For a constituent T of the old member the two endpoint differences telescope to $G = T(P^1) - T(P^0)$, where P^0 is the inner endpoint and P^1 the spliced endpoint. Take the comb logarithms B^0, B^1 in the common old box. The cap estimate gives $\|B^0\|_\infty < 1.42\alpha_{3,j}/L$ and

$$\|B^1 - B^0\|_\infty \le \tfrac{1}{2}\alpha_{3,j}e^{-\delta D_v/8}.$$

Here D_v is the old distance of the box read to the cutoff change, and the native near-window geometry gives $D_v \ge ML^{n_0-j}/5$, with n_0 the window level. This is a multiple of M/σ_j when the window levels agree. On the admitted old section use $B^0 + \lambda(B^1 - B^0)$ for $|\lambda| < e^{\delta D_v/8}$. If T has majorant n_v there, its difference from the value at $\lambda = 0$ is bounded by $2n_v$ and vanishes there. Schwarz's estimate at one gives $|G| \le 2n_v e^{-\delta D_v/8}$. On the native removed-parameter disc of radius $r_\square^{\mathrm{rem}}$ this holds for the whole holomorphic difference. Cauchy's inequality gives

$$|\partial_u G(0)| \le 2n_v (r_\square^{\mathrm{rem}})^{-1} e^{-\delta D_v/8}.$$

The same bound applies after integration of the real interpolation parameter. This is a single-run estimate of the combined jet. To use it for the actual brackets, match their two endpoint jets with these capped reads on one admitted old-core section and use their actual removed-parameter radius.

Fine brackets and the resulting formation estimate. We now make the base of an inner bracket explicit. For $j < k$ and one old base point z, let $\square = \square_k(z)$ be its assigned current window and $R_z = X_k'(z)$ its fixed enlarged box. There are only a fixed number of direction-partition windows near this base window. Group their directions by linearity before applying the box-background replacement, and choose R_z to contain their fixed enlargements. In eq. 4.cxlii their sum is the inner cutoff $\zeta_\square$; the remaining directions are outer terms. This is part of the fixed window-first rule. The derivative at zero is linear in these directions, so this grouping preserves the partition identity without changing any incoming pointed member. Let $\mathsf{A}_{j,z}(X, \cdot)$ be the fixed action-family filing

with total $A(h_z^{(j)},\cdot)$, and put $\widetilde{G}_{j,z} = G_{j,z} - b_{j,z}\mathsf{A}_{j,z}$. The one inner window member is the function

$$\mathcal{W}_{j,z}(P') = \sum_{\substack{X\ni z\\ X\subset\square^{\sim 2}}} [\widetilde{G}_{j,z}(X, P^{\mathrm{box}}_{j,z}(P'), z) - \widetilde{G}_{j,z}(X,(1,0),z)]. \tag{4.cliii}$$

Here P' is a local potential/current pair of the current resolved level k, on R_z. The map $P^{\mathrm{box}}_{j,z}$ first forms its actual nonlinear averaged datum and then takes the old-level constrained critical box pair of that datum. The same box-background map is used for every X in this sum. The own tent action is included in the near sum; its fixed support lies inside the assigned enlarged window. The declared domain of this entire member is R_z, and its fine-cube base is $B_z = \mathrm{Hull}_{\pi_k} R_z$. Its number of current fine cubes is bounded by a fixed constant C_{win}, independent of j,k,z. This is a presentation of an inner member before localization; we do not apply different old-X bracket operators to its summands.

Let $\mathcal{W}_{j,z,Y}(s,t,\nu)$ mean this one function evaluated by the assigned local response and the datum in eq. 4.cxlii on $Y \supset B_z$. The inner potential contributed by this member is

$$V^{\mathrm{in}}_{j,z}(Y) = \int_0^1 [\,\partial_\nu \mathcal{W}_{j,z,Y}(\,\cdot\,,t,\nu)|_{\nu=0}]\,[\,Y\setminus B_z \mid B_z\,]\,dt. \tag{4.cliv}$$

The brackets in this formula are linear in the whole function in eq. 4.cliii. Thus its cancellation and bound in eq. 4.cxlviii are established before this single bracket is estimated. Different z's need not have a common base: there is no cancellation between them, and their bounds can be added. Hereditary restriction identifies the bracket on Y with the bracket of the same ambient interpolation function whose parameters outside Y are zero. Finite fundamental theorem of calculus therefore gives, at a complete physical pair,

$$\sum_{Y\supset B_z} V^{\mathrm{in}}_{j,z}(Y;p_W) = \int_0^1 \partial_\nu \mathcal{W}_{j,z,\Lambda}(1,t,\nu;p_W)\big|_{\nu=0}\,dt.$$

Every local term uses only the pair on Y and the input members on its declared domain $B_z \subset Y$. This proves chart-coherent locality and the physical sum identity for this fixed window-first rule. Summing the window identities and the retained outer and removed origins recovers the old action difference. No equality of individual output domains with a different filing is required. The current-level origins $j = k$, and the far and removed origins, retain their own declared bases and the bounds already proved. For vacuum-only near origins the same window-first grouping may be used without a marginal subtraction.

The assigned maps are hereditary on active wall-components, and complete at all parameters equal to one. For an interpolation function Ψ, its bracket is

$$\Psi[K|N] = \int_{[0,1]^K} \prod_{\Delta\in K} \partial_{s_\Delta}\Psi(s_K + 1_N)\,ds_K. \tag{4.clv}$$

For eq. 4.cliv, $K = Y\setminus B_z$, $N = B_z$. For an origin retaining its own base X_0, use $K = Y\setminus X_0$, $N = X_0$. A component carrying a differenced cube and missing the base makes this bracket zero. Each coordinate has the disc $R = e^{\bar\kappa}$, so mixed Cauchy costs $(R-1)^{-|K|} \le e^{-(\bar\kappa-1)|K|}$, with no factorial. The common ν-disc and its one derivative commute with these brackets by joint holomorphy. The preceding amplitude bounds therefore retain this additional spatial factor.

Here is a quantitative rate allocation. For a retained old domain X and its current fine hull X_0, put $m = \#(Y\setminus X_0)$. The actual cube geometry and rooting give a fixed constant C_h such that

$$d_k(Y) \le C_h[d_j(X) + m + 1]. \tag{4.clvi}$$

To see this, view a tree covering X on the old lattice in current units and cover it by current fine cubes. Its hull has a covering tree of length at most $C(d_j(X)+1)$. Each component of the

additional cubes meets that hull, or its bracket vanishes. A rooted spanning forest adds at most a fixed number of edges per additional cube. This proves eq. 4.clvi. For an inner window member the same argument and $\#B_z \le C_{\mathrm{win}}$ give $d_k(Y) \le C_h(m+1)$, increasing C_h by a fixed factor if necessary.

Split the old input rate into positive parts $\kappa_{\mathrm{sum}} + \kappa_{\mathrm{far}} + \kappa_{\mathrm{ret}} \le \kappa$. Choose $\kappa_{\mathrm{sum}} > \kappa_D$ with enough strict gap to sum the fixed polynomial diameter factors, and use κ_{far} for the long-domain tail in eq. 4.cxlvii–eq. 4.clii. The retained old-domain factor is $e^{-\kappa_{\mathrm{ret}} d_j(X)}$. Put $\beta = \bar{\kappa} - 1$. Choose an output rate λ and a number $\epsilon > 0$ with

$$C_h(\lambda + \epsilon) < \min\{\kappa_{\mathrm{ret}}, \beta\}. \tag{4.clvii}$$

All rates are chosen once, sufficiently large for the subsequent ordinary polymer criterion. Combining the retained old factor with $e^{-\beta m}$ and eq. 4.clvi gives $Ce^{-(\lambda+\epsilon)d_k(Y)}$. For inner members the bounded base needs only the β part of this inequality. The number of possible current-window anchors at fixed Y is polynomial in $\#Y$; the old bases within one such window have already been counted by $C_M \sigma_j^{-4}$. The bound $\#Y \le C(d_k(Y)+1)$ and the remaining ϵ absorb this polynomial. This is a pointwise output-domain estimate; any later sum over output domains spends its separately declared entropy reserve.

The function $\rho_j^3 \sigma_j^{\alpha_H}$ is bounded by

$$\omega_{k+1-j} := C(1+k-j)^{3/2} L^{-\alpha_H(k-j)}, \qquad \sum_{n \ge 1} \omega_n < \infty. \tag{4.clviii}$$

All inner age functions use the same enlarged fine-parameter domains and the same ν-disc. The outer and removed functions use the enlarged fine-parameter domains with their respective directional bounds. At fixed j, z, eq. 4.cliii–eq. 4.cliv provide the common-root function before any bracket. The resulting bounds for distinct base points and levels are then added absolutely. No bound for a sum of differently based bracket operators has been inferred from a sup norm of their unbracketed sum. The uniform bounds justify passage through the bracket integrals and to limits of the old-level sum.

We have proved the following formation estimate. Let g_j be regular-member norms, d_j defect norms and r_j aged-remainder norms. Under the explicit background, window and geometry inputs above, the actual old-origin potential satisfies

$$\|\mathbf{V}_k^{\mathrm{old}}\|_\lambda \le C s_k \left[\sum_{j \le k} \omega_{k+1-j} g_j + \sum_{j \le k} \rho_j^2 d_j + \sum_{j \in \mathcal{J}_k} \rho_j^2 r_j \right]. \tag{4.clix}$$

These are local bounds on every specified complex core. At complete physical pairs, finite fundamental theorem of calculus, the window partition, and hereditary resummation of eq. 4.clv identify their sum with the actual old action difference. There is no assertion of a single global off-graph Gaussian or a global torus background for an arbitrary local pair.

