivative of the heat kernel has summed bound $C \max(t, b^2)^{-1}$. The mixed maximum principle bounds w_b. The term linear in $\nabla_b w_b$ is absorbed by smallness of the coefficient in the common gauge. Hence

$$\|\nabla_b w_b\|_\infty \leq C(1 + |\log b|).$$

The same logarithmic bound holds after adding the bounded transport term.

Apply the nodal restriction and multilinear test prolongation to the weak forms in these gauges, using even extension for the scalar quadrature on the doubled box. Split the complete interpolation stencils by whether they meet the strip, including the $O(\eta)$ stencil halo. The forms on the strip of width Cr cost at most $Cr^{1/2}(1 + |\log \eta|)$ times the test energy norm, by the volume of the strip and the preceding bounds. In the interior the flat equation with a cutoff changing on length r gives an L^2 bound Cr^{-2} on the second differences. The interior quadrature therefore costs $C(\eta r^{-2} + \epsilon_E(r))$. For the forcing the coordinate combs from y_0 to the points of the smaller rectangle stay within that rectangle. Use the per-length comparison on their full carriers. On the rim use the uniform bound on F_b, which requires the stated face property of the cutoff. This yields the energy error

$$C(r^{1/2}(1 + |\log \eta|) + \eta r^{-2} + \epsilon_E(r) + \eta^{1/2} + |a_h - a_\eta|).$$

Take $r = \eta^\gamma$ with $0 < \gamma < \min\{1/2, \alpha/(1 + \alpha)\}$. The mesh terms are $O(\eta^\nu)$ for any $\nu < \min\{\gamma/2, 1 - 2\gamma, \alpha - (1 + \alpha)\gamma\}$. On the read collar the one-run interior Lipschitz estimate and plateau normalization give the frame comparison with the cube root of the energy error. The plateau lower bound here also follows by comparing the forms for w_b and θa_b in energy, which uses only the small supremum of the mixed coefficient; interpolate the result on the interior collar. To apply this argument to the named smoothing rule use its actual edge stock, cutoff at the faces and anchored real input.

To compare regular activities use their own counterterms before estimating the old evaluations. Write $G^\sharp, G^\flat$ for partnered families, $e^\sharp, e^\flat$ for their scalar coefficients, and $A^\sharp, A^\flat$ for the actions. With $\widetilde{G} = G - eA$ in each run the exact decomposition is

$$\begin{aligned}\widetilde{G}^\sharp = (G^\sharp - \mathbb{M}^* G^\flat - (e^\sharp - e^\flat)A^\sharp) \\ + e^\flat(\mathbb{M}^* A^\flat - A^\sharp) + \mathbb{M}^* \widetilde{G}^\flat.\end{aligned} \tag{A.cviii}$$

The second-order test on a linear potential of constant curvature extracts e. The linearized averaging reproduces that potential in the coarser units. Thus the first bracket obeys the same cancellation as a regular counterterm-subtracted family. The action defect in the second term obeys the same quadratic cancellation. In a fluctuation insertion its value at the background is removed by the fluctuation derivative. Its variation is bounded by the regular perturbation estimate for the plaquette defect. The two powers of the radius in that estimate pay for extracting $e^\flat$ by Cauchy's inequality.

In the last term compare the two evaluations of the same counterterm-subtracted function. Integrating one derivative in each of N decoupling parameters gives an alternating sum of its 2^N vertex values. Use the regional response and frame comparison on the reduced polydiscs where the full vertex carrier admits it. For an outer evaluation, use the domain field at $B(t)$ plus w times its window direction. Write $\rho_j = a_{0,k+1}/a_{0,j}$ and $\sigma_j = L^{-(k-j)}$ in the partnered units. The one-run field bound on the full $X^\sim$ gives a direction of size at most $C\sigma_j\delta(\mathsf{t}) \le C\mathsf{s}\rho_j\sigma_j a_{0,j}$. The field at $B(t)$ has size at most $C\mathsf{s}a_{0,j}$, since $\sigma_j\rho_j \le C$. After allowing for the fixed transfer loss in the background radius, the disc $|w| \le c/(\mathsf{s}\rho_j\sigma_j)$ therefore fits the old radius on each cutoff. Choose c smaller than the available radius fraction divided by the one-run bound. The same disc gives the Cauchy cost $C\mathsf{s}\rho_j\sigma_j$ for the derivative.

For the raw switched outer field, restrict to the wall component supplying its read of X. If all determining rows of that component have complete averaging carriers disjoint from the window direction, its row datum is independent of the window parameter. Indeed the parameter enters the literal averages only through $(t + t_\square\zeta_\square)H_k$ on those carriers. The potential and assigned current of the restricted response therefore both have zero window derivative. When this holds at both cutoffs the two activity derivatives vanish at this vertex, even when their baseline fields differ.

For the named supply the vertex reduction is instead given by its alternating sum. Write F_a for the cutoff times the undecoupled field and current of the region Y_a, using that region's datum. At a vertex with active set v, only subsets $S \subset v$ survive the switch monomials. The coefficient of F_a is $\sum_{a\subset S\subset v}(-1)^{|S\setminus a|}$. It is zero for $a \subsetneq v$ and one for $a = v$. Thus the exact datum for the nonzero comparison is the one on Y_v's determining set. If the complete read lies inside the cutoff plateau of a common region Y_v, and its own sequence satisfies the direct top-inset criterion above, the full-switch response estimate applies on those reads even when v is a proper subset of the ambient cubes. The assignment of the region's own core and datum is needed before using that criterion. In particular the raw masked lift applied to a datum supported on a missing row can vanish on the read while the named all-one lift has that row as its linear constraint.

The outer and removed tails can be bounded before comparing the vertex fields. For an outer X away from the window, the window derivative has the distance gain of the one-run estimate. For X meeting $\square^\sim$ and leaving $\square^{\sim 2}$, $d_j(X) \ge \sigma_j^{-1} - C$, so use part of the old-domain decay instead. Each of the two removed directions already has this gain on its full carrier in eq. 4.cli. After the window count, the factor e^{-c/σ_j} in these estimates leaves the localization reserve. With age $n = k + 1 - j$, $\rho_j \le C(n+1)^{1/2}$ and $\sigma_j^{-1} = L^{n-1}$. Thus the two one-run bounds themselves give a factor $L^{-\alpha j}$ together with the fixed exponential age weight when $L^{n-1} \ge A(j+1)$, with A fixed sufficiently large. Use the actual outer vertex and removed segment comparisons at the remaining ages.

The first removed segment is affine in the two shift coordinates of its common response chart. On a matched complete carrier write it as $A_t = A_0 + t\Delta A,\ J_t = J_0 + t\Delta J$, where the current slot includes the fixed base current. To compare the segment at the two cutoffs, put the two endpoints

in the same frames before interpolating. Let h be the fine spacing in these units and let T be the relative potential transfer. Its second derivative in the potential slots is $O(h)$: the holomorphic map on the dimensionless stencil is evaluated at hA_t and its logarithm is divided by Lh. Consequently the difference between $T(A_t)$ and the affine interpolation of the transferred endpoints is bounded by

$$Ch\,t(1-t)\|\Delta A\|^2.$$

For the neighboring-stencil estimate take local units in which the reference scale is one. Compare the stencils by parallel transport. The base link arguments of the stencil differ by $O(h^2\kappa)$, where κ is the bound on the base curvature on the intervening plaquette strips. At an interpolated potential the difference of the angular arguments is bounded by $Ch^2 \sup_t \|\nabla_U A_t\|$. The second derivatives differ by Ch times the sum of these two argument differences. The two direction slots also vary, each by at most $Ch\|\nabla_U \Delta A\|$. After division by the mesh, the first difference of the affine defect is bounded by $Ct(1-t)$ times

$$h\|\Delta A\|\|\nabla_U \Delta A\| + h^2\|\Delta A\|^2(\kappa + \sup_t \|\nabla_U A_t\|).$$

All these norms use the complete neighboring stencils in the same local units. For the current transfer $\mathbb{P}_{\mathbf{U}_t} J_t$, a derivative of each path transport costs $Ch\|\Delta A\|$. Its second derivative and the product rule give the affine defect bounded by

$$Ct(1-t)(h\|\Delta A\|\|\Delta J\| + h^2\|\Delta A\|^2 \sup_t \|J_t\|).$$

Together with the transferred endpoint estimates, these defects give the comparison on this first segment wherever the paths are admitted in the common radius. The current used here is the assigned affine current.

For the second removed segment use the old box datum of [B87, (3.22)–(3.25)]. Write a for the upper fluctuation in angular units, u for the window parameter, and χ for the cutoff equal to one on $\square^{\sim 3}$ and zero outside $\square^{\sim 4}$. Denote the relative log of the full average at a row c by Q_c. In a common box frame the two relative data are

$$D_{\mathrm{mid}}(c) = \chi(c) Q_c((t + u\zeta_\square)a), \qquad D_{\mathrm{in}}(c) = Q_c((t\chi + u\zeta_\square)a).$$

Set $R = D_{\mathrm{mid}} - D_{\mathrm{in}}$. The row path runs from the inner term to the preceding term with $D_s = D_{\mathrm{in}} + sR$. For this comparison use complete old-row carriers, with every carrier reading $\zeta_\square$ in the plateau of χ and with $\chi(c) = 1$ on its row. On that carrier $R(c) = 0$. On the other carriers both data are independent of u. Thus R is independent of u, and its support is in the transition enlarged by the row reads. At $u = 0$ the fixed-base estimate for the full row logarithm bounds $R(c)$ by $C|t|\delta_k L^{q-k}$ on a level-q row of the old box.

The relative path multiplies the actual unperturbed row field V_0 on the left. Use the same native node gauge for both factors. The datum of the box solve is the absolute log

$$b_s(c) = \frac{1}{i}\log(e^{iD_s(c)} V_0(c)).$$

On the native second-removed path with the common rebuilt box base, the inner datum b_0 is the full average of its top-masked perturbation. Use the extra row datum $B'_s = b_s - b_0$ in the old-box response with its original truncated determining set. The product log has $B'_s = 0$ off the support of R and gives $|B'_s(c)| \le C|s|\,|R(c)|$. It is independent of u, since D_{in} is independent of u wherever R is nonzero. The admitted fluctuation margin keeps $\sup|B'_s| < \mathsf{c}_3 a_0$ in Prop. 3.135. Apply the local naturalizer to this absolute row difference before using the reduced response estimate. Its fixed reach enlarges the source support and leaves the separation from the inner read. In level-j units the increment of the potential, its first difference and the assigned current on the inner read is bounded by

$$C|st|\delta_k L^{j-k}\exp(-cML^{k-j}).$$

Here the response norm is the one on the native top read, and the distance is from the enlarged transition to that read. At $j = k$ use the thinner inner collar where this separation persists after adding the complete transfer and first-difference stencils. At full old switches the potential and its assigned current are those of the native critical pair in the box Landau representative.

Compare the row data before applying the paired native box estimates. The difference of the R's is the difference of the two full-average discrepancies with the common cutoff on the first. For either mask $m = t + u\zeta_{\square}$ or $m = t\chi + u\zeta_{\square}$, first compare the shifted fields at the one-step carrier. Replacing the mask there by its value at the coarse initial site costs at most $C_L\eta \operatorname{Lip}(m) \sup|a^{\sharp}|$ in the relative log. Moving this constant through the log costs at most $C_L(1 + \|m\|_{\infty})^2 \sup|a^{\sharp}|^2$ by Taylor's estimate at zero. The remaining input difference is that of the transferred unmasked angular shift and the flat shift, multiplied by m. The exact composition for the plain relative log and its fixed-base bound CL^q for q remaining stages transfer these errors to the old row. A difference between the rebuilt base fields or their node frames is accounted for in the same row comparison. Taking differences in the analytic product log gives

$$|\delta B'_s| \le C|s|(|\delta R| + R_*(|\delta D_{\mathrm{in}}| + |\delta V_0|)), \qquad R_* = \max_{a=\sharp,\flat} |R^a|.$$

This follows by writing B'_s as the integral of the derivative of the product log in the R direction. The common node frames and paired full-row comparisons supply the terms on the right. For paired unperturbed row fields the last term vanishes by nonlinear composition. With the native old-box response estimate this compares the whole segment on the admitted common top reads. Apply the scalar real-to-complex comparison on the admitted common lines before using Cauchy's estimate in the window parameter. For another continuation of this segment one must first identify its assigned base, row representative and current.

To use a paired response estimate at an activity, transfer the actual evaluation pair. On an admitted common read let $W = \mathcal{M}U$, let $A^{\sharp}, A^{\flat}$ be the two response potentials, and write $J^a_{\mathrm{tot}} = J^a_{\mathrm{base}} + i^a$ for their assigned currents. Use the paired base currents $J^{\flat}_{\mathrm{base}} = q_0 J^{\sharp}_{\mathrm{base}}$. The transfer of the fine pair averages $U' = e^{ihA^{\sharp}}U$ and uses $\mathbb{P}_{U'} J^{\sharp}_{\mathrm{tot}}$. Apply the inverse of the node gauge v of the straightened average to both components. The resulting potential relative to W is exactly $\breve{q}(A^{\sharp})$. At the start of a coarse bond c, the resulting current is

$$\operatorname{Ad}(v(c_-)^{-1})(\mathbb{P}_{U'} J^{\sharp}_{\mathrm{tot}})(c).$$

On the full double-block stencils each path transport and the node gauge change by at most $C_L h \sup|A^{\sharp}|$. This follows by telescoping the bounded products and using the regular contour mean on the admitted ball. The current in this display therefore differs from $q_0 J^{\sharp}_{\mathrm{tot}}$ by at most $C_L h \sup|A^{\sharp}| \sup|J^{\sharp}_{\mathrm{tot}}|$. No derivative of the current is used.