Adding a scalar Wilson-weight direction contributes at most $CM^4 s_k \alpha_k^2 \|u\|_\infty$, by the separate determinant/response-bracket argument. The formation rules are linear in their origins, so eq. 4.clix applies to their first source derivatives. For a frozen regular member that direction is $f(p_z)\mathcal{L}_j[1]$ with its own $b_j'(0)$; the remaining direction is the source defect. The finite potential-ball Taylor remainder justifies the chain rule even when the actual ordinary source families are nonlinear. This gives the formation inequality used in the linear source bootstrap, with no additional unexplained source-response norm assumption.

What remains as input is the actual joint complex window/core room, nonlinear averaged-datum estimates, Hölder response and compatible boundary comparison, and the outer/removed field locality for the assigned maps. None follows from a scalar stability bound. The result does not establish those background estimates, replace them by a formal graph identity, or address a large-field history operation.

Direct windows for the ordinary regular terms. In the ordinary constant-sequence part of the step one can localize the regular family by composing its members with the fixed box read before taking brackets. The complete box is then part of the term's carrier. The carrier and the pointing determine where the finished term is filed, as described below.

Write $(\mathbf{A}_s, \mathbf{K}_s)$ for the actual decoupled potential and current increment, in level-k units. On the ordinary constant-sequence core the response estimate gives

$$\|\mathbf{A}_s\| + \|\nabla_{\mathbf{U}}\mathbf{A}_s\| + \|\mathbf{K}_s\| \le C_R\delta_k \qquad (|s_\Delta| < R).$$

Fix the completed row source before varying the switches. The base of the response uses the independent current. For a fixed upper real factor U define the shifted pair by

$$P_{s,\lambda} = (e^{i\lambda\eta_k\mathbf{A}_s}\mathbf{U},\, \mathbf{J} + \lambda L^3\mathbf{K}_s)$$

in level-$(k+1)$ units. The potential and its first difference cost $L|\lambda|\|\mathbf{A}_s\|$ and $L^2|\lambda|\|\nabla_{\mathbf{U}}\mathbf{A}_s\|$ in these units. The current increment costs the stated L^3. Use upper target radii a fixed enlargement of the incoming radii, below the fixed window ceiling. On $|\lambda| < c/s_k$ the three changes are within the resulting reserve, for small fixed c. For the simple clauses this follows from the logarithm product and plaquette estimates. For the hereditary clauses use the proof of the outer substitution with the actual fractional room: put the same shift on a larger auxiliary amplitude disc, on which the simple bounds at most double, and apply the tower estimates there. Their holomorphic curvature and current readouts have the depth factors of eq. 2.vii throughout that disc. Schwarz then bounds their change by the reserved fraction of the same factors. The real factor is fixed, and the independent current is checked by its own affine formula. This admits the shifted upper pair on the full prescribed box, uniformly in the fine switches.

For inherited levels $1 \le j \le k$, far terms and a fixed number of the youngest ages restrict the original pair to the actual old domain and use the direct old substitution. Put $a = k - j$ and $\sigma_j = L^{-a}$. Its potential, first difference and current increment are $\lambda\sigma_j\mathbf{A}_s$, $\lambda\sigma_j^2\nabla_{\mathbf{U}}\mathbf{A}_s$ and $\lambda\sigma_j^3\mathbf{K}_s$ in old units. The base current is $L^{-3(a+1)}\mathbf{J}$. The two-level restriction leaves the old half-core room and the outer substitution admits a disc of radius $ca_{0,j}/(\sigma_j\delta_k)$. Far domains have the length loss $d_j(X) \ge c/\sigma_j - C$, which pays for the old base-point count. For the finitely many young ages this count is bounded directly.

For the remaining near terms use the same fixed window box, with its tower truncated at depth k. The comb map at level k applies to this determining set in the window box. Use the full averaged datum at $P_{s,\lambda}$, including the outer rows, and reconstruct its depth-k critical configuration in the flat-reference Landau chart. Its induced depth-j datum is formed on the truncation of that same tower. The nested continuation identity identifies the depth-j reconstruction with the depth-k field in its corresponding orbit. Read the field and its actual current in the admitted exponential representative. Thus the input current is used in making the shift and the window reads the current of its own reconstruction.

Take the window radii $a^\flat_{\iota,j} = \min\{a_{\iota,j}, c_\flat a_{\iota,k+1}\}$ with fixed $c_\flat > 0$. If b_ι are the admitted radii of the shifted upper pair, the running bounds give

$$\max_\iota \frac{b_\iota}{a^\flat_{\iota,j}} \le C(\sqrt{1+a} + c_\flat^{-1}).$$

Consequently the requirements $CM(b_0 + b_1)\sigma_j \le c' a^\flat_{0,j}$ and $CMb_0 \le c'$ of the window map hold from a fixed age onward, at weak coupling. In level-j units the simple bounds of that representative on the settled interior are at most $CMb_0\sigma_j$. Use the same bound for the curvature and current, which have additional factors of σ_j under rescaling. The tower estimate for simple data then admits both hereditary rules at the old window radii, since the age can absorb its fixed constant as well. On each of the two physical constant-sequence endpoints the depth-k box sequence is finer than the ambient one, and the depth-j box sequence is finer again. The no-inward restriction argument

applies at each restriction. Criticality at the induced datum and regular uniqueness then give the original activity value by real gauge invariance. On the inner read the six incident plaquettes of each current stencil are inside the box, so the constrained current of the restriction equals the ambient one in the same frame. Use the full-switch current identity and its node factors for the shifted physical endpoint. This gives the window identity at both endpoints of the bracket.

For the regular gain use the spatial estimate of the reconstructed upper field. The flat-reference Landau map in this box has the weighted first-datum-derivative bound of the walk estimate, including the Hölder seminorm of its first difference. Integrate this bound on the line from zero to the complete comb datum. The weighted sum over row sites is uniform. On the settled upper interior the local lengths equal one in upper units, and the reference connection is trivial. For the Hölder seminorm take cutoffs equal to one on the stencils of a fixed smaller neighborhood of each upper cell. Close points use a common cutoff, and the first-difference sup norm covers the remaining separations. The result is the ordinary C^{1,α_H} bound there, of size CMb_0. The central old double blocks are contained in this interior with their translated stencils. Applying the nonlinear row derivative estimates to this field gives eq. 4.xxxi with $\sigma = \sigma_j$. Take the root-z axial gauge on the settled old node lattice and extend it by the exponential of its logarithm times a cutoff supported inside that layer. The cutoff is one on the inner carriers and changes by $O(\sigma_j)$ per old link. The comb uses $O(\sigma_j^{-1})$ links of logarithmic size $O(CMb_0\sigma_j)$, so its logarithm is $O(CMb_0)$. The axial link identity also bounds its variation across one link by $O(CMb_0\sigma_j)$. The transition links therefore stay inside the regular logarithm chart, and the lower rows outside its support retain their complete original data. Choose the fixed ceiling on $b_0 + b_1$ to satisfy eq. 4.xxx. This admits the entire axial datum, including the remote rows, in the fixed continuation half ball uniformly in j, k. Define the window function by the old Landau continuation at this full axial datum. The central top rows have size $O(CMb_0\sigma_j)$; all remote rows have size $O(CMb_0)$, and are at old weighted distance at least c/σ_j from the inner read. The weighted Landau estimates for the potential and its first and second-order reads therefore give simple bounds $CMb_0(\sigma_j + e^{-c/\sigma_j})$ on the complete old stencils. The same bound holds for the physical current, by the full-switch first-variation formula. The tower estimate for these simple bounds admits both hereditary rules on the old window core, after increasing the fixed age threshold. This is the representative used in the Taylor calculation. The axial change is a real gauge at the physical endpoints, where invariance gives the same values. Use the resulting affine curvature for every member at the same base point and for its own plaquette tent. The old complete pointed subtraction and the retained domain tails then give the bound

$$Cg_j\,(\rho_j^\flat)^3\sigma_j^{4+\alpha_H}, \qquad \rho_j^\flat = \max\{1, \max_\iota b_\iota/a_{\iota,j}^\flat\},$$

before the bracket and the base-point count. A vacuum-only family uses its quadratic bound $C(\rho_j^\flat)^2\sigma_j^4$ times its own norm.

At a base point sum the near window functions before forming the bracket. Pin every switch cell meeting the full box, so a cut leaves all rows of this read in the active component of that base. The switch locality of the ordinary response then gives locality of the composed function on the same cut. At $\lambda = 0$ the function is independent of the switches. The alternating difference therefore vanishes at zero and Schwarz on the common amplitude disc gives the factor Cs_k. The fine-cell Cauchy factors pay for the added connected cells, and the fixed enlargement of the base costs a fixed constant. Summing the alternating differences gives the full shifted value minus the unshifted value of the same window function. The window identity identifies both values on the physical pair. Finally L^{4a} old base points cancel σ_j^4, leaving the summable Hölder gain for the regular family and the vacuum-only loads of eq. 4.clix. This supplies the ordinary regular bound on a source data line when the same direct window and pointing are used for all its systems.

The boundary assignment is made after formation. A cluster carrier contains the complete carriers of its vertices. If a window vertex uses a box crossing Λ^c, every cluster that contains it has a carrier outside Λ, even when its pointing lies in Λ^0. Its original endpoint contribution is then

in the boundary cluster family. The domain bound for that family must use the complete window read and its boundary pair. For the ordinary step, put $t = k+1$. The gap from Λ_t to Ω_t^c is at least $2\mathsf{a}_t = 2LM\check{R}_t$ in level-k units. A window box meeting Λ_t has diameter $12M$ in these units. The gap puts the whole box and any fixed enlargement for the response reads inside Ω_t, at weak coupling. This uses the ordinary sequence before preparations. A prepared stage can have $\Lambda_t = \Omega_t$.

On the ordinary crossing box the post-step pointwise and gauge bounds are those of the top layer t, in the upper units. They supply the simple core bounds on its full reads. Apply the tower estimate for simple data at fixed larger radii to obtain the hereditary core there. Complete the free source at the pivots on the actual level-k double blocks and set it to zero on the remaining bonds. Separation from Ω_k^c puts these double blocks in Ω_k. Use the response of this layered label on π_k, including when its active component extends past the window. The shift from this response uses the enlarged fluctuation bound $C_{\mathcal{A}}\delta_k$, including its collar coordinates. In the preceding upper substitution and the old window calculation the common amplitude disc can therefore be reduced to $c/(C_{\mathcal{A}}s_k)$. The box norms and old-age estimates remain the same, while the bracket now gains $CC_{\mathcal{A}}s_k$. The bound $C_{\mathcal{A}} \le C\varrho^{\mathrm{st}}(\theta_k)$ on the enlarged box is sufficient, since $\varrho^{\mathrm{st}}(\theta_k)s_k$ tends to zero.
4.5.4.4. The ordinary conditional Gaussian. Put $\mathsf{A} = \mathsf{C}^{\mathsf{T}}\Delta^{(k)}\mathsf{C}$ on the free fluctuation coordinates. Write I for the integration bonds, which have an endpoint in Λ_t, and E for the remaining free bonds with an endpoint in Ω_t. Let a denote the retained scaled exterior field. Completing the square at fixed a gives covariance $\tau_k^{-1}\mathsf{A}_{\mathrm{II}}^{-1}$ and mean $-\mathsf{A}_{\mathrm{II}}^{-1}\mathsf{A}_{\mathrm{IE}}\mathsf{a}$. The common ratio multiplies both blocks of the action and cancels from the mean. For a local integration set W, let P_W be the projection onto its integration coordinates. With the same guarded switches $\hat{s}$ in every factor, put

$$C = (P_W\mathsf{A}_{\mathrm{II}}(\hat{s})P_W)^{-1}, \quad \Gamma = P_W\mathsf{A}_{\mathrm{II}}(\hat{s})(1-P_W)R,$$
$$m = \mathsf{M}\mathsf{a}, \qquad\qquad \mathsf{M} = C(P_W - \Gamma R^{\mathsf{T}})\mathsf{A}_{\mathrm{IE}}(\hat{s}).$$

Here R is the inverse root in the switched walk expansion. The signed convention gives mean $-m$. At the full switches the block inverse identity gives $C(P_W - \Gamma R^{\mathsf{T}}) = P_W\mathsf{A}_{\mathrm{II}}^{-1}$, so this is the restriction of the same conditional mean. The local covariance and coupling to the auxiliary Gaussian are rescaled as $(\tau_k^{-1}C, \tau_k^{1/2}\Gamma)$.

The weighted row bounds for M and its difference from the real reference M_{r} have a common rate. Denote the small prefactor in the difference bound by ε_*. At a crossing bond the threshold is $\mathfrak{b}_b = \theta_{\mathrm{c}}\mathfrak{b}$; at other integration bonds it is $\mathfrak{b}$. The exterior datum is the sum of a real field obeying the three tiers and a complex correction. The collar bound is $\mathfrak{b}/C_{\mathrm{col}}$, the rim bound is $\theta_{\mathrm{c}}\mathfrak{b}$, and the bound beyond the rim is $C\mathfrak{b}$. The correction, of size at most $\varepsilon_{\mathsf{a}}\mathfrak{b}$, starts at distance $W_t - O(1)$ from the integration bonds, where $W_t = LM\check{R}_t$. Splitting the row sum at the collar width ϖ_T and at W_t gives

$$\frac{|m(b)|}{\mathfrak{b}_b} \le C\left(\frac{1}{C_{\mathrm{col}}\theta_{\mathrm{c}}} + e^{-c\varpi_T} + \frac{1+\varepsilon_{\mathsf{a}}}{\theta_{\mathrm{c}}}e^{-cW_t}\right).$$

The same estimate for the difference from M_{r} on the real exterior field has the factor ε_*. Since that reference mean is real,

$$\frac{|\operatorname{Im} m(b)|}{\mathfrak{b}_b} \le C\varepsilon_* + C\theta_{\mathrm{c}}^{-1}\varepsilon_{\mathsf{a}}e^{-cW_t} =: \varepsilon_\mu.$$

Choose the collar threshold and width as in the real step, then use the width of the rim to absorb the far-field enlargement. This gives $|\operatorname{Re} m(b)| \le \theta_\mu\mathfrak{b}_b$ with $\theta_\mu < 1/2$. The guard and small radii of the switched structure give $\varepsilon_\mu \le c(LM)^{-2}$.

To separate the real cutoff factors, fix the selected Mayer vertices and let Y_0 contain the free bonds on which they require a field box. In the signed convention above $B = \xi - m$ with ξ centered. On a bond of Y_0 split the displaced indicator into

$$\mathbf{1}_{\{|\xi_b - m_b| < \mathfrak{b}_b\}} = h_b(|\xi_b|) + \left[\mathbf{1}_{\{|\xi_b - m_b| < \mathfrak{b}_b\}} - h_b(|\xi_b|)\right],$$

where $h_b = 1$ up to $\mathfrak{b}_b/2 - 1$, decreases linearly to zero at $\mathfrak{b}_b/2$, and is zero beyond. The taper is fixed as the mean varies. At real data the bracket lies between zero and one, since the support of the taper is inside the displaced ball. Its support satisfies $|\xi_b| \geq \mathfrak{b}_b/2 - 1$. Outside Y_0 use one minus the failed indicator, whose failure implies $|\xi_b| \geq (1 - \theta_\mu)\mathfrak{b}_b$. Thus each selected remainder of a cutoff and each selected failure has a Gaussian tail cost. Summing these choices restores the physical product of cutoffs before taking the polymer logarithm.

For complex parameters continue the integral over the displaced ball by

$$f \longmapsto \int_{|A_b|<\mathfrak{b}_b} f(A_b + m_b)\, dA_b.$$

Here f is the common integrand in that centered coordinate. The taper integral keeps its real support fixed. The failure integral is the full integral minus the ball integral, and only coordinates outside the selected boxes use that full integral. To estimate a continued difference, freeze the integrand and subtract the ball integral with m_b replaced by $\operatorname{Re} m_b$. The difference integrates over the side swept by the real sphere as the imaginary part of m_b is turned on. Every point of that side has real radius at least $(1 - \theta_\mu)\mathfrak{b}_b$. The remaining difference is the real tapered shell or real complement above. This permits the Gaussian tail estimate on the difference itself. Joint holomorphy follows from the fixed-domain formulas by domination on the admitted boxes.

For the sharp radial tests, integrate the Gaussian auxiliaries and let Q be the marginal precision. It is complex symmetric, with a uniform real floor, bounded norm and small imaginary part. Write $m = u + iv$ and choose a smooth radial function ψ with values in $[0, 1]$, equal to one up to $3/4$ and zero from $7/8$ onwards. In each integration coordinate deform the real contour by

$$z_b = x_b - iv_b\psi(|x_b|/\mathfrak{b}_b).$$

Apply the deformation to the physical ball and complement integrals. The fixed taper is integrated on its real support. The deformation fixes the test sphere, is the identity on its complement, and stays inside the complex ball of each boxed holomorphic factor. Stokes' theorem therefore applies on each product piece of the radial tests. The Gaussian majorant permits passage to infinity on unrestricted coordinates, where the free quadratic potential is entire. The exterior test factor is constant in these integration coordinates.