For the potential the local Taylor error of $\breve{q} - q_1$ is quadratic. Compare the remainders on neighboring stencils after parallel transport. The potential inputs then differ by $C_L h \sup|\nabla_U A^{\sharp}|$. The transported base links differ by $C_L(h/\xi_y)^2$ when the normalized base curvature is bounded in the local units. This is the product estimate on the small plaquette strips joining the translated paths. The Taylor bounds with one more derivative give the same mesh gain in the scaled first-difference norm. Writing a_y for the scaled first-order norm of the fine potential on the full stencil and j_y for the scaled supremum norm of the total fine current, the errors beyond the paired response comparison are bounded by

$$C(\eta/\xi_y)a_y^2 \quad \text{and} \quad C(\eta/\xi_y)a_y j_y.$$

The remaining current difference is $q_0 i^{\sharp} - i^{\flat}$ because the base parts cancel. The remaining potential difference is $q_1 A^{\sharp} - A^{\flat}$. The relative log between the two perturbed fields obeys the same first-order bound, by the product and logarithm estimates on the small chart. The response comparison thus supplies the evaluation mismatch on these complete reads once its two native data and currents have been identified. For the reduced currents this use is on the common interior top reads.

To pass from a real evaluation mismatch to the value of a gauge-invariant activity, fix a real vertex and use a relative gauge for which the potential, its first covariant difference and the current mismatch have size at most $2b_0\vartheta$, where ϑ bounds the infimum in the mismatch norm. A zero infimum is handled by taking the bound to zero. Write the flat evaluation as $(\mathbf{U},\mathbf{J})$ and the two mismatches as A, I. Use the scalar activity on the disc of pairs

$$(e^{i\eta_j wA}\mathbf{U},\ \mathbf{J}+wI), \qquad |w|\le c/\vartheta.$$

The flat evaluation must have the half field radii and a fixed margin below b_0 in the current slot. Use $0<b_0\le b_1$, $b_0+b_1\le a^\sharp$ and $b_1^2\le \mathsf{c}_\natural b_0$. The outer substitution theorem admits the disc when the potential and its covariant difference stay below $b_0/[128K_{\mathrm{red}}(1+\mathsf{c}_\natural)]$, and $|\mathbf{J}+wI|<b_0$. The fixed choice of c ensures both bounds. When the mismatch is small enough that the disc radius is at least two, Cauchy's inequality bounds the change from 0 to 1 by $C\vartheta$ times the activity norm. Larger mismatches use the individual bounds. The value at 1 is the fine evaluation after transfer and gauge change, so gauge invariance identifies its value. The relative gauge is chosen only on real data. For complex interpolation use the scalar difference of the original two evaluations, which are holomorphic on their admitted lines.

The single-lattice bound on the larger polydisc retains the decay in the size of the carrier. Combining the smallness at the vertices with this decay costs part of the localization exponent, which pays for the 2^N terms. In the inner term subtract the value at the flat pair and use the vanishing of the first derivative there. The quadratic bound on the two nearby linear-response evaluations then retains the small radius factor in the difference. To retain an age weight as well, the one-run estimate for this difference uses the second renormalization at a Hölder exponent strictly larger than the exponent in the age weight. The reserve in the age exponent pays for interpolation.

The resulting regular commutation defect of an input formed with j fine levels has a factor $\omega_{k+1-j}\min\{1, CL^{-\alpha j}\}$ in the step with $k+1$ fine levels, with some $\alpha>0$. The unmatched input at the finest scale has the age weight ω_{k+1}. A marked remainder uses its squared radius ratio in place of the age weight. To obtain the regular two-run bound, sum these defects and join the two inverse covariances and the two auxiliary Gaussian kernels by line segments in their admitted complex balls. Cauchy's estimate on the available radius bounds the change in the small-field expansion by the size of the Gaussian and potential differences. The change in a scalar weight costs $C|x^\sharp-x^\flat|/\mathsf{t}$ on a disc of radius $c\mathsf{t}$. The Gaussian normalizer is compared separately.

In the covariant regular chain this gives, at equal deviations, an inequality of the form

$$D_s \le C\lambda^{K-s} + \varepsilon \sum_{s<t<K} \omega_{t-s} D_t,$$

where D_s is the distance between the families at depth s. Choose $\lambda<1$ larger than the geometric rates of the mesh defects and age weights, absorbing polynomial factors in $K-s$. Choose ε with $\varepsilon\sum_{m\ge1}\omega_m\lambda^{-m}<1$. Downward induction then gives $D_s\le C'\lambda^{K-s}$. The constant-source coefficient is read from this distance by the same quadratic test. The full step still needs the sourced estimate on position-dependent arrays and the matching of the marked histories. Those terms have no common covariant quadratic cancellation to which the regular age estimate can be applied.

A.9.0.8. Sharp background tests on the matched histories. The approximate fluctuation test of §4.17.1.1 compares the nonpivot values of $V_k(\mathcal{M}^k U_{t,\square}(V_t))^{-1}$ with the identity. The threshold is $2\delta_k$. Even when the two retained fields agree, the regional background $U_{t,\square}$ is computed with a different bare depth. Work on a common partial history up to the first differing decision. One must first compare the availability of the reads, since the test convention assigns failure to an undefined read.

Consider a newly inserted ordinary plaquette test on a cube $\square'$ tested in both runs. On the common prefix the incoming positive density tests cover the entire footprint of the one-step average for the lifted datum on $\square'^{\sim 4}$. To see this on either lattice, measure lengths in units of the incoming $k=t-1$ lattice. Put $s=LM_2\check{R}_t$ and $W=LM\check{R}_t$. The four enlargements cost at most $4s$, and

completing the one-step averaging blocks adds at most L. A level-k density cube covering a corner of a plaquette in this footprint has side at most Ls, by the neighboring-scale bound for $\check{R}$. The total $4s + L + Ls < W$, since $W \geq L^2 s$. The ordinary plaquette test region has four coarse layers to the old large region. Even in the first step there is one coarse layer to the hull of the failed bare tests. Thus all the incoming density cubes just selected have their positive test, and none is in an omitted second-class inset.

The full bare averaging blocks of a level-k plaquette with a corner in such a density cube lie in its one-layer enlargement. The positive density test gives bare curvature less than $\varepsilon_k \eta_k^2$ there. The local small-curvature average estimate gives $|\partial V_k - 1| \leq 2\varepsilon_k$ on the one-step footprint, since the localized orbit has the prescribed V_k there. At $k = 0$ use the bare test itself. The ordinary averaging row prescribes $V_t = \mathcal{M} V_k$ on the top bonds inside $\square'^{\sim 4}$. Thus the one-step bound gives $|\partial V_t - 1| < 3L^2 \varepsilon_k$ there. At weak coupling $\varepsilon_1 = 3L^2 \varepsilon_k \leq a_1$ and $B_3 \varepsilon_1 \leq \varepsilon_{\mathrm{v}} \leq a_0$. The real existence and orbit comparison theorem therefore admits the lifted datum at the test radius ε_{v}, independently at both cutoffs.

A newly inserted approximate fluctuation test is reached only on a cube whose own plaquette test passed. It uses that same orbit on the fourfold box. The third enlargement lies in the top member with a margin containing the full averaging blocks of its top sites. Earlier determining rows have no endpoint there, so the only nodes in the axial-gauge carrier are its top sites. On each of their bare blocks the orbit curvature is bounded by $B_3 \varepsilon_1 \eta_t^2$ by the admission just proved. Local averaging bounds the level-k plaquettes in the contour blocks by $2L^{-2} B_3 \varepsilon_1$. At the same weak-coupling floor, $L^{-2} B_3 \varepsilon_1 \leq c_2^{\mathrm{elem}}$, so the contour means exist. For $k = 0$ use the bare curvature bound. The regular orbit on this box therefore has an axial representative with a unique center on the tested bonds.

These admission checks apply to ordinary tests at their first insertion on the common prefix. A carried test reproduced on its original reads belongs to its original decision.

For a failed ordinary plaquette test, the fourfold read can be exposed in the raw incoming stock. Take the complete read with every fine double block of its top rows inside the raw footprint of the failed component. In the first step the incoming field there is raw Haar, without earlier averaging constraints. Keep the nonpivots fixed and use each top row's private middle link to expose its generated top output. The literal row Haar kernel has mass at most $2L^9$ on a generated target. Distinct rows read none of the other's pivots, so the joint upper bound is the product of these row factors times Haar on the top read. The remaining factors use the true inverse graphs and their reference majorants.

The admitted top curvature bound on this read puts its axial logs in the ball of radius $CD\varepsilon_k$, for a box of side D in the test units. The radial argument at the ordinary threshold ε_t then gives the factor $Cn\vartheta$ in the top Haar bound. The row costs grow at most exponentially in the number of top rows of the read. This calculation concerns the first split and a later reference stock in which these generated values remain free. At a later ordinary step the selected incoming pivots must remain free after the earlier eliminations. A subsequent prescribed outgoing row can constrain the exposed top values and must be included in that reference chart.

The marked tests have their own admission arguments.

At stage zero the first regularity guard uses the untouched incoming datum, with the incoming profile. Its positive branch enters the first prospective guard. For that guard and the later prospective guards, use the promoted datum bounds on the entering support. These bounds, Ce_q in each layer q, use the actual promoted averages before their delta functions are integrated. Localizing the stage to its class component gives the joined determining set with its prescribed collar. A tested holonomy in the joined set either agrees with a tested holonomy on the global datum, is one in the lifted collar, or equals a tested top holonomy of the datum being lifted. Hence the joined datum is $\bar{\varepsilon}$-regular for $\bar{\varepsilon} > C \max_q e_q$. At weak coupling take $\bar{\varepsilon} \leq a_1$ and $B_3 \bar{\varepsilon} \leq \varepsilon_{\mathrm{v}} \leq a_0$. The regular orbit for the localized set in force therefore exists before the prospective guard is applied. The inset

and crossing tests that use this same orbit also have defined reads. Passing their layer thresholds requires their separate curvature estimates.

For the last-shell test take $h = m_\flat$ and the full fourfold test box in $Z''_{h+1} \cap \Omega_h$. The entering prepared datum bounds its original level-h plaquette defects by Ce_h. Keep the specified links meeting the inner cutoff. Every link set to one belongs to $\mathbb{B}_0$, so the preceding positive main-shell test and the basic reference bound give distance at most $\delta'_m + CL^{h-m}\varepsilon_m$ from one at that link. Telescoping at most four replaced factors bounds the plaquette defects of the artificial datum by

$$Ce_h + 4\delta'_m + CL^{h-m}\varepsilon_m.$$

This lies in the fixed lifted-datum existence radius at weak coupling, independently of the waiting depth. This proves admission before the last-shell decision, whose half-threshold is a smaller requirement.

On a passing last-shell cube the local test transfers to the glued background U^0 at the same plaquettes. In the tested curvature units its bound is

$$\tfrac{1}{2}\varepsilon_h + C\varepsilon\big(L^{-\mathsf{N}} + e^{-\delta_0 D_2}\big).$$

Here N is the waiting length and D_2 is the clearance of the tested enlargement inside its full fourfold box, in level-h units. This is a one-run comparison of the two lifted fields from the same inner datum. The band for the last-shell decision is a function of that retained level-h datum. In the framed integral it stays fixed through the V' integration at fixed datum, so its thickness must be estimated in the retained-field law. On the identity side of the mask, a tested plaquette with a complete vacuum top box around its carrier has normalized curvature at most $Ce\,e^{-cD}$, where e is the admitted radius and D the distance to that box's complement in level units. This is the real collar comparison with the vacuum at the same retained data. Such plaquettes cannot attain a maximum in the threshold band once this bound is below $\varepsilon_h/4$. The remaining test depends on the actual determining links of the retained h-datum. The ordinary radial change holding those links fixed gives no shell gain for this test.

The effect of a change of site gauge before masking can be assigned to the erased rows. Write J for the map setting the erased links to one. With gauge action $V_b^g = g(b_-)V_b g(b_+)^{-1}$, pull $J(V^g)$ back by g^{-1}. Its kept links are those of $J(V)$, and its erased links are $g(b_-)^{-1}g(b_+)$. The plaquette norms of the constrained background are invariant under this gauge pullback. In the lift to the complete test tower an induced link is either unchanged or copies one changed link between level-h blocks. If the erased-link jumps have logarithms of size at most b and their logarithmic interpolation lies in the common regular domain, apply the curvature response bound along it. In the units of the test the change at a plaquette is at most Cbe^{-cD}, where D is its tower distance to the affected determining rows. Use this comparison in each fixed tower before comparing the two cutoffs. It isolates the gauge contribution to the band on the actual read.

There is a shell estimate on a different chart, when all kept links in the complete test read are free and can be scaled together from the vacuum. In a wholly kept box with a full product Haar stock, fix a rooted axial tree. The tree change of variables leaves independent Haar on the n non-tree links. The bound in Lem. 3.22 puts their logarithms in a ball of radius $r \le CDe_h$ in the maximum bond norm for a box of side D. The test is gauge invariant on this whole read, so the tree gauge factors can be held fixed. In a box meeting the cut use this calculation only on a product log-Haar chart in which scaling all kept logs preserves the identity mask.