Put $y = x + u$ and $w_b = v_b[1 - \psi(|x_b|/\mathfrak{b}_b)]$. Where $w_b \neq 0$ one has $|y_b| \geq |x_b| - |u_b| \geq \mathfrak{b}_b/4$, so $|w_b| \leq 4\varepsilon_\mu|y_b|$. It follows that

$$\operatorname{Re}\left((y + iw)^{\mathsf{T}} Q(y + iw)\right) \geq y^{\mathsf{T}}(\operatorname{Re} Q)y - C(\varepsilon_\mu^2 + \varepsilon_\mu\|\operatorname{Im} Q\|)|y|^2.$$

The complex Jacobian on one bond is $1 - iv_b \cdot \nabla[\psi(|x_b|/\mathfrak{b}_b)]$, with modulus at most $e^{C\varepsilon_\mu^2}$. For the normalized Gaussian comparison use the real precision obtained by subtracting this quadratic loss from $\operatorname{Re} Q$. The trace-log estimate between the resulting normalization and that of Q costs at most the dimension times $C(\|\operatorname{Im} Q\| + \varepsilon_\mu^2)$. With the Jacobian this is $O((LM)^{-4})$ per variable, since the guarded comparison gives $\|\operatorname{Im} Q\| = O((LM)^{-4})$. Each selected tail is estimated with a small centered quadratic tilt. The tapered shell starts at $\mathfrak{b}_b/2 - 1$, and the failed cutoff and the displaced side start at $(1 - \theta_\mu)\mathfrak{b}_b$ in the real part of the centered coordinate. The shifted-side bound pays a factor $C(1 + |v_b|)\exp(C|v_b|^2)$ on that bond in addition to the real Gaussian tail. The bound on ε_μ and the weak-coupling floor on the thresholds absorb this factor into the tail, leaving $e^{-c\mathfrak{b}_b^2}$ per selected bond. The free quadratic vertex is estimated using its own local support. On a fine cube Y its bound after the translation is $C|\tau_k - 1|(M^4\mathfrak{b}^2 + \sum_{b\in Y}|y_b|^2)$. Its Mayer estimate uses weight $C_M|\tau_k - 1|\mathfrak{b}^2$ in a boundary formation. Choosing the constant in that weight large enough makes the centered quadratic tilt $O((LM)^{-4})$ per variable after summing the local free cubes. The boundary ratio disc keeps this weight small. In formations contained in Λ_t the mean is zero, and the centered estimate gives the sharper interior weight. The fixed real contour gives holomorphy by local domination.

4.5.4.5. Differences of displaced tests. An exterior selector of the ordinary integral stays in the real retained kernel. In the unchanged collar its fluctuation coordinate is the original one. On the cutoff zone a sharp bond test at threshold at most δ_k is unchanged by the real substitution. The test against an approximate background is instead read using the localized backgrounds on its retained cubes. These identities apply before assigning switches to the analytic terms. In particular a sharp selector is not evaluated on a complex field. For the ordinary step on the standing part with its frames, sum out the passengers before forming the conditional integral. The new tests force the carried gauge indicators and the old plaquette tests on the integration region to equal one. The block-field tests read the fixed upper datum. The adjacent approximate bond factors that read the integration variables also equal one there: the ball test bounds the deviation from the global background by δ_k, and the interior comparison to the test background leaves room below the threshold $2\delta_k$. The remaining factors of those tests are carried by the real exterior kernel. This removal is an identity on the support of the whole term. It uses both the internal ball tests and the retained fluctuation factors in the unchanged part of the strip. At pivot bonds use the local constraint reconstruction on the full double block. This gives back the value in the retained test. With the zone equations the old whole-term description puts the characteristic functions and constraint distributions in the real kernel as the analytic pair varies. The conditional integral thus has precisely the product over $\mathfrak{X}_{\mathrm{I}}$ of its ordinary and crossing balls for the conditional integral.

For an integrated selector whose domain does move, write D_b for its nominal real ball and let ϕ_{b,ζ_b} be a transport of the ball, with $\phi_{b,0}$ the identity. At a real displacement it gives the tested domain $D_b(\zeta_b) = \phi_{b,\zeta_b}(D_b)$. Suppose the transport and its spatial derivative continue on the displacement disc, with their images in the common holomorphic read. For the calculation hold the Gaussian and the selected potentials fixed as a common integrand. On the coordinates in S take the difference between the transported and nominal domains. Expanding the product gives the alternating sum over $T \subset S$, in which exactly the balls of T are transported. At the physical real arguments the result is the integral of the common integrand times

$$\prod_{b\in S} (\mathbf{1}_{D_b(\zeta_b)} - \mathbf{1}_{D_b})$$

and the unchanged selectors. The product vanishes unless each bond of S is in its own difference of test domains. A change of the integrand between endpoints belongs to a separate analytic difference.

To continue this identity, use the pullback by ϕ_{b,ζ_b} of the holomorphic integrand and volume form to the fixed ball. Equivalently, for $b \in S$, integrate over the chain swept by ∂D_b under $\phi_{b,r\zeta_b}$, $0 \le r \le 1$, with boundary orientation giving the difference of the two balls. This follows by Stokes' theorem in that coordinate, and iteration gives one chain per moved test. A difference of complementary selectors has the opposite sign and the same chain. In the bounded logarithm chart the real strip shift and its first derivative have sizes $O(|H|)$ and $O(|H|/\delta_k)$, respectively, before scaling the field. In the plain zone the group multiplier itself continues holomorphically. In a cutoff zone any occurrence of the smooth cutoff in a transport formula must stay at the real parameter of the chain.

For transports whose whole disc gives a displacement $o(\mathfrak{b}_b)$ and bounded first derivatives in the scaled coordinates, the chain of a nominal sphere has real coordinate within $o(\mathfrak{b}_b)$ of that sphere, and its imaginary coordinate is $o(\mathfrak{b}_b)$. Thus the centered real coordinate on the chain has norm at least $\mathfrak{b}_b/3$, by the tier bound. In the other coordinates use the ordinary Gaussian contour above. The additional imaginary part on the chains costs an arbitrarily small multiple of $\sum_{b\in S} \mathfrak{b}_b^2$ in the quadratic estimate, by the uniform operator bound and the real floor of Q. To see this, apply the quadratic inequality to the cross term between the additional imaginary part and the ordinary imaginary part, using the bound $4\varepsilon_\mu|y|$ for the latter. The cross term with the real vector has coefficient $\|\operatorname{Im} Q\|$. Together they cost $O((LM)^{-4})|y|^2$ and a fixed multiple of the squared norm

of the additional imaginary part. The chain volume is at most a fixed polynomial in $\mathfrak{b}_b$ per bond. These costs leave $e^{-c\mathfrak{b}_b^2}$ for each moved test. The carrier includes the test bond and the reads of its transport. Summing the mixed differences over S at their physical endpoints recovers the full transported product by inclusion and exclusion.

For the product balls of the ordinary step one can bound the large switch discs by recentering before forming these differences. Use the prescribed radius $\rho = (\log \theta_k)^{6r+1}$ for the new switches. Choose the constant in the enlarged fluctuation box $C_{\mathrm{form}}\rho\mathfrak{b}_b$ after the absolute row bound for the mean. This fixed enlargement fits in the reader estimates because $C_{\mathrm{form}}\rho\delta_k/\alpha_{\iota,k} \to 0$. It changes the bound on the cubic potential only by a fixed factor, since $(C_{\mathrm{form}}\rho)^3\theta_k^{-1/2}\mathfrak{b}^3 \to 0$. The later stage therefore has the prescribed switch radius available for its Cauchy estimate. Inherited spectator switches keep their original discs. In a local Gaussian activity let m_μ be the signed mean with each new near field entering as $\mu_{b'}\mathsf{a}(b')$. The boxed factors in the centered coordinate y read $B = y - m_\mu$ and keep the same analytic arguments throughout the following calculation. Write their product, including the free factors, as $H_\mu(y)$. At a physical real point the success domain in y_b is $D_b + m_b$, and the failure domain is its complement. Replace each success by the centered success plus its translated-domain difference. Replace each failure by the centered failure minus that same difference. The integrand H_μ stays fixed in each of these operations.

For a row b of the mean split off the exterior bonds within weighted distance $D = C_0(1 + \log \rho)$ of b, using the distance of the kernel bound. Use only columns of the local mean. The weighted row estimate makes the contribution from the other bonds, after amplification by ρ, smaller than $c(LM)^{-2}\mathfrak{b}_b$ if C_0 is sufficiently large. For the close near bonds N_b keep their real values as spectators. In the translated-domain difference for b, use the shifts

$$\zeta_{b,T} = m_b\big(\mathsf{a}_{N_b}\mathbf{1}_T,\, (\mu\mathsf{a})_{N_b^c}\big), \qquad T \subset N_b.$$

Here only switched coordinates in N_b^c carry multipliers, and far analytic fields use their given arguments. Take the sum of the resulting swept chains with coefficients

$$\prod_{b' \in T} \mu_{b'} \prod_{b' \in N_b \setminus T} (1 - \mu_{b'}).$$

The tier estimate for the real close fields still holds when some are set to zero. The far tail estimate and the comparison to the real kernel give $|\operatorname{Re}\zeta_{b,T}| \le \theta'\mathfrak{b}_b$ with $\theta' < 1$, and $|\operatorname{Im}\zeta_{b,T}| \le C(LM)^{-2}\mathfrak{b}_b$. Indeed the unamplified far data outside the real tiers begin at distance $W_t - O(1)$ and give the same exponentially small error as in the mean estimate. The translated boundary thus remains at distance at least $(1 - \theta')\mathfrak{b}_b$ from zero in its real coordinate. The chain estimate for the centered Gaussian applies on the whole switch disc.

In the ordinary step the distance in the kernel bound controls the distance in level-k units between these top-layer bonds. Thus the number of close bonds is at most $C(D+1)^4$. The sum of the absolute interpolation coefficients costs at most $(1 + 2\rho)^{C(D+1)^4}$ for one translated test. Its logarithm is $O((1 + \log \rho)^5) = o(\mathfrak{b}^2)$. This spends only part of the tail charge for that test, even when many exterior switches enter the same row. An original failed test thus retains a tail factor, whether read as a centered failure or as a swept boundary. Differences of the mandatory success tests of a boxed vertex are on the union of the boxed reads. Count each bond in that union once, even when several vertices read it. Summing the choices over a cube adds at most $(1+e^{-c\mathfrak{b}^2})^{C(LM)^4}$ to the local bound.

The recentered integrand is admitted on these chains. At a mandatory boxed coordinate $|y_b| \le C\mathfrak{b}_b$, while $|m_\mu(b)| \le C\rho\mathfrak{b}_b$ by the absolute row bound. The formation-box constant accommodates the sum in the enlarged fluctuation box. The free quadratic factors on unrestricted coordinates have the centered tilt and a local cost bounded by $C_M|1 - \tau_k|\rho^2\mathfrak{b}^2$. This tends to zero in the boundary tube, where $|1 - \tau_k| \le C(\log \theta_k)^{-2q_{\mathrm{t}}}$ and $q_{\mathrm{t}} \ge q > \mathfrak{p}_0 + \deg \rho$; here $\deg \rho$ is the power of $\log \theta_k$ defining the switch radius. The same bound applies to the boxed quadratic correction.

The other vertices use their enlarged-box estimates. The estimates are uniform on the Gaussian decoupling discs, so the usual Cauchy bounds for those switches still apply.

At $\mu \equiv 1$ each chain sum selects the original shift. The affine substitution $y = B + m$ puts each original cutoff ball on the translated chain $D_b + m_b$. In a complementary test use full space minus the ball. Where the domain is full space the remaining factors are entire in that coordinate, and the Gaussian floor permits the affine contour to return to the real space. This recovers the original local activity before resummation, also at the admitted complex arguments. At $\mu_{b'} = 0$ the analytic arguments and all chain sums forget $\mathsf{a}(b')$. At $\mathsf{a}(b') = 0$ the two corresponding endpoints agree and their weights add to one, so the result forgets $\mu_{b'}$. The continuations are integrals over fixed real parametrizations and are jointly holomorphic with the real spectators fixed. They factor over wall components because the cut mean has zero columns off its component and all the selectors are coordinate factors. On the cutoff zone the smooth function in the real strip map and its Jacobian still use the retained real variable. For a mixed-history operation before passengers have been removed, or with additional integrated selectors, we must first reduce those selectors to the same product or transport their actual domains.

The window is inside Ω_t, while a cluster containing it can also have other carriers outside Ω_t. Use the new cluster estimate at formation, since the long-carrier estimate for an inherited boundary term requires support on both sides of Ω_t. When a window is unavailable, the corresponding origin still needs its assigned boundary or direct read with the same physical endpoint identity.

For the source comparison fix the label, Gaussian centre and retained exterior data. For the regular origins let $D_E(X)$ be the age-weighted sum of local differences of the inherited pointed families on the full reads of X. Vary each member with its companion and its own tent coefficient. The defects, aged remainders and local Wilson weights have the corresponding loads in eq. 4.clix, with the actual layer radii for Wilson terms off the regular region. Write $D(X)$ for the sum of these loads. The crossing vertex bound just proved is linear in the old origin, so a changed vertex has bound

$$C\varrho^{\mathrm{st}}(\theta_k) s_k D(X)\, e^{-r_V d_k(Y)}$$

on its actual carrier Y. In a selected rooted cluster interpolate its input arrays on the common data line. Differentiation selects one changed vertex; the derivative of its Mayer factor is $e^V \dot V$, with the same uniform sup bound on V as in the unmarked expansion. The absolute rooted summation at that vertex, with the unused decay for the other branches, gives

$$|\Delta B_{\mathrm{cross}}(X)| \le C\varrho^{\mathrm{st}}(\theta_k) s_k D(X)\, e^{-\kappa_{\mathbf{T}} d^\sharp_{k+1}(X)}.$$

The same proof bounds a fixed partial sum of complete clusters, by the same positive majorants. In particular one can select the clusters with a crossing origin by its record in the formation list. It applies to the source line over the changed slots, with the full pointed member retained at each slot. The small factor is uniform over the enlarged box. The endpoint identity uses all filed pieces at their actual physical switches.

The changed crossing clusters are used a second time in the ordinary strip transfer. Write $E^\sharp$ for their complete formed crossing sum and let $\mathbf{S}$ be the sum of the nonempty strip-displacement brackets. It is linear in the input potential, with each bracket formed on the actual enlarged strip carrier. The strip input is $E^\sharp + \mathsf{K}^{\mathrm{kp}} + \mathsf{B}^\times + \mathsf{B}^\tau$ minus the local Haar logarithms. The strip output is $\mathbf{S}$ of this input plus its strip Jacobian differences. At fixed geometry, fields, θ_k and scalar center x_k, a change of the regular input arrays or of the spatial Wilson weight enters through the formed vertices. Indeed the nonconstant part $x_k(\cdot) - x_k - \zeta_k(\cdot)$ is a Wilson potential, while the scalar center enters the Gaussian ratio. Thus the direct crossing output changes by $\Delta E^\sharp$, and the strip output changes by $\mathbf{S}[\Delta E^\sharp]$. The separate form and normalizer outputs and the strip Jacobians agree on this comparison. A change of the scalar center requires their own ratio and form estimates. Changes of old boundary or standing factors in the same formula use their own loads and majorants.

In each nonempty strip bracket, subtract the evaluations before summing the bracket. A displacement direction has size controlled by the localized response from the strip to its localization boundary. Cauchy's estimate on the transfer disc bounds that difference by the input norm times the displacement divided by its available radius. The exponential in the strip-to-boundary distance pays the enlargement factor of the strip disc and the ratio of the field radius to the fluctuation radius. The total strip term uses its own absolute majorant on the enlarged data line. This yields the strip source slope in its own decay norm. The direct crossing slope and the slope of the displaced output are assigned on their respective carriers.

For a carrier $X \subset \Lambda$, the ordinary formula is used with its actual vertices. It is filed in the regular family at $z \in \Lambda^0$, and in the edge sum $E^\partial(X)$ at $z \notin \Lambda^0$. At most $CM^4(1 + d_{k+1}(X))$ such sites can point into X, by the connected cube count. The spare unit in the pointed rate pays this factor. Thus the edge sum has the ordinary bound with one unit of decay spent, and its source difference has the corresponding data-line slope: the common $\mathbf{N}^\circ$ and $\mathbf{G}_\tau$ cancel before the sum. The Gaussian normalizer outside Λ is a separate term. This assignment retains the terms of the exponent with each complete carrier counted once.

Reconstructing the field of an old near term. On a box of the size of a level-$(\ell - 1)$ cube about its base point, a local level-ℓ triple has curvature, potential and current radii b_0, b_1, b_2. Its box reading uses the full box in the triple's domain and requires that the radii have small sum. Take the averaged datum of the product field in the axial gauge of that box and solve the old constrained critical problem for that datum [B87, (3.26)–(3.27)]. Evaluate the old term at the reconstructed field and at its current. This is a holomorphic function of the input field on the box. It ignores the independent input current. Its reconstructed potential has positive Hölder exponent. The absolute smallness conditions are $CMb_0 \le c$ and $CMb_0 L^{-a} \le c a_{0,j}$, where $a = \ell - j$ is the age and $a_{0,j}$ is the old curvature radius. Independence of the input splitting uses the stronger condition $CM(b_0 + b_1)L^{-a} \le c a_{0,j}$. At a matched real critical endpoint the box reading agrees modulo gauge by the restriction and uniqueness argument above.

On upper triples with $b_0 + b_1 \le C\alpha_k$ the old half-core condition holds at every sufficiently large age, since $\alpha_k / a_{0,j} \le C\sqrt{1+a}$. For the finite set of younger ages, use the old core interpolation when the whole old carrier is in Ω_j. For old term radii $a_{\iota,j} \ge \alpha_{\iota,j}$, the step uses at most $\phi_j^+ \alpha_{\iota,j}$, with $1 - \phi_j^+ \ge c_0/2$. The allowed disc in the dimensionless amplitude of the old response has radius

$$\left[C(1-\phi_j^+)^{-1} \frac{\delta_k}{\alpha_*} e^{C\varkappa} e^{-\delta_* \mathsf{d}_k(X)} \right]^{-1}, \qquad \alpha_* = \min_\iota \alpha_{\iota,k}.$$

Here $\mathsf{d}_k(X)$ is the response distance of the old carrier. At these ages the number of old base points per window is bounded by a fixed constant. The ordinary core estimate then supplies the corresponding young-age bound without a Hölder improvement. The dimensionless amplitude in this estimate is the old term's own interpolation parameter.

This use of the reconstruction requires an admitted triple on the complete box in eq. 4.cxlii. For the ordinary bracket the full-box frame gives the row comparison for the unamplified path and its cutoff perturbation. To use the positive Hölder bound we also need the prescribed reconstruction and the compatible boundary comparison on the entire addressed old domain.

Own readouts and the order of localization. The scalar readout is taken before the old member is evaluated on the new box background. We record the resulting algebra because it fixes both the normalization and the first jet.

At old level j and base point z, write $A_{j,z}$ for the member's assigned tent action. Let b_j be its pointed scalar readout with the fixed free-response kernel and fixed chart. Its definition is a linear combination of second derivatives at the identity with absolutely convergent moment weights. Hence it is complex linear and continuous in that Hessian-moment norm. Its action normalization

is $b_j(A_{j,z}) = 1$, as in the pointed quadratic classification. Set

$$\mathcal{R}_{j,z}G = G - G(0) - b_j(G)A_{j,z}. \tag{4.clx}$$

The zero denotes the identity point of the potential chart. The own coefficient and own action are held together in this definition. The quadratic classification proves the cancellation for this pair; it is not a cancellation between a coefficient and a tent action taken from unrelated families.