Along a ray write the log datum as tB with $\sup|B| = 1$, $0 \le t \le r$. The kept logs give the corresponding lifted row logs, and the masked row logs are zero. Thus the vacuum continuation of Prop. 3.117 admits a fixed complex disc in the radial variable, on the separated tower with complete top test stencils. For a tested plaquette p let $F_p(t)$ be its matrix curvature increment divided by the squared bare mesh in level-h units, in the holomorphic slice. The uniform bound eq. 3.mlxiv bounds this function on the disc, and $F_p(0) = 0$. Use r at most half the disc radius. The real norm

is the norm on the actual orbit. Cauchy's estimate gives

$$|tF_p'(t) - F_p(t)| \le Cr^2.$$

Put $\lambda = \varepsilon_h/2$. For real fields F_p is a quaternion, so the operator norm is Euclidean in its four real coordinates. Where $|F_p|$ lies between $\lambda/2$ and $3\lambda/2$, its derivative in $\log t$ is at least $\lambda/2 - Cr^2$. If $Cr^2 \le \lambda/4$, every active maximizer has slope at least $\lambda/4$ in this range. The band of relative width $\vartheta \le 1/4$ for the maximum can be crossed only upward. It therefore occupies an interval of length at most 8ϑ in $\log t$ on any ray.

Along each ray the Haar radial density is $t^{3n-1}w(t)$, where w is the product of the sinc-squared Jacobians and is decreasing on the small ball. Its cumulative mass H satisfies $tH'(t) \le 3nH(t)$. An interval of logarithmic length 8ϑ therefore contributes at most $24n\vartheta$ times the mass of the whole ray. Integrating the ray directions gives the same relative bound for the product Haar ball. For $n = 0$ the band is empty. To use it in the weighted history estimate, these retained coordinates must survive the outgoing inverse as a product stock. The band is taken in the stored frame before the exterior supremum. On a wholly kept box the exterior compensator acts by a gauge on the full datum, so the band is the same for every admitted exterior. For a cut box use the actual mask-preserving pullback to check this property. The remaining reference integral must have its bound uniformly in these coordinates.

These conditions hold for the reference integral of an unmarked late last-shell drop-out before a later constraint, when the full level-h box read, including its endpoints and lift halo, is kept and lies in Ω_h. In (1.145) those links are in the dV_h Haar stock, separate from the relative field V'. The ordinary strip pivots at fixed V_h are already eliminated. Unresolved raw targets have both endpoints in Ω_h^c in the old core and are outside this stock. With the test stock fixed, eliminate those remaining targets against their own averaging constraints and keep the old strip variables in their original charts. The unmarked late product envelope after eq. 4.diii then has the same conditional integral bound for every value of the test stock. The radial restriction gives the stated gain in that reference integral, with any already justified event payments. Subsequent constraints that prescribe some of these links require the bound on the corresponding conditional chart.

The same reference calculation applies to a test box crossing the identity cut if its full level-h read lies in Ω_h and all its kept links are in the retained Haar stock. In the class geometry the inner cut is one coarse layer from the hull of the old core and two layers from the outer prepared face. In level-h units write $A = LM\check{R}_{h+1}$ for the coarse layer and $d = LM_2\check{R}_h$ for the test cube side. A fourfold box crossing the cut has width $9d$. Even after the endpoint padding, $9d + 2 < A$, by $\check{R}_h \le L\check{R}_{h+1}$, $M \ge L^2M_2$, and $L \ge 13$. Thus the full padded read clears the old core and stays in the prepared member. Its kept links, including those crossing the cut, are in the second Haar stock of (1.143). The gauge-nest convention excludes the crossing links from $\mathbb{B}_0$, so (1.145) retains them in dV_h. Use this stock after the compensating change of (4c). At fixed exterior and frame this change is a Haar translation at the endpoints of every kept link. With those translated coordinates fixed, the last-shell test sees their masked field directly. Read the other factors at the inverse translation. The conditional reference bound is uniform in those values, so the band in these coordinates can be restricted before the exterior supremum.

To obtain the free logarithmic chart, form the finite graph of the full read and contract each connected component of its identity edges. On the quotient choose a rooted spanning tree from the kept edges. The tree change of variables is triangular: after fixing the tree links it multiplies each non-tree link on the left and right by fixed group elements. It leaves independent Haar on the non-tree links. The site gauge is constant on each contracted component, so every identity link stays at one.

If the artificial plaquette defects on the read are at most e, first apply the ordinary axial estimate on the full box. All its transformed links differ from one by at most CDe. Along any original identity edge the two axial site gauges therefore differ by at most CDe. Replace the gauge on each

contracted component by its value at a chosen vertex. Paths in each component have length at most CD^4, so this changes the gauged kept links by at most CD^5e. Choose the quotient tree by shortest paths from the root. Its depth is at most CD, since contraction cannot increase distance. Putting the field in that gauge costs at most another CD, by telescoping the tree paths. Thus the non-tree logarithms lie in the product ball of radius CD^6e when that radius is small. Apply the radial estimate when its square meets the half-threshold condition. The whole kept graph must be free in this calculation, including the kept crossing links.

The same last-shell restriction applies on a marked late branch whose triangular lower reference chart leaves this full kept Haar stock. Hold its recorded post-gauge coordinates and the inner variables fixed while integrating the lower Lebesgue blocks. The uniform inverse Jacobian and Gaussian bounds give the same conditional majorant e^{CV° as for the triangular reference integral. The bounds for closed inner leaves remain functions of their own stored variables. The last-shell band is Borel in the fixed kept stock and can be inserted before the compatible-evaluation supremum. Integrate it with the Haar and quotient calculation above. This gives the factor $Cn\vartheta$ in the weighted outer integral, with the same inner masses and charged events. The argument requires the stock in the recorded coordinates to remain free after the lower eliminations. For the comparison of runs, the paired reads must place their disagreements in this band uniformly over the admitted evaluations.

The final density test that classifies a restored component uses the reference draw. On that support the restored top field has plaquette defects bounded by $C(M)\varepsilon_m$. The estimate follows by changing the at most four plaquette factors from the reference field, including on the face where the reference agrees with the exterior. Each fourfold density box based in the six-cell inset is contained in the component. Apply the same lifted-datum existence estimate on those full boxes before either classification outcome.

On a complete fourfold test read wholly in the fresh box, first use the normalized reference law at fixed exterior, before prescribing new outgoing rows or splitting the two classes. In a fixed frame the denominator is the centre action factor times $(\theta^{-3/2}\sigma_0)^{n_{\mathsf{G}}}$ times the admitted fluctuation normalizer. The latter has bounded log. The centre action costs at most $Cp_0(g_m)^2(M\check{R}_m)^4$ in the exponent, and n_{G} is at most $C(M\check{R}_m)^4$. Hence the inverse denominator is bounded by $\exp[C(\log\theta)^c]$ on this slice.

The numerator density is at most one relative to the off-tree Haar product. In physical coordinates the non-tree translations preserve Haar. For the gauge-invariant test and its top curvature bound the choice of tree values is immaterial, by site gauges fixing the root. Thus one may integrate the tree values against Haar as well when bounding that event, and discard fresh variables off its read. The top curvature bound places the read in the small axial logarithm ball. The radial estimate at threshold $\lambda = \varepsilon_m$ gives Haar band mass at most $Cn\vartheta$, where n counts the free links of the read. The fixed-exterior probability of this band is at most $C\vartheta\exp[C(\log\theta)^c]$. For the weighted history envelope after lower eliminations, the same radial factor applies where the complete product stock is still free, the remaining reference bound is uniform with that stock fixed, and the band is Borel in the recorded coordinates.

The six-cell inset places the test box inside the component. A test box entirely outside the restored stock reads only the retained field, and a box meeting the restoration boundary can read fixed nonzero links as well as the new draw.

There is a crossing case with the fixed links separated from the tested stencils. Fix the physical tree values first. On a chart whose remaining free links have product Haar reference, use the tree frame to write the retained logs as B_{fix} and the free logs along a ray as tB, $0 \le t \le r$. The fixed logs are held at every t. If all the fixed edges, including the physical reference-tree edges, extend to a common tree with compatible prescribed root gauges, their values can be gauged to the identity. Otherwise retain their actual B_{fix}. The fixed-coordinate part of the lifted datum is formed by the same block copies. Let $F_p(t)$ be the normalized matrix plaquette read of this datum. On the fixed

small response disc the previous Cauchy calculation now gives

$$|tF_p'(t) - (F_p(t) - F_p(0))| \le Cr^2.$$

It is enough that $\sup_p |F_p(0)| + Cr^2 \le \lambda/4$. The active norm slopes in the band are then at least $\lambda/4$, giving the same $Cn\vartheta$ radial bound.

To check the centre condition, interpolate from the vacuum to B_{fix} with the free logs zero. When the complete lifted carriers of all nonzero fixed logs are at distance at least D_0 from the tested stencils, the weighted response eq. 3.mlxvii gives $\sup_p |F_p(0)| \le C\|B_{\mathrm{fix}}\| e^{-cD_0}$ in the normalized curvature units. Thus the radial comparison also applies when the full test box meets the old field but its tested stencils and their padding are separated from the nonzero fixed data by the prescribed collar. This uses the actual product stock in the fixed tree frame and the admitted interpolated data.

For a crossing chart with unscreened fixed rows we must control the centre curvature on its own constraints. The two class weights are compared before removing any implied reference cutoff or frame factor on the first-class side. In the quiet nest, the final test bases in the old enlarged hull lie in the region excluded from the earlier ordinary plaquette-test insertion. The inherited top plaquette bound there admits the background, while the band of its derived bare curvature still needs control in the retained-field integral.

In each case compare like reads on the part of the history where the earlier decisions agree. For a plaquette test the numerical quantity is the curvature at the finest scale of the local minimizer divided by η_t^2 on each respective lattice. A bound on the response at the common top alone does not control that read.

There is a mesh comparison on a matched input to these plaquette tests. For the ordinary and final density tests, take an aligned fourfold box and the same level-i field on the entire lifted read in a common frame. The third enlargement lies in the top member of the separated tower. The tested first enlargement and its complete difference stencils are therefore inside that member. If the top plaquette defect is at most e_i, the common comb gauge bounds the top logarithms by $N = CM_2\check{R}_i e_i$, and the block lift copies them to the induced rows. The comparison of common trial fields below now applies to this read: the complete common row data coincide, the lower unmatched rows are screened, and on the top stencils the first differences have the same two-mesh and Hölder bounds. Pair the literal plaquettes of each orientation by inward rounding. For a bare mesh η in level-i units this gives $|q_\sharp - q_\flat| \le CN\eta^{\min(\alpha,\beta_H)}$ for the maxima. It also applies to a last-shell box when the complete masked top datum is common. Use the ordinary incoming or final reference curvature bound for e_i, or the admitted masked-field bound for the last shell. With the running threshold bounds their ratios to the common test threshold cost at most powers of the scale parameters in this comparison. This gives the numerical part of the test comparison on matched input.

On the region where the two reads are defined and the lesser value is at most twice the threshold, we must show a relative comparison with a positive power of the ratio of the bare mesh to the tested scale, allowing the powers of $\log\theta$ in the history estimates. If the two tested numbers q_A, q_B differ by at most $\vartheta\lambda$ at threshold λ, then

$$|\mathbf{1}_{q_A<\lambda} - \mathbf{1}_{q_B<\lambda}| \le \mathbf{1}_{|q_A-\lambda|\le\vartheta\lambda}.$$

For the approximate test q_A can be the maximum over its nonpivot bonds. The shell is then determined by at least one bond attaining that maximum. The same argument applies to each subsequent decision on the part of the history where the preceding decisions agree.

On a disagreement with $\vartheta \le 1/2$, both numerical reads are at least $\lambda/2$. For the tests with an energy witness obtained by forcing the read below threshold at small energy, run that calculation with threshold $\lambda/2$. In the ordinary plaquette and approximate tests this reduces the witness constant. In the main and last-shell tests it also requires a smaller bound on the reference-field

errors at weak coupling. The witness can therefore be taken on either history, including the passing one. Using it in the mass requires the unspent share of the action or form on that same history. A stopped root whose payment was reserved for a later read uses that reserve only there. This gives the corresponding ordinary-creation or marked-event energy on the full compatible carrier. Its use depends on which action or Gaussian share is available there. The thickness of the near-threshold set still has to enter its integral.

At fixed coarse datum the approximate test has a fixed center on each tested bond. In the strip where the cutoff equals one, the substitution gives $V_k(b)D_b^{-1} = W'X_b$ with X_b fixed by the retained exterior datum and D_b the cube center at the bond. Thus on this strip the read is a radius of a translated stored coordinate. Where the cutoff is less than one, the strip's center reserve keeps the approximate test below $2\delta_k$. In the admitted deep ordinary box the global radius bound and the local-to-global offset also keep it away from $2\delta_k$. Both observations use the margins in the ordinary step. To estimate the first approximate failure, the runs must be compared before the test has fixed Q_t and hence Ω_t. The ordinary fluctuation chart on $\Omega_t^{\sim -1}$ is then unavailable on the failing side.

Before the Q_t split one can use the gauge draw itself on a tested footprint in the gauged blocks. The approximate-test cubes are inset one coarse layer in the gauge region. Their two test layers and one bond reach stay in that region by the cube-size floor. Fix the input before this draw and the preceding plaquette decisions. For a fine test bond choose an endpoint x off the top lattice in a block where the draw is made, and hold the other draws fixed. If y is the block centre, the coordinate $W_x = V_k(y,x)u(x)^{-1}$ has the normalized one-site density of the gauge-fixing factor. Its Haar density is at most $C\mathfrak{t}_k^{3/2}$, by the lower bound on the gauge normalizer. Here $\mathfrak{t}_k = g_k^{-2}$ is the coefficient of the auxiliary gauge weight: it is x_k in the own run and θ_k in the reference run. The transformation is the identity at the top sites, so the coarse average and the local approximate test centre at the bond stay fixed. The relative tested link is a fixed left and right translate of W_x or W_x^{-1}.

The Haar volume of the band about $2\delta_k$ is $C\vartheta\delta_k^3$, for either side of the threshold. Thus the conditional probability for this endpoint is at most $C\vartheta\mathfrak{t}_k^{3/2}\delta_k^3 \le C\vartheta p_0(g_k)^3$. Sum over the bonds that can attain the test maximum. Earlier approximate decisions may be retained as indicators bounded by one in this estimate. This gives a band bound relative to the positive mass before the gauge draw, for both outcomes of the test. The residual half of the gauge exponent in the ordinary-event majorant has the same pointwise bound with the original normalizer. Its mass is bounded uniformly above and is at least one, since the positive exponent cost has been halved. The same band factor therefore applies in that residual reference integral. Any test gain uses the assigned Wilson and gauge share before this integral. To apply it inside a later history mass, the chosen endpoint coordinate and fixed centre must still be available in its reference integral.

For a bond from a block centre to an adjacent site x in that block, the contour mean is just the link and the local axial centre is the identity on it. The test on this bond is therefore radial in the actual W_x. Its threshold in eigenangle is $r_0 = 2\arcsin\delta_k$, inside the gauge draw cutoff by the threshold ratio. In the angular coordinate r the density is proportional to $\sin^2 r\, e^{-\mathfrak{t}_k(1-\cos r)}$ on this chart. On both shells of width $w = g_k/(Cp_0(g_k))$ at r_0, its log derivative has absolute value bounded by $C(\delta_k^{-1} + \mathfrak{t}_k\delta_k) \le C'/w$. The same bound holds for the residual half weight. A one-sided band of width $u \le w$ has at most Cu/w times the mass of that side's shell of width w. Thus a relative band about this single-bond decision has cost $C\vartheta p_0(g_k)^2$ in its own pass or failure mass. Other tests that read this same gauge variable can restrict the comparison shells; they retain their indicators in the actual prefix law.

On the failing side of a first ordinary approximate decision, the enlarged failed cube is outside Ω_t. A complete endpoint block of the test in that enlargement uses the old raw Haar field and the averaging delta in the retained one-step operation. Use the rooted tree coordinates of that block, with the top site fixed and all incident links of the moving sites included. They separate the block

quotient and the site gauges with Jacobian one. At fixed quotient the change from the site gauge to W_x is a Haar translation and inversion. The outgoing average is independent of these site gauges. The centre is thus fixed in the reference coordinates, both if the outgoing datum is retained and if it is eliminated against its own averaging delta. The band is a function of the recorded stock before the exterior-pair supremum.

On an untouched piece with this complete block free of incoming constraints on the moving sites, keep the quotient fixed while applying the residual product majorant. Extract the assigned failure gain first. The remaining one-site gauge factor is the half-weight above, and restricting it to the band gives $C\vartheta p_0(g_k)^3$ with the other factors in the same majorant. The first step has no earlier averaging constraints. At a later step the same argument requires that the earlier constraints and reads leave these gauge coordinates available. A passing coordinate integrated in Λ_t uses its own conditional window.

There is a local estimate before the Q_t split. Fix V_t, the recorded plaquette decisions, and the other free variables in a complete row chart for $\mathcal{M}V_k = V_t$. On a branch where the actual middle pivots can be eliminated and b is a free bond, its reference factor is Haar. Reconstruct the pivots and evaluate the density and gauge factors at those reconstructed values. The centre $D_b(V_t)$ is fixed. A band of relative width ϑ about the group-norm threshold $2\delta_k$ has Haar measure at most $C\vartheta\delta_k^3$. In $SU(2)$ the operator-norm distance from the identity is $2\sin(\phi/2)$, which has derivative bounded away from zero at these small radii. Thus the restricted integral in this slot is at most $C\vartheta\delta_k^3$ times a pointwise upper bound for the reconstructed density in the slot, including its pivot Jacobians. A union over the free bonds that can attain the maximum gives the bound on these charts. In the full pre-Q_t history one must still control those densities uniformly in the retained coordinates in the order of the weighted mass integral.

The main-shell fluctuation test has a different shell estimate. On the preceding positive exterior and extendibility support, the box critical-orbit construction gives V_Λ and the mixed reference center V_0 from the fixed exterior. These are available before the main-shell decision at each cutoff. In one retained frame use the relative links $V'(b) = V''(b)V_0(b)^{-1}$. First eliminate the central delta chain from the top down. The relative Haar translation and the normalized tree constraints then leave the free indices $(\mathbb{B}_0 \cap X) \setminus rT_0$. The test reads the largest $SU(2)$ eigenangle of these links, with $\phi(-1) = \pi$. Thus the logarithm cut gives a numerical failure at the threshold $\delta'_m < \pi$. On each free Haar factor the band $|\phi - \delta'_m| \le \vartheta\delta'_m$ has measure at most $C\vartheta(\delta'_m)^3$, by integrating $\sin^2\phi\, d\phi$. The condition is independent of the exterior in the relative coordinates of that run and frame. At a matched stored link and frame, the difference of the two relative angles is at most the group distance of the two centers by the bi-invariant triangle inequality. The maximum obeys the same bound. Comparing the centers between the two cutoffs still uses the response comparison. In the admitted passing-side product envelope eq. 4.diii without earlier marks, use the product majorant in the free B-coordinates after bounding the exterior dependence. Replace a scaled B-ball of radius δ'_m/g_m by its inner annulus of relative width ϑ. Its volume is at most 3ϑ times the ball volume. Sum over the free coordinates that can realize the maximum, with the same other factors in the envelope. This gives a relative $Cn_B\vartheta$ bound for that product estimate, where n_B is the free-coordinate count.

On the failing side, consider a late drop-out with no earlier marks in the core. The completed frame operation leaves normalized Haar in each non-tree shell slot. In its recorded frame it is the relative link V' that is held fixed in the exterior supremum in eq. 4.cdlxxi. Changing the exterior reconstructs $V'' = V'V_0$ at that same slot. The shell indicator is therefore a function of the stored variable. It can multiply the pointwise majorant before the exterior supremum in eq. 4.dviii. The unmarked late reference bound after eq. 4.diii is independent of the shell Haar variables. Restricting that product envelope to the band gains $Cn_B\vartheta(\delta'_m)^3$ relative to its full Haar integral, with the same strip factors. Any event payments used here are the ones already justified on that failing history. To use the bound for disagreement, the paired centres must place the disagreeing records in this band uniformly over the admitted evaluations.

The failing-side gain also holds for marked late branches with the triangular reference charts of eq. 4.dii, provided the selected shell slots remain free Haar factors. Write the outer reference measure as $dv_{\mathrm{sh}}\, d\mu^{\circ}_{v_{\mathrm{sh}}}$, where v_{sh} comprises the relative shell slots and dv_{sh} is product Haar. Keep v_{sh} and the inner variables fixed during the successive integrations of the lower Lebesgue blocks. Their inverse Jacobian bounds and Gaussian reserves are uniform in these group arguments. The strong majorants of the closed leaves in eq. 4.dviii depend on their own stored variables. Thus

$$\int g_{\omega}(v_{\mathrm{sh}}, \cdot; \xi_{\mathrm{in}})\, d\mu^{\circ}_{v_{\mathrm{sh}}} \le e^{C_5 V^{\circ}}$$

uniformly in v_{sh} and ξ_{in}. Integrate only the shell band in dv_{sh}. The right side then acquires the factor $Cn_B\vartheta(\delta'_m)^3$ before the same sum and integration of the inner histories. The event payments and volume weights are those of the original history.

This applies with closed inner leaves and older regular strip charts whose pivot eliminations are complete. An older raw row with a free Haar target can also be eliminated by substituting its average for the target in the remaining reads, starting from the highest such row. Here the substitutions must leave the same lower reference charts, with their bounds uniform in the fixed shell. Fixing a shell link can change the coarse datum of an ordinary pivot chart. The unresolved lower raw targets of the frozen core lie inside the inner cut. They are separate from the native shell slots.

For prescribed targets in the first outgoing rows of the late stop, fix the reconstructed exterior and the old shell. Each row that reads the fresh box has a free middle Haar link, including a row crossing its face. The old frame tree acts on the old field. Use the joint inverse of the fresh rows at the prescribed targets, with their native branch version, and evaluate the retained weights at the reconstructed links. The factor per row is bounded by $2L^9 + 1$, uniformly in the old shell. These factors use the existing first-outgoing volume count.

An older restored box also gives its joint first-outgoing density at prescribed targets in its protected row stock. There is a two-level case in which one such target is the fixed middle link of the next raw row. Suppose the complete two-level backward blocks of this row lie in that restored box and the row is still carried in the ordinary raw graph. Its alternate face link belongs to the same first-outgoing stock and is left free. The restored cutoff bounds the plaquettes on the backward blocks. The local averaging estimate in Prop. 3.6, applied to the complete two-level carriers, gives small curvature on the next double block. The regular alternate pivot then gives the joint bound at the fixed middle link and fixed next output, with the same other stored variables. Both inverse densities enter the old core integral. They are uniform in the relative shell and use its slots only through the fixed parameters of their charts. A prescribed output in a different graph still requires the joint bound for that graph with the shell fixed.

For a sharp preparatory collar test there is a conditional shell bound in its native free exterior stock. Fix the other stage variables, including the top datum determining the centre. In the scaled coordinate the threshold is $t = \delta'_i/g_i$. Use the width $W = (C_{\mathrm{sl}} p_0(g_i))^{-1}$. The surviving ordinary completion factors use the separate strip stock. The other test on this coordinate is the approximate collar bound at $2\delta'_i$, with the regularity read fixed in this conditional integration. In the local convention the two centres coincide. In the global convention their scaled separation is at most $W/4$ by the collar response. Since $W = o(t)$, the approximate test passes on both one-sided shells of width W. The density slope in eq. 5.cdxiii is at most $2/W$ there, using the waiting-window comparison of p_0. The radial Jacobian varies by a fixed factor. Consequently restricting one of these shells to distance $u \le W$ from the threshold gains Cu/W in the conditional stage mass. In angular units a relative width ϑ corresponds to $u = \vartheta\delta'_i/g_i$.

In the part of the outer collar receiving a fresh normalized gauge draw, the same one-site argument applies to the local sharp test before its decision. Take a tested bond with a noncoarse endpoint in a complete new block and keep the other variables fixed. The site gauge must fix the determining

nodes of the prospective centre. The relative link then has a translated one-site density bounded by $C\mathsf{t}_i^{3/2}$. A band at angle δ_i' has conditional mass at most $C\vartheta(\delta_i'\sqrt{\mathsf{t}_i})^3 \le C\vartheta p_1(g_i)^3$. On this band the same-centre approximate test on the bond passes. This calculation uses the untransformed local prefix, on either side of the sharp threshold. If the bond joins the block centre to its neighbour and the stage uses the same axial gauge, the test is radial in that draw. The preceding one-sided shell argument with δ_i' gives the bound $C\vartheta p_1(g_i)^2$ relative to the single-bond outcome. For the full maximum use the predecision union bound over the bonds with such a draw. Carried strip links and the other selectors still use their own reference factors.

For a stopped component, the top datum determining this centre can be reconstructed from the carrying field in the compatible-evaluation supremum. The conditional collar bound fixes that datum first. To use it in the marked integral we need a relative shell coordinate in the actual stored stock, or a uniform centre-spread bound in a fixed chart.

On a global sharp failure with the full sharp mask in the transformed free exterior stock, this band is fixed in the stored coordinates W_b'. For relative width $\vartheta \le 1/8$, the band about δ_i' lies below the onset $4\delta_i'/3$ of the cutoff substitution. Indeed, above the onset the original global angle is at least $4\delta_i'/3 - \delta_i'/8$, outside the band. Below the onset it is exactly the angle of W_b'. The substitution there is a right translation with Haar Jacobian one at fixed exterior. The maximum band is therefore Borel in the stored stock. On the part of the weighted envelope with these slots still free, restrict one slot that attains the maximum and use its Haar volume $C\vartheta(\delta_i')^3$. Summing over the free slots gives the band bound with the same conditional majorant for the other variables. A tested bond outside the transformed mask has to keep its own read. In particular the local sharp failure uses the preceding conditional calculation on its untransformed prefix.

For the other marked histories we must show that restricting the weighted mass of the operation to this shell gains a factor $C\vartheta^a \exp[C(\log\theta)^c]$ over its large-field bound, for some $a > 0$. Here θ is the frame at the finest depth held in the histories counted by that operation. The comparison must also sum these restricted masses over the possible first decisions with the localization weights of the recursion. The window estimate eq. 5.cdxix uses Lem. 5.73, which fixes the other stage coordinates and varies a literal nonpivot logarithm. To use it on a derived background read would require a change of variables controlling the conditional mass and preserving the readsets of the surviving history. Even for a literal translated coordinate the remaining tests can have distinct centers. The full shell comparison uses the stage law after summing the earlier gauge draws. A bound on the normalized positive survival probability at a fixed exterior pair does not bound the mass in eq. 4.cdlxxiv, where the exterior-pair supremum and the mark weights enter before the integration and summation. For the extendibility test the infimum is a function of the prescribed top exterior alone. Its shell indicator is constant on the central fibre at fixed exterior.