Fix j, z and its current window $R_{k,z}$. Let $\mathcal{N}_{j,z}$ be the near domains retained in eq. 4.cliii, and let $b_j(G)$ be the coefficient of the complete incoming pointed member, extracted before this truncation. Write Φ_{G_X}, $\Phi_{G_X(0)}$ and $\Phi_{A_{j,z}}$ for evaluations through its one common constrained box map. The bracket $\mathcal{L}_{Y;R_{k,z}}$ has the fixed declared root $R_{k,z}$; it differentiates each selected fine-cube parameter once and takes the prescribed fluctuation difference. In finite volume linearity gives exactly

$$\begin{aligned}
&\mathcal{L}_{Y;R_{k,z}}\left[\sum_{X\in\mathcal{N}_{j,z}}(\Phi_{G_X} - \Phi_{G_X(0)}) - b_j(G)\Phi_{A_{j,z}}\right] \\
&= \sum_{X\in\mathcal{N}_{j,z}} \mathcal{L}_{Y;R_{k,z}}[\Phi_{G_X} - \Phi_{G_X(0)}] \\
&\quad - b_j(G)\mathcal{L}_{Y;R_{k,z}}[\Phi_{A_{j,z}}].
\end{aligned} \tag{4.clxi}$$

For an infinite absolutely convergent old-domain sum, the same identity follows by uniform convergence on a slightly larger interpolation polydisc and Cauchy's formula. The own counterterm occurs once with the complete member's coefficient. The domains omitted by the near truncation remain in the separately estimated tail; no scalar coefficient is assigned to an individual domain.

This is the precise use of window-first normalization. It allows the pointed cancellation to be bounded before applying one bracket at the fixed j, z. Different z's may have different roots; their bounds are summed afterwards with the site and age counts of eq. 4.clv. No bound on a sum of functions is applied to a sum of different bracket functionals. Nor does eq. 4.clxi assert that the newly formed bracket member has scalar readout $b_j(G)$. That readout belongs to the old member before localization.

If $G(w)$ is a differentiable source family in this fixed presentation, continuity and linearity give

$$\partial_w \mathcal{R}_{j,z}G(w)|_0 = \dot{G} - \dot{G}(0) - b_j(\dot{G})A_{j,z}. \tag{4.clxii}$$

Thus a derivative of the formed member loses no normalization merely because its scalar coefficient has already been extracted. The derivative has its own coefficient, computed with the same free response. This is the rule used in the linear bootstrap.

If the presentation instead moves its readout or own action, the complete elementary product rule is

$$\partial_w[b_j^w(G^w)\,A_{j,z}^w]\Big|_0 = \{\,\dot{b}_j(G^0) + b_j^0(\dot{G})\,\}A_{j,z}^0 + b_j^0(G^0)\dot{A}_{j,z}. \tag{4.clxiii}$$

In this display the superscript zero denotes source parameter zero; G^0 is a member, rather than its value at the identity chart point. The distinction matters in a reference-change argument. eq. 4.clxii uses the fixed-presentation case; it cannot remove either extra term of eq. 4.clxiii.

4.5.5. *The many-scale first-source recurrence.* This section isolates a linear consequence of the ordinary local formation bounds. It uses the inserted-potential and renewed-pointing estimates at one step, rather than a larger domain of physical sources. In particular, it distinguishes the derivative of a newly generated activity from the old background action that is carried to the next scale. The formation and domain hypotheses below concern the actual local maps. Their statement is not an assertion that a nonlinear history construction satisfies them.

Meshes, norms, and the fixed ordinary run. Work first on a finite periodic lattice. Let $h_j = L^j h_0$ be the physical mesh of level j, with $L > 1$. A source profile is a bounded Lipschitz function on the physical torus; complex profiles are allowed by complexification. Put

$$\|f\|_{\sharp,j} = \max\{\|f\|_\infty, C_M h_j \operatorname{Lip} f\}. \tag{4.clxiv}$$

At level j, a pointed localization domain X contains its base point z. Its enlarged source region $X^\sim$ and the fixed plaquette point p_z satisfy

$$\sup_{p\in X^\sim} |p - p_z|_{\mathrm{tor}} \le C_M h_j (1 + d_j(X)). \tag{4.clxv}$$

Distances and diameters in this section use the torus metric. The family norm with rate γ is the supremum of $e^{\gamma d_j(X)}|F(X,P,z)|$ over the actual specified complex field domain and all X, z. Companion families, when present, are included in the same norm. A bound with rate $\kappa + 1$ therefore leaves one unit of rate for a diameter.

The ordinary run fixes all Gaussian structures, background maps, thresholds, label spaces and reference operations. Sources change local exponent members only. Let

$$\alpha_j = \theta_j^{-1/2}(\log\theta_j)^q, \qquad \delta_j = \theta_j^{-1/2}(\log\theta_j)^{p_0}, \qquad s_j = \delta_j/\alpha_j, \qquad q > p_0 \ge 0. \tag{4.clxvi}$$

Fixed multiplicative constants in these definitions can be included. Assume the ordinary flow bounds, with constants independent of the number of levels,

$$c(k-j) - C_0 \le \theta_j - \theta_k \le C(k-j) + C_0 \qquad (j \le k). \tag{4.clxvii}$$

All θ_j are sufficiently large. These bounds imply, with a uniform constant C_F, that for $1 \le j \le k$,

$$\begin{aligned} \alpha_{j-1}^2 s_{j-1} &\le C_F \alpha_k^2 s_k, \\ \varrho_{k,j}^2 \alpha_{j-1}^2 s_{j-1} &\le C_F \alpha_k^2 s_k, \qquad \varrho_{k,j} = \alpha_k/\alpha_j, \\ \varrho_{k,j}^2 &\le C_F(1 + k - j). \end{aligned} \tag{4.clxviii}$$

Indeed the functions $t^{-1}(\log t)^{2q}$ and $(\log t)^{p_0-q}$ are decreasing for sufficiently large t. The bounded displacement C_0 in eq. 4.clxvii changes their ratios by at most a constant. The second line also uses the bounded consecutive ratio α_{j-1}/α_j. The upper flow bound and $\theta_k \ge 1$ prove the last line. These observations also give $s_j \le C_F s_k$ when $j \le k$.

Locality supplies the source-gradient gain. Let E_j^w be an ordinary sourced regular family, holomorphic in a neighborhood of $w = 0$. Define its first derivative by

$$\mathcal{L}_j[f] = \frac{d}{dt} E_j^{tf}\Big|_{t=0}, \qquad A_j = \sup_{f\neq 0} \frac{\|\mathcal{L}_j[f]\|_{\kappa+1}}{\|f\|_{\sharp,j}}. \tag{4.clxix}$$

The supremum is taken over the permitted profiles and the tori in the run. At a fixed finite lattice all differentiations are in finite-dimensional source coordinates. Locality means that the value indexed by X depends only on the values of f on $X^\sim$. To apply the following argument it suffices that the source class admit bounded Lipschitz truncations of a profile and constants, as does the class defined by eq. 4.clxiv. No density claim about an infinite-dimensional algebraic dual is used.

The derivative defect at a base point is exactly

$$\mathcal{D}_j[f](X,P,z) = \mathcal{L}_j[f](X,P,z) - f(p_z)\mathcal{L}_j[1](X,P,z). \tag{4.clxx}$$

We claim

$$\|\mathcal{D}_j[f]\|_\kappa \le C_M A_j h_j \operatorname{Lip} f. \tag{4.clxxi}$$

To prove it, fix X, z, and subtract $f(p_z)$ from f. On $X^\sim$ the resulting profile has modulus at most $C_M h_j(1 + d_j(X)) \operatorname{Lip} f$. For real f, clip its values outside an interval twice this large, using a Lipschitz scalar map that is the identity on that interval and has Lipschitz constant at most a fixed constant. For a complex profile clip the real and imaginary parts separately. The resulting global profile g agrees with $f - f(p_z)$ on $X^\sim$ and satisfies $\|g\|_{\sharp,j} \le C_M h_j(1 + d_j(X)) \operatorname{Lip} f$. Locality

and linearity give $\mathcal{D}_j[f](X,P,z) = \mathcal{L}_j[g](X,P,z)$. Apply eq. 4.clxix and $(1+d)e^{-d} \le 1$ for $d \ge 0$ to obtain eq. 4.clxxi. Smooth profiles may instead use a smooth clipping map with the same fixed bounds. This proof applies uniformly at every external complex field point in the family norm. For a source measured at level $m \ge j$, it gives in particular

$$\|\mathcal{D}_j[f]\|_\kappa \le C A_j L^{-(m-j)} \|f\|_{\sharp,m}. \tag{4.clxxii}$$

Thus the derivative defect retains the response amplitude A_j and the scale-gradient gain together. The precise one-step inputs. For clarity we list the ordinary inputs needed for the bootstrap. The first two are estimates for local formation and the finite regular gas, at fixed background maps; they are not estimates for complex history masses.