On the complete exterior carriers of the extendibility witness there is a uniform separation at low energy. Let E be the assigned exterior Wilson share at level i. The axial extension with the old exterior and the lifted-datum estimate give a candidate whose tested curvature, in level-i units, is at most $C(M)\sqrt{E/\theta_i}$. The infimum is no larger. Hence $E \le c(M)\theta_i\varepsilon_i^2$, with $c(M)$ chosen for the half-threshold, puts the read at most ε_i. This leaves a margin of at least ε_i to the test value $2\varepsilon_i$. Apply this on both runs when the complete carriers are available in both. There is no disagreement on that low-energy part. On the rest, a shell gain requires a bound using the exterior read. The central fibre estimate supplies no such bound.

The two infima can be compared on regular trials near their common threshold. For a trial V let $q_b(V)$ be the normalized tested supremum at cutoff b, and put $q_b^* = \inf_V q_b(V)$. The box clearance puts the full averaging blocks of the top plaquettes changed by the trial, including its outer layer, in the tested top inset. If $q_b(V) \le 5\varepsilon_i$, the local averaging bound gives defect at most $2q_b(V)$ on each of those coarse plaquettes. With the prepared exterior regularity on the unchanged carriers, the same trial bonds are therefore admitted at the other cutoff, at weak coupling. Use the actual extension class over that exterior.

On aligned class boxes the near-threshold trial supplies a small datum on the entire lift. A top plaquette of the box whose full averaging carrier is inside the tested inset has defect at most $10\varepsilon_i$ by the local average estimate. The remaining top plaquettes are within a fixed top stencil width of the outside of that inset. Choose a density cube containing one of their corners. It lies in the carried positive region $\Omega_i^{\sim 4}$. Its one-layer enlargement contains the full read of the plaquette, in the top part of its own fourfold tower. The clearance between the trial box and this read leaves that density datum unchanged. The positive test and the same averaging bound give defect at most $2\varepsilon_i$ there. The lift on the class box uses only its top links and complete backward blocks. In a rectangular lift the top field in a common rooted comb gauge has logarithms bounded by $N = CM\check{R}_i\varepsilon_i$, and the induced lower row logs have the same bound.

The test lift is on the minimal recursive tower of the component. Use the same physical comb on the top field in both runs. The block lift is the identity on internal bonds and copies a top link on each bond crossing its corresponding block face. Each one-step averaging path is either internal, with transport one, or crosses that face exactly once, with transport equal to the copied top link. Its contour transports are one. Thus all paths in the mean give the same value, and the one-step average of the finer lift is exactly the coarser lift. Hence the literal prescribed datum agrees on complete common rows, and the reduced datum agrees where its outward read also agrees. The physical recursive tower has the two-cell inset at every level above its first lower layer. The two cutoffs therefore have the same upper regions on this aligned box. The reduced outward read uses only the adjacent lower block, so the unmatched stock stays in a fixed number of lower layers after enlarging it by that read. At the trivial base, Cor. 3.178 identifies the Landau potential of the test lift with the response to these actual reduced data. Use the two-depth response estimate on the common top layer, with the error weight screening the unmatched lower stock. On the full common top stencils it gives a difference bounded by $CN\eta^{\alpha}$ between the transferred fine potential and the coarse potential, including one difference. The individual first differences have a Hölder bound of size CN there.

To compare the literal plaquettes, in this chart expand the four links in the mesh. The normalized curvature has the linear curl and the quadratic commutator of the potential, with an error $C\eta(N + N^2 + N^3)$. At the trivial base the per-length linear transfer is the straight path mean: the coarse component is the average of the transported fine component along the L-step straight paths, with total weight one. A coarse difference of this mean is an average of fine differences, by telescoping the L fine translations. The difference from any of the nearby fine first differences costs $CN\eta^{\beta_H}$ on the common stencil. The same pairing compares the potential values in the commutator. Each tested plaquette has a same-orientation partner within $C\eta$ by rounding inward in the common tested box. The clearance to the tower boundary puts these partners on complete top stencils. Taking the maxima in both directions therefore gives

$$|q_\sharp(V) - q_\flat(V)| \le CM\check{R}_i\varepsilon_i\,\eta^{\min(\alpha,\beta_H)}.$$

Here the box, the exterior data and the top trial are the matched ones. The unmatched bottom rows use their one-run bounds and screening. In the class range $\check{R}_i \le i$, so in the flat level units $\eta = L^{-i}$ this gives a relative error CL^{-ci} for some $c > 0$. If the exterior links instead differ by at most b_{e} in a common top frame, use the same free trial links and substitute the other exterior. The lift copies these links or the identity. Its induced row logs differ by at most Cb_{e}, provided both data stay in the small chart. At a single cutoff the screened derivative of Cor. 3.178 gives an additional Cb_{e} in the normalized curvature on the tested top stencils. This term uses the actual exterior matching estimate.

Suppose the smaller infimum is at most $4\varepsilon_i$, and the comparison of the two bare lifts on these common trials gives $|q_\sharp(V) - q_\flat(V)| \le d$, with $d < \varepsilon_i/2$. Use a trial arbitrarily close to the smaller infimum. Its value bounds the other infimum above by the first plus d. Trials approaching that

other infimum also lie below $5\varepsilon_i$, so reversing the argument gives $|q_\sharp^* - q_\flat^*| \le d$. This reduces the pointwise transfer to the uniform local comparison on the near-threshold trial class.

The infimum also has a radial band estimate on a free exterior logarithmic chart. To see this on the aligned class box, fix a rooted tree of the exterior graph. The exterior of the inner rectangle has paths of length $O(D)$ to the root along the outer faces, where $D = CM\check{R}_i$ is the box side. Choose the tree with those path lengths. Include the outer crossing links of the test read as leaves. At an aligned rectangular face each outside site on such a link has just one neighbor inside the box. Extend it into the inner rectangle by axial columns from a face. The added tree links are free trial links. In the extended tree gauge all paths to the root still have length $O(D)$, and this gauge keeps the prescribed exterior in its original tree chart.

A near-minimizing trial in the threshold band has top plaquette defects at most $C\varepsilon_i$, by the preceding trial and density bounds. Its ordinary full-box axial gauge has links within $CD\varepsilon_i$ of one. Each link in the fixed extended tree gauge is a loop of length $O(D)$ in that field. Thus the exterior and free trial logs in the fixed chart are bounded by $r = CD^2\varepsilon_i$.

Write $\lambda = 2\varepsilon_i$. For a combined vector B of exterior and trial logs with $\sup|B| \le r$, the vacuum continuation of the test lift is holomorphic on the fixed datum ball. For each normalized matrix plaquette read F_p, its Taylor series at the vacuum gives, uniformly for $0 \le u \le 1$,

$$|F_p(uB) - uF_p(B)| \le Cu(1-u)r^2.$$

Indeed the constant term is zero and the linear term cancels. Each term of degree $m \ge 2$ has factor $|u^m - u| \le (m-1)u(1-u)$, and Cauchy's bound sums the resulting series.

On an exterior ray let $t_1 < t_2$ both lie in the band of relative width $\vartheta \le 1/4$. Take a trial arbitrarily close to the infimum at t_2 and multiply every log, exterior and interior, by $u = t_1/t_2$. The tree links remain fixed and the scaled trial lies in the admitted class at t_1. The previous inequality and passage to the infimum give

$$q^*(t_1) \le uq^*(t_2) + Cu(1-u)r^2.$$

The condition $Cr^2 \le \lambda/4$ holds at weak coupling: D is bounded by a fixed power of $\log g_i^{-2}$, while $\varepsilon_i = g_i p_0(g_i)$ and p_0 is a fixed power of that logarithm. Hence $r^2/\lambda \le CD^4\varepsilon_i \to 0$ as $g_i \to 0$. The band bounds then give $1 - u \le C\vartheta$ and $u \ge c > 0$. The band's logarithmic radial diameter is therefore $O(\vartheta)$. The Haar radial estimate gives a relative bound $Cn_{\mathrm{e}}\vartheta$ on a product ball of n_{e} exterior non-tree links.

At the native extendibility stop the top exterior is fixed in the infimum defining q^*. The product bound enters a history integral only where those exterior links form a free stock in a containing operation and the uniform reference bound is taken with that stock fixed. A prescribed outgoing row can have its whole double block in the exterior. In that case its constraint belongs to the same stock, and the weighted shell requires the bound on the constrained coordinates.

There is an integrated exterior stock when this extendibility stop is immediately below the floor $h = i + 1$ of a containing operation that reaches its shell or last-shell stop. Take an old component whose tested box and stencil pad are disjoint from the other marked charts. Include both its tested exterior and its previously generated targets in Z_i'' when listing the ordinary h-rows that read it. With the full row carriers in the eight-cell raw buffer, every target on this list belongs to the integrated inner field in (1.145). The old prepared targets in Z_i'' and the old exterior links retain their separate factors in the joint integral. Integrate the listed h-targets against their own Haar deltas, substituting their row values in every remaining factor. The other h-rows do not read the listed old stock. In the absence of a later prescribed target on this list, this leaves product Haar on the old exterior, with the old inner graph evaluated on its own targets.

Apply the pointwise reference majorant of the containing operation before taking the exterior supremum. On its admitted chart the majorant is uniform in the free old group links after the other reference factors have been bounded. The exterior tree change preserves their Haar factors. The

band depends only on these stored exterior coordinates at level i. It therefore costs $Cn_{\mathrm{e}}\vartheta$ relative to the product-ball majorant for this chart. With identical top exteriors the relative tolerance above is $O(D\eta^{\min(\alpha,\beta_H)})$. Since $n_{\mathrm{e}} \le CD^4$ and $\check{R}_i \le i$, the resulting $CD^5\eta^{\min(\alpha,\beta_H)}$ is still geometric in i.

In the same immediate-floor geometry, take an old second-class component of level i with a final density test. Use the complete fourfold read and its row carriers in the raw buffer and include its old exterior and restored links in the list of reads. If all affected h-targets are integrated, the same Haar delta elimination leaves product Haar on the old exterior of the test. A read wholly outside the old proposal box uses only this stock. The negative test of the old second-class component belongs to the containing core's payment. Keep its actual failed cube for that payment before bounding the remaining reference factors.

For a read crossing the old proposal boundary, use the physical off-tree links in the recorded frame. The old reference centre is determined by the old exterior stock. At fixed old exterior the relative non-tree Haar factors give the physical ones by right translation. After bounding the reference density, restore the interior site gauges for this invariant band event, fixing the exterior sites. This replaces the interior tree constraint by normalized Haar integration. Together with the old exterior factors, Fubini gives a product Haar majorant on the complete physical test read. The complete top curvature bound and the radial estimate at $\lambda = \varepsilon_i$ give a factor $Cn\vartheta$ relative to its product majorant, with n the free-link count. The reference normalization is bounded uniformly on the admitted slice; use that bound once if it has not already been included in the pointwise envelope. The band here is a function of the recorded physical links and can be imposed before the compatible-exterior supremum.

Some of these estimates also hold with prescribed h-targets. Consider rows crossing a face of the old trial box Λ^{prop}. Its faces are aligned with the h-blocks. The middle link of such a row crosses the face and is among the free trial links in (1.142). It is thus outside the exterior read of the infimum. The trial box includes a full M-layer beyond Z_i'', so this link is also separate from the old prepared targets. It is an original Haar link in the ordinary raw average. Solve the prescribed row in this link, keeping its two endpoint blocks and all weights that read the solved link in the joint integral. Distinct rows have private middle links. The row kernel has mass at most $2L^9 + 1$ per prescribed target, uniformly with the exterior stock fixed. Each such row still reads the old exterior in its outside endpoint block.

There is another choice of link for rows that cross the outer face of the old rectangular component. The middle link can now be in the test read, since the lift uses links meeting that component. Orient the row outward and choose an axial link on the part of the straight path strictly in the outside endpoint block. Take it beyond the test pad and before or at the outside coarse centre. The choice is available for large L and for the complete face carriers in the raw buffer, disjoint from other marked charts. This link also has original Haar measure.

The carried positive density cubes in the outer collar supply the regularity for this second choice. At the face their tested enlargements cover the two endpoint blocks, including the full averaging reads of the top plaquettes there. Thus the top defects on the double block are at most $C\varepsilon_i$, also on a failing extendibility branch. Choose a rooted tree of the double block avoiding the chosen link. The small-plaquette estimate puts every admitted field into a log ball of radius $C_L\varepsilon_i$ in this gauge, which depends only on the other links. At the vacuum the derivative of the logarithm of the row in the chosen link is $m\mathbf{1}$, with $m \ge L^{-3}$. Indeed, the L starts on the straight axis in the contour formula each contribute the link once in the positive direction. The off-axis starts can read it only on the reversed contour in the outside block, also in the positive direction. Regularity of (1.28) gives derivative distance at most $m/2$ from $m\mathbf{1}$ on a small convex log ball. There is at most one inverse there, with Haar density bounded by C_L.

An outside endpoint block of a face-crossing row has only one neighboring block in the aligned rectangle. Distinct such rows therefore use different outside blocks, and none reads the chosen link of another. First use the private middle-link kernels for the inner-face rows, conditional on all

the outer-face links. The outer-face rows do not read those middle links. Then use the outer-face inverses, with all retained factors evaluated at the solved links. The resulting bound has the same $Cn_e\vartheta$ from the exterior stock, with the product of the row constants in the reference bound. Those constants are charged to the number of prescribed rows. Other affected targets must be integrated or have their own inverse estimate with the test stock held fixed. In particular a row wholly in the exterior can constrain the quotient links. Its site-gauge variables give another case in which the band estimate applies.

For the final density test there is also an outside-pivot construction relative to its complete fourfold read S. Take a rectangle S aligned with the next averaging blocks. A prescribed row crossing its face has a straight-axis link strictly in the outside endpoint block, beyond S and before the outer centre. Use that link as its pivot when it remains in the raw Haar stock. The six-cell inset leaves the complete double block inside the component. The physical field on the final reference support has top plaquette defects at most $C(M)\varepsilon_i$ there. The tree avoiding this link therefore gives the same small regular inverse ball as in the outer-face argument, with constants depending on L, M. Different face-crossing rows use different outside blocks. Solving them consumes no link of the test read. Other rows reading these pivots must have their targets integrated or be solved in a compatible inverse order. A row whose whole double block lies inside S has no outside pivot of this kind.

In the rooted exterior tree coordinates write the actual exterior field as $V(b) = g_{b_-}^{-1}\widehat{V}(b)g_{b_+}$, where $\widehat{V}$ is the tree-gauged field. The change separates product Haar on the non-tree links and on the nonroot site gauges. The extendibility infimum depends only on $\widehat{V}$, since a site gauge extends to the trial fields over the inner box. Suppose the remaining prescribed rows have their full double blocks in the exterior stock and form a forest of coarse bonds. Choose a root for each tree, using the fixed root of the exterior gauge if the tree contains it. Take the nonroot coarse sites to have their full fine link stars in the free stock. By covariance each prescribed value is

$$W(c) = g_{c_-}^{-1}\mathcal{M}(\widehat{V})(c)g_{c_+}.$$

For fixed quotient links and fixed root gauges solve the rows in the child gauges, starting at the roots. The conditional Haar factor is one for each solved row. Substitute the gauges in all remaining reads before applying the reference bound. This keeps the full quotient Haar integral for the band. The previous face-row inverses, if needed, can be taken first with these gauges fixed, since the forest rows read none of their pivots. This forest calculation also applies to the final density read on a physical stock with these free site gauges. A reference tree delta still present before classification must be included in the joint gauge calculation with the prescribed rows. Its removal after a successful class test does not supply the gauge variables for the preceding decision. On an already ungauged stock the plaquette norms are gauge invariant, so at fixed quotient links the values prescribed on a forest change the solved site gauges and leave the test value unchanged. The children must have their complete link stars in the free stock. If the prescribed graph has cycles, solving a spanning forest leaves a constraint on the ordered product of the quotient row values around each fundamental cycle. That product must equal the product of the prescribed values conjugated by the root gauge. The remaining estimate is on these constrained quotient coordinates.

Some of the remaining cycle constraints can be treated together. Use the same forest and give each nonforest row its private fine middle link. The exterior tree can avoid all these links. A transverse plaquette detour replaces each forbidden link in an exterior path by a nonmiddle crossing and two within-block links. The root paths still have length $O(D)$. Thus the near-minimizing trial estimate in this tree again gives the log radius $r = CD^2\varepsilon_i$.

Let x denote the non-tree exterior logs apart from the selected pivots. For a coarse vertex v, let $A_v(x)$ be the ordered product of the quotient row values from its forest root to v, and T_v the product of the prescribed values on that path. If the root gauge is g_0, the solved gauge at v is

$A_v(x)^{-1}g_0T_v$. The remaining equation for a row c from v to w is therefore

$$\mathcal{M}(\widehat{V})(c) = A_v(x)^{-1}Z_cA_w(x), \qquad Z_c = g_0T_vW(c)T_w^{-1}g_0^{-1}.$$

The forest paths read none of the selected pivots. Each remaining row reads only its own pivot from this stock. Thus the inverse in all these links is diagonal even when the forest paths overlap. At the vacuum the single-row pivot derivative is $L^{-3}\mathbf{1}$ in the oriented log coordinates by (1.31). The regular one-row chart gives a unique inverse $p_c = P_c(x)$ with conditional Haar density bounded by C_L per row on the near-band chart. In taking the radial integral keep the prescribed values and root gauges fixed.

Write ℓ_* for one plus the greatest sum of the two forest path lengths used by any such row. The geometry gives $\ell_* \le CD^4$. On the near-band chart $|Z_c - \mathbf{1}| \le C_L\ell_*r$. On a complex radial disc of radius $c_L/(\ell_*r)$, the forest products stay in a fixed small ball by the product estimate. The target of each one-row inverse stays in its regular ball at weak coupling. Cauchy's estimate on this disc gives, for $0 \le u \le 1$,

$$|P_c(ux) - uP_c(x)| \le C_L(1-u)(|Z_c - \mathbf{1}| + \ell_*^2r^2).$$

Indeed $P_c(0)$ has size $C_L|Z_c - \mathbf{1}|$. The linear part cancels, and the terms of degree at least two cost $C_L(1-u)\ell_*^2r^2$.

To compare two radii on this graph, scale a near-minimizing trial at the larger radius, then correct all its selected exterior pivots to their values at the smaller radius. The corrections are to the non-tree links in the fixed chart. Their lifted data and their reduced data use the full local carriers of the corrected links. For pivots whose target products satisfy $|Z_c - \mathbf{1}| \le c_L\varepsilon_i$ use the unweighted normalized response bound. For the others suppose the complete carriers are in the middle of the two-cell outer density collar, a distance $d_0 \ge cM\check{R}_i$ from all tested stencils. In eq. 3.mlxvii use the weight given by distance to the union of their carriers. This gives a normalized curvature response bounded by Ce^{-cd_0} times the supremum of their corrections. Including the curvature scaling error of the trial itself, the extra term in the radial inequality is bounded by

$$C_L(1-u)\big[c_L\varepsilon_i + \ell_*^2r^2 + e^{-cd_0}(\ell_*r + \ell_*^2r^2)\big].$$

The terms containing r^2 are $o(\varepsilon_i)$ by the logarithmic class size. The screened term linear in r is also $o(\varepsilon_i)$, since $\ell_*D^2e^{-cd_0}$ tends to zero. Choose c_L small so the total coefficient of $1-u$ is below $\lambda/4$. The earlier logarithmic radial diameter bound applies to x. The product of the one-row inverse bounds is charged to the number of prescribed rows, and the band still contributes $Cn_e\vartheta$. For a nonscreened pivot at a general target product one must control the curvature produced by its offset on the constrained exterior chart.

For a final test it suffices to screen the pivots from the actual tested stencils. With $r = CD^2\varepsilon_i$, the required bound on the linear offset is

$$C_Le^{-cd_0}\ell_*D^2 \le c_0.$$

Since $\ell_* \le CD^4$, a sufficiently large multiple of $\log(2+D)$ for d_0 suffices. The outer part of the fourfold test box can provide this clearance to its tested first enlargement. Use the complete lifted pivot carriers in measuring that distance.

There is a sufficient rule for choosing the forest in the screened case. Declare a prescribed edge near when the complete lifted carrier of its available private pivot is within d_0 of the tested stencils. If those edges form a forest, extend it to a spanning forest of the prescribed graph. Every remaining chord then has a far pivot, so its cycle-product offset enters only through the screened carriers above. The forest rows are solved in the site gauges. The criterion uses the whole pivot carrier, including its double block and induced outward rows. A cycle among the near edges leaves a near chord under every choice of forest, and its invariant target product remains in the centre comparison.

To compare the two cutoffs on this chart, take the same prescribed graph, forest and exterior tree at the common top level. Use the same remaining quotient links in the two reference integrals.

The row maps at levels i and $h = i + 1$ have the same double blocks at matched depths. The forest products $A_v(x)$ therefore agree. Different prescribed forest values change only the solved site gauges. The test infimum is invariant under those gauges. For the remaining rows the only prescribed values entering the quotient graph are the root-conjugated cycle products Z_c. If these agree, so do the solved quotient links. This also treats prescribed forests, for which there are no cycle products. If the two prescribed fields are related by coarse site gauges u_v, their path products satisfy $T_v^\flat = u_0 T_v^\sharp u_v^{-1}$. Choose the root of the exterior tree at a fine site outside the prescribed graph. Pair the free forest root gauges by $g_0^\flat = g_0^\sharp u_0^{-1}$. This preserves their Haar measures and gives equal Z_c on all remaining rows. For the test read alone the two prescribed forests may even differ, provided their site gauges are free on the same exterior stock. Each forest removes only its own gauge coordinates, so the test uses the same quotient field in the two integrals. The same observation applies to additional branches attached to a common cyclic part at one vertex each. Such branches leave its cycle products unchanged. Use the reference bound of each graph for its other factors.

For unequal products compare the two one-row inverses at fixed x. The targets differ by $A_v(x)^{-1}(Z_c^\sharp - Z_c^\flat)A_w(x)$. On the common regular ball the difference of the solved log links is at most $C_L|Z_c^\sharp - Z_c^\flat|$. At fixed root gauges the difference of the products is bounded by the sum of the prescribed row differences along the two forest paths and the remaining row. This follows by telescoping products of real unitary matrices in a common root frame. The regular Haar inverse density for such a row is the same function of x and Z_c at both cutoffs. Its logarithm is Lipschitz in the solved log link on the fixed regular ball, by the determinant formula and the local inverse bound. Thus the absolute log ratio of these row factors is at most $C_L \sum_c |Z_c^\sharp - Z_c^\flat|$. In particular these factors agree for equal products.

Write b_{near} for the maximum product difference on the unscreened rows and b_{far} for the maximum on the screened rows. The other exterior links agree on the quotient graph. Transfer a near-minimizing trial from the passing side by keeping its free interior links and replacing the exterior pivots by those of the other graph. First compare the two lifts at the original trial, then replace the pivots in the other lift. The pointwise comparison at the original trial and the unweighted and weighted response bounds on the two sets of pivot carriers give an increase of at most

$$d = CD\varepsilon_i\,\eta^{\min(\alpha,\beta_H)} + C_L(b_{\mathrm{near}} + e^{-cd_0}b_{\mathrm{far}}).$$

Here the changed data must stay in the common regular ball. If one test passes and the other fails, the failing infimum is at most the passing infimum plus d. Consequently both infima are within d of λ. It suffices to use the band of the reference graph on the remaining quotient stock. When $d/\lambda \le 1/4$ and the radial bound applies to this graph, the factor is $Cn_{\mathrm{e}}d/\lambda$ in the common reference majorant. The inverse row densities remain in that majorant. A geometric bound in the bare mesh uses a mesh-small product discrepancy in the normalized width d/λ. The reference graph's prescribed cycle products must be fixed at this stage, as in the fixed-output convention for the compatible evaluation supremum. The other graph can vary there if the comparison by d is uniform. The reference band is then independent of that evaluation. Integrate it at fixed reference root gauges, and then integrate those gauges against Haar.

Replacing the sharp tests by Lipschitz functions allows pointwise telescoping, with a separate estimate for the modified one-run operation. The marked remainders and hence the tuned coordinates in that argument belong to the modified recursion.

Calibration maps and their admitted cocycle. For the same bare integral let $C_a(\beta)$ and $C_b(\beta)$ be two actual terminal-coupling coordinates, on domains where the branches are holomorphic and invertible. Define

$$H_{ab} = C_b \circ C_a^{-1}. \tag{A.cix}$$

On an admitted common domain with the same bare branch, one has

$$H_{bc} \circ H_{ab} = H_{ac}, \qquad H'_{ab}(x) = \frac{C'_b(\beta)}{C'_a(\beta)}, \qquad \beta = C_a^{-1}(x). \tag{A.cx}$$

These follow by composition and the chain rule. Every intermediate inverse must be the admitted branch. Geometric overlap of two complex discs does not establish that fact.

Moreover $|H_{ab}(x) - x| = |C_b(\beta) - C_a(\beta)|$. This is the actual calibration discrepancy to estimate. Equality after a change of physical units does not bound it. If the two presentations are known to represent the same bare integral on an admitted real open overlap, their holomorphic identities extend from that overlap by the identity theorem. The real admission is an input, as in the flow section.

Typed closure is a family of finite-grade estimates. A nonscalar insertion must come with its own gauge-covariant source core, counter-insertions, and tensor readout. At finite grade, label every source monomial and all cross terms created by the actual finite map. If several directions share one potential or zone reserve, their joint radii obey eq. A.xcix, with the multi-direction cost following it. A scalar α^2 gain is not copied into another channel without its own field-degree and counter-insertion calculation.

Parity proves eq. A.c only for the actually admitted unmarked family. Its one-loop coefficient in eq. A.ci, the marked corrections, and the finite-grade closure still have to be computed for that channel. For the optional anisotropy Ward route an estimate of size $K^{-c_*}(\log K)^A$ multiplied by $g_0^{-1} \asymp K^{1/2}$ tends to zero from this bound if $c_* > 1/2$. At equality the logarithmic factor must itself tend to zero; a mere bounded-power estimate does not settle it. A fixed-torus estimate does not give a growing-volume Ward limit unless its volume factors are controlled at that rate.