The formation of potentials is linear in each origin. When a source is differentiated at zero, the regular-origin direction at a site is $f(p_z)\mathcal{L}_j[1]$, accompanied by its own coefficient, and the remaining direction is eq. 4.clxx. We require the following ordinary formation estimate on the actual localized complex pairs:

$$\begin{aligned}\|\dot{\mathbf{V}}_k[f]\|_\lambda \le C s_k \Big[&\alpha_k^2 \|\dot{u}_k[f]\|_\infty + \sum_{j\le k} \omega_{k+1-j} A_j \|f\|_\infty \\ &+ \sum_{j\le k} \varrho_{k,j}^2 \|\mathcal{D}_j[f]\|_\kappa + \sum_{j\in\mathcal{J}_k} \varrho_{k,j}^2 \|\dot{R}_j[f]\|_\kappa \Big].\end{aligned} \tag{4.clxxiii}$$

Here $\omega_n \le C(1+n)^C L^{-\alpha_H n}$ with $\alpha_H > 0$, and $\mathcal{J}_k$ contains the aged remainder origins that actually enter the regular part. Younger remainders remain in the remainder class. The factor s_k is the fluctuation-amplitude/field-radius ratio. In a formulation with additional positive powers of θ_k^{-1} in this factor, they are bounded by a constant times s_k at weak coupling. The current scalar-origin term in eq. 4.clxxiii follows more sharply from its fluctuation-difference estimate $C\alpha_k\delta_k\|\dot{u}_k[f]\|_\infty$. All substitutions in eq. 4.clxxiii must lie in their actual specified cores; a norm inequality does not create those inclusions. In particular, a proof of the pointed Hessian cancellation and nonlinear window estimate on constrained critical backgrounds alone does not prove eq. 4.clxxiii for independent potential/current pairs used in localization. Passing from those background estimates to all the actual localized pairs remains part of this ordinary formation input.

The inserted-potential estimate for the actual finite Mayer/decoupling series, followed by its actual renewed bond pointing, gives

$$\|\mathcal{L}_{k+1}[f]\|_{\kappa+1} \le C_P \|\dot{\mathbf{V}}_k[f]\|_\lambda. \tag{4.clxxiv}$$

Its proof uses the ordinary spare-potential slot. The auxiliary potential parameter is not a physical source in a history box. The normalized Gaussian, all reference measures, and $\mathbf{N}^\circ, \mathbf{G}_\tau$ have zero source derivative. These facts are essential to eq. 4.clxxiii–eq. 4.clxxiv.

The ordinary constant-source construction supplies numbers $b_j'(0)$ with $\sum_j |b_j'(0)| \le B_0$, uniformly in the cutoff. Its fixed tents and stage factors satisfy

$$\dot{u}_k[f](p) = f(p) + \sum_{j\le k} b_j'(0)\varphi_j(p) \sum_y h_y^{(j)}(p) f(p_y), \qquad \|\dot{u}_k[f]\|_\infty \le (1+B_0)\|f\|_\infty. \tag{4.clxxv}$$

The last bound uses $0 \le \varphi_j \le 1$, $h_y^{(j)} \ge 0$, and $\sum_y h_y^{(j)} = 1$. The coefficient of $\mathcal{L}_j[1]$ is exactly $b_j'(0)$: the free response and coefficient extractor are fixed and complex linear. Thus no coefficient of another member enters eq. 4.clxxiii, even when $f(p_z)$ varies with the site.

Finally suppose the ordinary remainder families are bounded by $C_R\theta_j^{-p}e^{-\kappa d_j(X)}$, with $p > 3$, on the fixed physical source disc $|t| < r/\|f\|_{\sharp,j}$ around zero. Cauchy's inequality at half that radius proves

$$\|\dot{R}_j[f]\|_\kappa \le (2C_R/r)\theta_j^{-p}\|f\|_{\sharp,j}. \tag{4.clxxvi}$$

This is the only source-disc estimate needed for the small remainder class. It is not used to produce an α_j^2 factor for regular activities.

The regular family in a history. Let Λ be the small-field region of the intermediate label and Λ^0 its set of admitted base points. A pointed term at (X, z) is filed in the regular family when $X \subset \Lambda$, $z \in \Lambda^0$ and all its vertices are regular [B88b, §3]. The fluctuation expansion places a fine vertex with domain Y in this term only when the hull of $Y^\sim$ in the level-$(k+1)$ grid lies in X. Thus its complete determining set is interior. The boundary, standing-operation and exterior-quadratic vertices vanish there, and the Gaussian has no exterior mean. The local Gaussian and threshold structure is that of the whole-lattice rule. At a fixed local field the normaliser, free potential and Gaussian ratio use the unsourced parameters (θ_k, x_k). The physical source enters the local potentials.

The quadratic gauge correction also has a regular part and a rim part. In the free fluctuation coordinates let K_A and K_G be the Wilson and gauge-fixing forms at the reference weight. With $\tau_k = x_k/\theta_k$, the actual precision is $\tau_k K_A + K_G$. The reference Gaussian of precision $\tau_k(K_A+K_G)$ therefore requires the potential $(\tau_k - 1)B^{\mathsf{T}} K_G B/2$, as in eq. 4.ccxxiv. The gauge coordinates eq. 4.ccxvii use only bonds inside their blocks. Thus this form splits into fine-cube terms $(\tau_k - 1)q_Y(B)$, where q_Y is the sum of the local gauge squares assigned to Y. The field B includes the stored exterior coordinates. Completing the square for the reference precision puts its mixed block in the conditional mean. Substitute the shifted integration coordinate into the entire $q_Y(B)$, including its mixed terms. A physical source in this presentation enters the Wilson potential at fixed τ_k.

When the coarse hull of Y with its neighbors lies in Λ, use the relative quadratic bound of the ordinary Gaussian leg. In the remaining cubes use the bounded rim vertex. On the real cut the local row bound and the number of bonds in a fine cube give

$$|(\tau_k - 1)q_Y(B)| \le C|1 - \tau_k| M^4 \mathfrak{b}_k^2.$$

The centered relative quadratic estimate allows a fixed disc about $\tau = 1$. At the rim use the disc of radius $2(\mathfrak{t}_k + \bar{c})/\theta_k$, where $\mathfrak{t}_k$ is the real weight tolerance and $\bar{c}$ the bounded weight displacement allowed by the tube. The choices of the tube pay for $\mathfrak{b}_k^2$, also on the enlarged field box used in the rim estimates. The two assignments sum to the original quadratic correction, and the choice between them reads the collared hull. Every quadratic vertex in a regular output satisfies the interior hull test, so it uses exactly the ordinary relative quadratic term. The same test applies in the ordinary recent-remainder contribution. Rim vertices enter the boundary expansion with their own bounds. The global cancellation of the marginal coefficient is the uncut Gaussian identity eq. 4.ccxxvii.

An old remainder of level j is aged here when $M\check{R}_j \le L^{k+1-j}$. It can enter a regular term and then contributes to the marked part of that term. Its origin carries the squared-radius weight $\varrho_{k,j}^2$. The weight ω_{k+1-j} applies to regular origins with their own pointed subtraction. Terms containing a recent remainder go to the new remainder on the one-layer inset of Λ and to the boundary family elsewhere. Terms with all vertices regular that are based at $z \notin \Lambda^0$ use the edge rule.

On the complete reads of a regular term, the sourced array uses the regular member for the constant $w(p_y)$ at each old base point y, its own Wilson coefficient, and the defect at y. The Wilson shift is the actual plaquette array with the stage factors and tents. The summable slopes of the scalar increments and the local defect and remainder bounds put this array in the ordinary source box about the same real centre. All its interior potentials, including those for a spatially varying shift, use the same local rule on every label. Therefore the term filed at (X, z) is the same function of the same local array as in the whole-lattice rule. Its field argument can vary with the history. For constant sources the defects vanish and the same pointing gives the Euclidean family with its source-dependent Wilson coefficient. A constant shift c is included as a Wilson-weight vertex of the rule at (θ_k, x_k).

To compare two arrays at this centre, join them inside the ordinary box. The difference of the local vertex potentials is linear in the input differences, with the four weights in eq. 4.clxxiii, before differentiation. In the convergent fluctuation expansion, differentiate along the line by inserting that difference at one vertex. The Gaussian terms are fixed, and the inserted-potential bound and the renewed bond pointing give the output rate $\kappa_{\mathbf{T}}$, where $\kappa_{\mathbf{T}} = (1+4\beta_{\mathrm{s}})\kappa \geq \kappa+1$. Equivalently the finite difference is bounded by $C\vartheta_k^{\sharp} e^{-\kappa_{\mathbf{T}} d_{k+1}(X)}$ times the weighted distance of the two arrays, where

$$\vartheta_k^{\sharp} = s_k + CM^4\theta_k^{-1/2}\mathfrak{b}_k^3 + \theta_k^{-1/4} \leq Cs_k$$

at weak coupling. Apply this comparison to $w = tf$ and to zero. The difference quotients of the four inputs give the actual shift derivative, the frozen regular derivative with its own coefficient, the defect derivative, and the aged remainder derivative. This gives the input to eq. 4.clxxviii on the common regular family once the vertex estimates on the assigned complex domains hold.
The absolute bound needed on a source data line. In the ordinary regular region $X \subset \Lambda$, retain the Gaussian compensation, cutoff and interaction legs in that order. Use the same pointing for the step and its constant-source companion. The comparison of two arrays at fixed Gaussian proves a difference bound for their interaction legs. To recover the absolute bound first sum the interaction vertices on an admitted line. For the regular, defect and aged-remainder norms in eq. 4.clix, the enlarged box gives, respectively, a fixed bound, $CL^{-(k+1-j)}$, and $C\theta_j^{-p}$. The three sums are therefore bounded by constants times

$$\sum_{a\geq 0}\omega_{a+1}, \qquad \sum_{a\geq 0}(1+a)L^{-(a+1)}, \qquad \sum_{a\geq 0}(1+a)(\theta_k+ca)^{-p}.$$

The first uses the positive Hölder gain and the third is $O(\theta_k^{2-p})$. In the Wilson direction the weight norm is at most $3r$; its vertex costs at most $CM^4 s_k \alpha_k^2\, 3r$. Add the intrinsic and coarea vertex bounds on the enlarged field box. They cost at most $CM^4\theta_k^{-1/2}\mathfrak{b}_k^3$, using $\mathfrak{b}_k \geq 1$.