The outstanding weighted task is therefore the actual finite-map extension with the weights in eq. A.lxxxvi, not just ordinary source holomorphy. The outstanding zone task is the complete incidence and original-weight reserve in eq. A.xcvii–eq. A.xcix. The matched task is the actual common-domain generator estimate in eq. A.civ–eq. A.cv, with its summable or direct two-cutoff error. Typed closure requires these assertions at the stated finite grade. These are separate optional routes; the estimates they require are not additional hypotheses of the ordinary scalar angular argument.

Appendix B. Index of notation and conventions

The table gives the principal notation and links to its definitions.

Notation	Meaning	Definition
$\mu_e, q(e), \nu_G$	Zero-source conditional law, clean conditional probability, and exterior-preserving clean resampling.	eq. 6.l; eq. 6.lii; Prop. 6.11
$d_S, b_n(D)$	Weighted exceptional mixed moment and its connected-error polynomial.	eq. 6.lvii; eq. 6.lxiv
A_B	Mixed source derivative of the complete effective action.	eq. 6.xc
$\alpha, L(A)$	Complete residual oscillation and Gaussian quadratic coefficient size.	eq. 6.clxvii; eq. 6.clxxiii
$\mathsf{D}_\eta, \mathcal{B}_{\omega,\chi}$	Lattice displacement vector field and its exact shell flux.	eq. 6.ccclxviii; eq. 6.ccclxxxviii
Lattices, fields, and action		
$G, \mathfrak{g}, N, d_G$	$G = \mathrm{SU}(2)$, $N = 2$, and $d_G = N^2 - 1 = 3$; Hermitian traceless matrices with $\langle X, Y\rangle = \frac{1}{2}\operatorname{tr}(XY)$.	gauge convention; appendix A.3

Notation	Meaning	Definition
L, M	Odd blocking integer $L > 1$ and localization cube side M. The rooted-source construction takes $M = L^{m_0}$ and compatible tori $\ell = 2L^m$.	localization cubes; eq. 5.cdxlvi
K, j, s, a_s, η_j	Cutoff depth K, level j, remaining depth $s = K - j$, physical spacing $a_s = L^{-s}$, and bare spacing $\eta_j = L^{-j}$ in level-j units.	level and depth; gauge convention
$\Lambda_{K,\ell}, \mathbb{T}^{(j)}$	Finite torus lattice $(L^{-K}\mathbb{Z}/\ell\mathbb{Z})^4$ and the lattice retained after j blockings.	lattice units; gauge convention
$U_b, U_p, \partial U$	Bond variable, ordered plaquette transport, and its alternate notation. Reversal gives $U_{\bar{b}} = U_b^{-1}$.	bond fields; gauge convention
$a_p, A(w,U), \beta$	Plaquette action $1 - \frac{1}{2}\,\mathrm{Re}\,\mathrm{tr}\,U_p$, weighted action $\sum_p w(x(p))a_p$, and bare inverse coupling $\beta = g_0^{-2}$.	action and sources; first passage
$\mathcal{O}(f), S_n^T$	Smeared action density $\sum_p f(x(p))a_p$ and its joint cumulants. No spacing prefactor occurs in $\mathcal{O}$.	observables; action and sources
Averages and propagators		
$\mathcal{M}, Q_k, Q_k^\sharp$	Contour block average, linearization of its plain iterate, and straightened linearization after removal of the coarse gauge factor.	eq. 2.iv; iterated averages
Q_k^{st}, Q'_k	Straight covariant bond average and site-function average.	iterated averages
$\mathrm{d}_0, \mathrm{d}_1, \mathrm{d}_\eta$	Unscaled scalar difference, plaquette coboundary, and physical difference; in the scalar block convention $\mathrm{d}_0 = \eta\mathrm{d}_\eta$.	block inner products; curvature kernels
$Q, P, \mathcal{A}, G'$	Scalar arithmetic mean, block-constant projection $P = Q^*Q$, operator $\mathcal{A} = \mathrm{d}_\eta^*\mathrm{d}_\eta + P$, and inverse $G' = \mathcal{A}^{-1}$.	block mean; scalar operator; scalar projection
$R, \mathbf{R}, R^{(j)}$	Scalar orthogonal projection onto $\ker(QG')$, large-field operation, and local remainder family, respectively.	scalar projection; § 4.17; activity families
$P_{\mathrm{ex}}, K, \mathsf{K}$	Projection onto exact lattice two-forms and continuum curvature covariance at unit coupling. The physical lattice kernel is $a^{-4}P_{\mathrm{ex}}(p,q)$.	curvature kernels; appendix A.3
$U_j(V), \mathsf{G}, \mathsf{H}$	Constrained regular background, constrained inverse, and response operator, with the gauges and domains specified in the background hypotheses.	background orbit; background operators
$\Phi_\Lambda(B), r_B$ Z_y	Potential/current background on the datum ball $\sup_c \lvert B(c)\rvert < r_B$ and local output $Z_y = (\xi_y H, \xi_y^2 \nabla H, \xi_y^3 J)$.	eq. 4.xxv; eq. 4.xxvi
Couplings and sources		
x_j, g_j, b_j	Running inverse coupling $x_j = x_{j-1} - b_j$, $x_0 = \beta$, and coupling $g_j = x_j^{-1/2}$.	flow recursion; frames and tests
c_0, b_j^0	Leading drift c_0 and designated one-loop increment b_j^0. The numerical flow theorem assumes an interval-sum law for these increments.	flow recursion; eq. A.lxvii
$\theta_j, \bar{g}_j, x_j^\natural$	Auxiliary frame, its coupling $\bar{g}_j = \theta_j^{-1/2}$, and inverse coupling computed with auxiliary choices frozen at $\theta_j = g^{-2} + c_0(K-j)$.	frames and tests; frozen coupling
$K(\beta, g)$ $\mathcal{W}_K(g)$	First entry into $g^{-2} < x_K \le g^{-2} + B_\sharp$ and the set of bare couplings with this stopping index.	first passage

Notation	Meaning	Definition
w, c, z, f_i	Source triple with function $w = c + \sum_i z_i f_i$ on each fixed finite real test family.	source triple
$\|\cdot\|_{\sharp,s}, \|\cdot\|_{\flat,s}$ $\mathcal{W}_r^{(s)}$	Test norm $\max(\|f\|_\infty, c_M L^{-s} \operatorname{Lip} f)$, source-triple norm $\|c\| + \sum_i \|z_i\| \|f_i\|_{\sharp,s}$, and its open radius-$r$ ball.	source norms
$h_y^{(j)}, \varphi_j, \zeta_j$	Anchor partition, fixed coupling profile, and running source shift defined by the exact counterterm identity.	source profiles
ϱ, ρ $\alpha_{0,j}, \alpha_{1,j}$	Source or coupling-disc radii in the stated estimate and complex field radii. Their meanings are local to that estimate.	source triple; frames and tests; eq. 2.v
$p_0, \check{R}_j$ ε_j, δ_j	Deposit scale, localization/waiting scale, and curvature and fluctuation thresholds formed from the fixed auxiliary frame.	frames and tests; eq. 2.xx
Local families and histories		
$E^{(j)}, R^{(j)}$ $B^{(j)}$	Regular activities, remainder activities, and boundary activities; pointed families also carry a base point.	activity families; eq. 2.xiv
$\mathsf{b}(E), e_j, \mathcal{E}$	Scalar marginal extractor, local source energy, and its sum. The vacuum constant E has a different role.	eq. 4.xix; local source energies
$d_j(X), \kappa, \kappa_{\mathcal{D}}$	Localization tree length, decay exponent, and domain-counting exponent. Summability requires decay greater than the counting exponent.	tree length; eq. 5.cdxlvi
Ω_j, Λ_j, Z_j	Regular region, buffered inner region, and complement $Z_j = \Lambda_j^c$ in the specified history geometry.	history regions
h, ω	Full history and local history inside a stored operation.	histories; stored operations
Ξ_ω, μ_ω Φ_ω, Ψ_ω	Stored integration space, positive reference measure, exponent, and excess source exponent. The integration domains and evaluation fibers are part of the construction.	eq. 2.xxv; eq. 5.xiv; excess source exponent
$\Theta^{(k)}, q_a, \Sigma_k$	History deposit/volume mark, age-survival rate $q_a = e^{-c_a}$, and integrated aged load.	eq. 2.xxx; survival rate; aged load
$\mathfrak{C}_k, \mathcal{U}_j^c$	Class of complete presentations and complex pair domain. The current in a pair is an independent coordinate.	presentations; eq. 2.v
$\mathcal{G}_z, \mathcal{K}_z, A_z$	Complete pointed total, its response-composed Hessian, and midpoint tent action for the same member.	eq. 4.ii; eq. 4.iv; eq. 4.xxi
$\rho, \sigma, a, a_{\text{out}}$ (window)	Field-radius ratio $\rho = a_{\text{out}}/a \geq 1$, scale ratio σ, member radius, and output radius.	eq. 4.xxix
$\tau_S(w), N$ (history sum)	Complex label measures, positive at zero, and the site count in the ordinary stability criterion.	eq. 5.cdxxiii
$E(z), E_{\ell,K}, A_K$ (transfer)	Common cell normalizer, finite-torus vacuum constant, and companion vacuum density used in the finite-reference route.	eq. 6.iv; eq. 6.vii; eq. 6.viii
Limits and reconstruction		

Notation	Meaning	Definition
$\mathfrak{T}_{\mathbb{E}}(\mathsf{d};\vartheta)$ $\mathfrak{T}^{(4)}_{\mathbb{E}}(\mathsf{d};\vartheta)$	Positive test pairs with quantitative mass and Lipschitz bounds, and quadruples whose pairs belong to this class, with small supports around collinear centres.	positive test pairs; four-point tests
$\mathfrak{S},\sigma$	Separated compact test tuples, including the empty tuple, and their moment functional, extended to finite linear combinations.	separated tests; moment functional
$\mathsf{d}(X)$	Minimum distance between distinct test supports; support-containing balls do not define this distance.	separated tests
σ_S,σ^0	Canonical centered functional: the partition sum over blocks of size at least two, with empty value one and singleton value zero.	centered functional; eq. 5.cdlxxv
$\mathcal{S}_{\neq},\lvert\varphi\rvert_k$	Schwartz tests flat with all derivatives on every coincidence diagonal, and the weighted derivative seminorm, written $p_k(\varphi)$ in the extension proof.	diagonal-flat space; eq. 5.cdlxxix
$m(X),X^+$	Minimum cubical tree-edge count and the fixed-layer source-dependence enlargement in the rooted geometry.	eq. 5.cdxlvi; eq. 5.cdxlvii
$k,B(R)$	Factorial exponent and support-radius factor in the graded all-state estimate; one may take $B(R)=C(R+1)^4$.	Prop. 5.76
$k_{\mathrm{E}},\kappa_{\mathrm{E}}$	Diagonal-flat extension exponents; the quantitative theorem permits $k_{\mathrm{E}}=20$ and $\kappa_{\mathrm{E}}=k+32$.	Prop. 5.78
$\mathsf{p},\wp$	Uniform insertion exponent and analytic plate-density exponent $\wp=\mathsf{p}+5$.	Prop. 6.23; Prop. 6.24
$G_{\varphi,\psi},\mu_\varphi$ Γ_φ,L_s	Transversely smeared planar kernel, positive spectral measure, Laplace norm, and spectral boost.	eq. 6.cccxviii; eq. 6.cccxxi; eq. 6.cccxxii; eq. 6.cccxlvi
$\vartheta_*,u(d),c_m,b_n$	Fixed positive-shape threshold, ultraviolet error function, angular coefficients, and largest nonconstant angular frequency.	eq. 6.cccxxvi; eq. 6.cccxxvii; eq. 6.ccli; harmonic degree
$\mathcal{G}^{\mathrm{tor}}$	Limits of periodically lifted torus measures at fixed spacing and coupling.	torus-limit states; eq. 5.cdlx
$\mathcal{G}_j,\mathcal{E}_j,D_j$	Translation-invariant DLR class, its ergodic states, and the decomposition law of the centering state on those states.	invariant DLR states; ergodic decomposition
$\mathcal{I},\mathrm{Pl}_\nu$ $\mathcal{N}_{\nu,r}$	Invariant sigma-field, conditional-expectation plateau pairing, and reflected size in the lattice plateau estimate.	plateau quantities; Prop. A.12
$\mathsf{X},\lambda,\sigma_\xi$	Compact support of the phase-coordinate law, that probability law, and its continuous component evaluations.	phase coordinates
$\theta,\mathcal{H},H,P$ Ω,P_0	Time reflection, Hilbert completion of its positive form, time and momentum generators, empty-tuple vector, and projection onto $\ker H$.	eq. 6.cdxlv; eq. 6.cdxlvii; § 7.8
$\mathfrak{U},\mathfrak{B},W_4$	Ward defect, shell insertion, and signed coordinate permutation group, with the specified covariance and flux conventions.	Ward insertion; eq. 4.xvii

Conventions. Lengths are physical unless a level or local lattice unit is stated. In particular, a_{K-j} and η_j express different unit conventions. An adjoint always uses the stated inner products on both spaces.

Constants may depend on fixed geometric and analytic parameters. The stated parameter dependence and uniformity are part of each estimate. A radius used for coefficient extraction is the radius in that estimate.

Concatenation of test tuples is used only when the resulting supports remain separated. Centering changes the first cumulant and leaves higher cumulants unchanged. Two-state moments retain the stated centering state.

The letters K, R, P, ρ, N have several local uses, distinguished above by their arguments and spaces. The window exponent is a local Hölder exponent; it is independent of the field analyticity radii.

In the usual Wilson coupling convention, $\beta = 2N/g_{\mathrm{std}}^2$. All logarithms are natural. Near-identity group logarithms use the branches specified in the defining chart. A pair current is independent of its field coordinate unless the pair is explicitly restricted to a background graph. Each use of a construction retains its stated existence, domain, and uniformity hypotheses.

Analytic operators and domains. The following symbols refer to the constructions in the analytic estimates. Their transposes use the physical measures unless a counting normalization is displayed.

Notation	Meaning	Definition
$Y, Y^{\flat}, Z$	Balanced first-order site space, its source space under pairing with $\ell^2 u$, and the site second-difference energy space.	eq. 3.cmxxix.
$\mathcal{A}_\alpha, \mathcal{F}_p$	Strong field space and normalized finite-p force space. A cell force has norm $\xi^{3-4/p}\|f\|_p$.	eq. 3.dccclxxxvii; eq. 3.mclxxxiii.
$\widehat{F}, \widehat{M}$	Site columns and their positive Gram matrix in counting top coordinates; the column injection is $q^{\sharp}\Xi^{-4}$.	eq. 3.cmxcv.
Λ, S, Π_U	Linear gauge restoration, its complement $S = 1 - D\Lambda$, and the selected finite gauge chain with derivative S.	eq. 3.mcxxxix; eq. 3.mcxlii.
G_F, G_0, G, G_1	Positive field primitive, projected zero-current inverse, first current inverse, and second current inverse.	eq. 3.cmxcix; eq. 3.miii; eq. 3.mxiii.
G_0^a, G^a, H^a; ω^a, G_1^a, H_1^a	Weighted canonical inverses and lifts. The multiplier is $(H^a)^{\sharp}J$, formed before the second inverse. Their auxiliary field output has two finite-p differences.	eq. 3.mcccclxxxiii; eq. 3.mcccclxxxiv; eq. 3.mcccclxxxv; eq. 3.mcccclxxxvi.
H, H_1, ω_*	First and second row lifts, and the multiplier readout $H^{\sharp}J$. The readout uses the first lift.	eq. 3.mvii; eq. 3.mxiv; eq. 3.mix.
K_4, G_4, M_4	Fourth-order site precision, its inverse, and the counting coarse matrix qG_4q^*. They give a new strong family for G_sR.	eq. 3.mclxv; eq. 3.mclxxvii; eq. 3.mclxxx.
$\mathcal{S}_\alpha, Y^{2,\alpha}$	Fourth-order source class $\Delta C_2^\alpha + D^{\sharp}L_3^\infty + L_4^\infty$ and its strong site output space.	eq. 3.mclxix; eq. 3.mxxiv.
$\mathcal{L}_{U,J}, A(b), C(B)$	Selected auxiliary action, its constrained potential, and its finite gauge completion. The potential has $D_bA(0) = H_1$; the literal completion has $D_BC(0) = SH_1Db_U(0)$.	eq. 3.mcxlviii; eq. 3.mclii; eq. 3.mcliv.

Notation	Meaning	Definition
$\Gamma_P, K_\tau(P)$	Mass-subtracted coarse form and its outer plain-constraint precision, including the multiplier times the second chart derivative.	eq. 5.cclix.
$\mathcal{W}_p, \mathcal{L}_{0,a}$	Field norm with two physical L^p differences, and the full weighted trial saddle. The principal perturbation acts from $\mathcal{W}_p$ to $\mathcal{F}_p$.	eq. 3.mcccli; eq. 3.mcccliv; eq. 3.mccclvii.
$M_{\mathrm{c}}, M_{\mathrm{G}}, M_{\mathrm{h}}$	Carrier cube size, Gaussian parameter cube size, and a prescribed history cube size. Their separation requirements are stated at their respective uses.	eq. 3.cmlxxxvii; eq. 5.cclxix.
$D_W(s), R_W(s)$	Local Gaussian covariance and its root. At complete parameters they give the actual matrix marginal.	eq. 5.cclxxi; eq. 5.cclxxii.
$p_j^{\mathrm{lit}}, \mathsf{p}_j$	Literal intermediate mean of the physical critical orbit. Its raw bond amplitude is bounded by C/L times the output amplitude.	eq. 3.mcccvi; eq. 4.cccxcii.
$e_{s,z}, T_{i,k}$	Original fine-plaquette action pointing and complete physical transport with exact hat refinement.	eq. 4.ccclviii; eq. 4.cdxvii.
$\mathfrak{H}_{r,\kappa,\gamma_{\mathrm{per}}}$	Compatible pointed interaction space: fixed analytic radius, carrier decay and finite-period tail bound.	eq. 4.ccclxxxviii.
$\mathbf{F}_j(x,h), N_j$	Vacuum-subtracted formation map and physical Gaussian logarithm in the literal regular step. N_j is independent of x, h.	eq. 4.cdxiv; eq. 4.cdv.
$\mathcal{B}_{j,e}$	Complete rooted sphere family: the moving-centre logarithmic weight jet minus the fixed-kernel jet. Its six curvature readouts vanish.	eq. 4.cdxxxix; Cor. 4.55.
$\widetilde{\beta}_a^{\mu\nu}(z)$	Weighted massive Wilson coefficient in one plane, with vector regulator $z\mathsf{A}$ before congruence.	eq. 5.cli; eq. 5.clii.
$x_j, h_j, \|\cdot\|_{j,*}$	Tuned coupling, zero-readout regular profile, and horizon-adapted profile norm.	eq. 5.cccxxi; eq. 5.cccxvi.
$P_{j\ell}, U_{ji}, B^+, K^+$	Backward scalar and forward profile propagators of the mixed-end linear response, with positive majorizing kernels.	eq. 5.cccxliii; eq. 5.cccxlv.
$T_N, O_N, \nu_{N,t}$	Bare tuned scalar insertion, its nonconstant conditional coarse image, and the capped regular terminal law.	eq. 5.ccclxxxi; eq. 5.ccclxxviii.
$\delta\alpha_N, \psi_N$	Bare tuning with its value at the reference endpoint subtracted, and its local inverse in the bare scalar source. Neither subtracts a random field.	Lem. 5.60 and Cor. 5.62.

B.1. **Proof references.** The table locates the component arguments. Each result is used with the hypotheses stated at its cited location.

Proof task	Arguments and precise references
Projected Landau inverse	Local gauge regularity in § 3.16; the all-mesh projected gap and actual-slice saddle inverse in § 3.17; curvature-only periodic localization in § 3.18.

Proof task	Arguments and precise references
Normalized interacting extraction	Positive history aggregation, weighted exceptional moments and exterior cumulants in § 6.4; mixed source derivatives in § 6.5; the complete-oscillation Gaussian criterion in § 6.7.
Four-point and Ward calculations	Quantitative free-kernel signs and shape comparison in § 6.8; exact Haar divergence and contact terms in § 6.14; off-shell invariant classification and the weighted smooth Wilson expansion in § 6.15.
Averaging and the flat reference	Pivot coordinates, the contour-gauge gap, bounded lifts, and exponential kernels: §§ 3.3 to 3.6.
First constrained background	Nonflat first-step precision, the regular critical orbit, and the relative-current extension: §§ 3.7, 3.8 and 3.10.
Multiscale backgrounds	Pairings, core domains, hierarchy identities, nonlinear responses, and local Hölder estimates: §§ 3.9, 3.11, 3.14 and 3.15. Layered precision is treated in § 3.13.
Local interactions	The member's quadratic counterterm is given by eq. 4.xix and eq. 4.xxiv. The nonlinear window estimate is Prop. 4.5; insertion and the source bootstrap are Props. 4.8 and 4.10.
Histories and stability	History counting and mass estimates: § 4.18. The ordinary stability upper bound and positive floor are eq. 5.cdxxvi and eq. 5.cdxxviii, under their respective hypotheses.
Flow and coupling comparison	First-passage arithmetic: § 5.1. Joint-source comparison and the terminal coupling limit: Lem. A.14 and Prop. A.15. Weighted comparison domains: appendix A.9.
States and continuum limits	Periodic-state mirror positivity: Prop. A.11. Common state normalizers and factorial moment bounds: Props. 5.75 and 5.76. Subsequence compactness and flat-test extension: Props. 5.77 and 5.78.
Free and interacting two-point functions	The free-kernel estimate is eq. A.iii. Conditional covariance and Gaussian cutoff calculations are in §§ 6.3 and 6.6; the extraction and common-normalizer transfer estimates are in § 6.2.
Insertions and rotations	Uniform insertion, plate density, the planar kernel, and harmonic elimination: Props. 6.23 to 6.26 and § 6.11.
Fields and operator domains	Energy-band fields: § 7.2. The matched scalar reconstruction is Prop. 7.6; its representation domains are in § 7.5.
Phases and spectra	The conditional probability kernel is Prop. 7.7. Phase coordinates, the vacuum space, and the scalar direct integral are treated in §§ 7.7 to 7.9.
Gauge observables	The cutoff orbit coordinates and continuum extension criteria are in §§ 7.11 and 7.13. The scalar observable information is characterized in § 7.12.

B.2. **References for the analytic constructions.** These references distinguish the completed operators from their local coefficient families, and the regular step from its complementary history operations. Each construction retains its stated reference, geometry and parameter domain.

Construction	Proof and scope
Strong response at an independent current	The actual Wilson stencil, finite-p bootstrap and current adjoints are in §§ 3.25 and 3.26. The completed strong estimates do not require DJ.
Local positive inverses	Prop. 3.102 uses genuine Dirichlet compressions, slow cutoffs and full geometry carriers. The positive coarse inverse is Prop. 3.103.
Named current families	Prop. 3.112 constructs $G_0, G, H, \omega_*, G_1, H_1$ in that order, with normalized physical row transposes. It retains the bare current readout separately.
Strong restoration coefficients	Props. 3.154, 3.159 and 3.160 prove the fourth-order realization, its exact G_sR identity and its new $C^{2,\alpha}$ coefficient family.

Construction	Proof and scope
Strong saddle coefficients	Prop. 3.163 uses the finite-p force classes and the strong restoration. Its current ceiling may shrink with the fixed Hölder exponent and carrier rate.
Nonlinear current germ	Props. 3.149 to 3.151 give the selected auxiliary action, its physical matching and its current update. The H_1, SH_1 and literal datum jets are distinct.
All-degree nonlinear coefficients	Props. 3.167 to 3.169 give the convergent connected tree series for that selected germ, including joint base and datum variables. Local-data suprema precede all carrier sums.
Weighted connected germ	Props. 3.205, 3.207 and 3.208 construct the weighted principal and current inversions before the actual nonlinear tree series. Prop. 3.209 identifies its admitted physical curvature-atlas branch.
Actual hierarchical row density	Prop. 3.187 computes the one-step second jet and the full chain sum. Uniformity in depth does not make the nonlinear radius independent of L.
Homogeneous critical fields	Prop. 3.183 constructs the physical orbit. Flat reference descent is Prop. 3.192; Prop. 3.120 also allows a current-regular trial.
Curvature-only homogeneous data	Props. 3.193 and 3.194 construct the trial from a smooth quaternionic bundle, then correct its actual mean and current. The atlas allows large coarse holonomies and nontrivial bundle topology.
Weighted physical atlas	Lem. 3.195 and Props. 3.199, 3.201 and 3.202 retain two L^p differences before perturbing the principal part. The physical gap includes both constraint curvatures and the row-mass subtraction.
Outer nonflat Gaussian	Props. 5.41 and 5.42 prove the real physical gap and the canonical local Gaussian extension near that reference, retaining the mass subtraction and chart curvature.
Cutoff covariance	Prop. 4.25 uses the middle crossing pivots and real colour-ball cutoff. It proves covariance of the actual regular integral before pointing or filing.
Physical irrelevance	Prop. 4.36 uses the literal intermediate field, complete Ward cancellation, block interpolation and explicit finite-period tails. Individual local pieces need not be invariant.
Fixed-radius formation	Prop. 4.46 and Cors. 4.47 and 4.48 admit the old interaction on its own ball, prove the coupling and profile slopes, and close one regular step on the common radius.
Fixed-kernel stress response	Prop. 4.54 and Cor. 4.55 compare the moving weight jet with the fixed kernel by a normalized rooted sphere family. Prop. 5.54 uses the corrected profile forcing in its coupling-weighted memory sum.
Actual scalar one-loop limit	The bare Wilson calculation is Prop. 5.9; physical gauge change is eq. 5.civ. The regulator and Taylor-vertex comparisons are §§ 5.7, 5.9 and 5.10.
Diagonal one-loop response	Props. 5.14, 5.47, 5.48 and 5.50 retain the actual weight parameter, its principal-part perturbation, the weighted regulator and its differentiated Gaussian polarization.
Regular tuning	Prop. 5.51 solves the mixed end conditions. eqs. 5.cccxxxi and 5.cccxxxii differentiate one frozen presentation, with constants uniform in the horizon.
Bounded initial irrelevant profiles	Props. 5.52 and 5.53 retune the same finite regular problem. eqs. 5.cccxlvii and 5.ccccliv give the mixed-end inverse and all fixed-order initial-profile jets.

Construction	Proof and scope
Scalar normalization and nonvanishing	Props. 5.55 and 5.59 retain the numerical vacuum derivative before centering and prove a positive variance in the capped regular law. Prop. 5.61 extracts a nondegenerate coarse subsequence at fixed volume and cutoff.