The coordinate Cauchy bounds on the old and coarea legs and the normalized intrinsic pointing in eq. 4.cxxx give these bounds for the integrated bond roots in eq. 4.cxii. Insert each root as in eq. 4.cxv. The rooted cutoff term in eq. 4.cxxxix contributes at most $Ce^{-c\mathfrak{b}_k^2}$, on its own leg. Midpoint tents cost a bounded number of bond roots at a pointing, so retain an output rate $\kappa' \geq \kappa+1$. The free quadratic root eq. 4.cxxiv separately gives $C_{\mathbf{M}}|1-\tau_k|e^{-\kappa' d_{k+1}(X)}$. Consequently the three legs, after subtracting their common normalizer $\mathbf{N}^{\circ}$, give

$$|E(X,\cdot,z) - \mathbf{N}^{\circ}(X,\cdot,z)| \leq \left(C\vartheta_k^{\sharp} + C_{\mathbf{M}}\mathfrak{t}_k/\theta_k\right) e^{-\kappa' d_{k+1}(X)}.$$

Take the tube and weak-coupling ceiling so that the parenthesis is at most $1/2$. For the ordinary regular origins use the direct window construction on their complete bases throughout the enlarged data line. The other formation rules need their own local domains and bond-root estimates. Use the identical local pointing for the regular member in the sourced and unsourced arrays.
The induction and its constants.

Proposition 4.10 (Linear regular-response bootstrap)**.** Under eq. 4.clxiv–eq. 4.clxxvi, suppose the initial regular list is empty. There are $M_0 < \infty$ and $s_\star > 0$, independent of the number of levels, cutoff and volume, such that $s_j \leq s_\star$ for all j implies

$$A_j \leq M_0\alpha_{j-1}^2 s_{j-1} \qquad (j \geq 1). \tag{4.clxxvii}$$

■

Proof. Divide eq. 4.clxxiii by $\|f\|_{\sharp,k+1}$. Use eq. 4.clxxii with $m = k+1$, eq. 4.clxxiv–eq. 4.clxxvi, and the monotonicity $\|f\|_{\sharp,j} \le \|f\|_{\sharp,k+1}$. This gives

$$A_{k+1} \le C_1 s_k \left[\begin{array}{l} (1+B_0)\alpha_k^2 + \sum_{j\le k} \omega_{k+1-j} A_j \\ + C \sum_{j\le k} \varrho_{k,j}^2 A_j L^{-(k+1-j)} + C_r \sum_{j\le k} \varrho_{k,j}^2 \theta_j^{-p} \end{array} \right]. \tag{4.clxxviii}$$

There is no sum over the number of source labels in this inequality. The norms of linear directions have already combined them into f. The flow bound and eq. 4.clxviii imply

$$\sum_{j\le k} \varrho_{k,j}^2 \theta_j^{-p} \le C \sum_{a\ge 0} (1+a)(\theta_k + ca)^{-p} \le C_p \theta_k^{2-p} \le C_p \alpha_k^2. \tag{4.clxxix}$$

To check the middle bound, compare the sum with its first term and the integrals of $(\theta+ct)^{-p}$ and $t(\theta+ct)^{-p}$ on $[0,\infty)$. They are fixed constants times θ^{1-p} and θ^{2-p}, respectively; the latter integral is finite exactly when $p > 2$. The final bound uses $p > 3$, $q \ge 0$, and large θ_k.

Assume eq. 4.clxxvii through level k. Both sums involving A_j in eq. 4.clxxviii are at most

$$C M_0 \alpha_k^2 s_k \left(\sum_{n\ge 1} \omega_n + \sum_{n\ge 1} L^{-n} \right)$$

by eq. 4.clxviii. Consequently, for constants C_2, C_3 independent of k,

$$A_{k+1} \le \alpha_k^2 s_k (C_2 + C_3 M_0 s_k).$$

Choose $M_0 \ge 2C_2$ and $s_\star \le (2C_3)^{-1}$. The right-hand side is at most $M_0 \alpha_k^2 s_k$, as required. At the first step there are no old regular members, so the same argument starts the induction. The direct bottom-level scalar potential, if it occupies a separate initial slot, must satisfy the same fixed-reference fluctuation estimate used in eq. 4.clxxiii. □

A consequence on the near, non-wrapping window class. Let the final fluctuation size be $\delta_n = \alpha_n s_n$, and consider only terms for which the actual local window chart, the pointed affine comparison and its complex domain inclusions hold without a field-independent wrapping or holonomy tail. In addition, the axial and Hölder bounds of the nonlinear window proof must hold for the *complete* near background-plus-fluctuation pair with output size $a_{\mathrm{out}} \le C\delta_n$. A bound on its fluctuation increment alone is insufficient: an unrestricted background of size α_n would require that larger size in the radius ratio. The intended near class is the one on which the actual small-field tests impose a fixed multiple of δ_n on the complete field. Here the complete box includes the upper comb, every lower-row double block and the cutoff frame. The retained real profile in this class is bounded by $C\delta_n$ on that box and on the enlarged neighborhoods used by its gauge clauses. Then eq. 3.cdiii, with its local gauge estimate and tower restrictions, allows the real upper curvature radius $A_0 = C_M \delta_n$. The real reference has zero potential slot; for its perturbations use $A_1 = C_M \delta_n$ and the already required complex-domain inclusions. Those inclusions, rather than the real profile alone, admit the varied potential and independent current. The unamplified transported fluctuation is at most $C_R \delta_{n-1} \le C\delta_n$, together with its first difference on the settled box; the last inequality follows from the adjacent flow bound. Apply eq. 4.cxlv and its central axial estimate with $k = n-1$. It gives $C_M \delta_n$ on the whole raw and axial datum, including the remote rows, and $C_M \delta_n L^{j-n}$ on the central rows, absorbing one factor L in the constant. At depth $j = n$ use the upper datum itself. The far response therefore has size $C_M \delta_n e^{-cL^{n-j}}$, with the same homogeneous amplitude as the central estimate. This verifies the remote-amplitude requirement for this complete near class. It does not apply to a box whose tests control only an inner read or to an independent physical correction of larger size. For ordinary formation on the enlarged disc $|\nu| < c_\nu / s_k$, the fluctuation bound in

the inner substitution is instead $C\alpha_k$. The same calculation therefore supplies the required whole-datum and remote bound $C_M\alpha_k$ on that disc. No δ_k bound on the amplified ordinary disc is used. Keep the true ratio $\rho_j = \delta_n/\alpha_j$; it need not exceed one. The actual window-domain input includes $\alpha_j/r_{B,j} \le C$, where $r_{B,j}$ is the independent-coordinate datum radius, and the absolute full-datum inclusion of eq. 4.xxx. The central half-datum-disc condition holds uniformly at all ages: with $\sigma = L^{-(n-j)}$, the flow gives

$$\frac{C_{\mathrm{ax}}\delta_n\sigma}{r_{B,j}} \le C\rho_j\sigma \le Cs_n(1+n-j)^{1/2}L^{-(n-j)}.$$

Choose $s_\star$ smaller by a fixed factor so that the right-hand side stays below the required half-disc constant. The remote rows are admitted by the separate fixed absolute ceiling, with no age gain asserted for them. On the complete near class just specified, the preceding whole-window calculation supplies their proportional amplitude $C\delta_n$. Their response is therefore $C\delta_n e^{-c/\sigma}$ in the pointed-window estimate. This amplitude comes from the complete input and eq. 4.cxlv; the fixed ceiling supplies its domain. For other classes without that proportional estimate, the remote response remains a separate tail outside the homogeneous near contribution. This uses the near-domain proof for $\rho_j > 0$ itself and avoids the young-age core-only fallback, which would lose a ρ_j^2 gain when $\rho_j < 1$. After the four-dimensional fine-site count, the renormalized constant-member contribution at age $a = n - j$ is bounded by

$$CA_j\|f\|_\infty \left[\left(\frac{\delta_n}{\alpha_j}\right)^2 L^{-\alpha_H a} + \left(\frac{\delta_n}{\alpha_j}\right)^3 L^{-2a}\right]. \tag{4.clxxx}$$

The value at the identity and this member's own $b_j'(0)A(h_z,\cdot)$ are removed here. By eq. 4.clxxvii–eq. 4.clxviii, $A_j/\alpha_j^2 \le Cs_n$ and $\delta_n/\alpha_j \le Cs_n(1+a)^{1/2}$. The sum of eq. 4.clxxx is therefore at most $C\delta_n^2 s_n\|f\|_\infty$.

For the defect, the vacuum-only window estimate instead gives

$$C\|\mathcal{D}_j[f]\|_\kappa \left(\frac{\delta_n}{\alpha_j}\right)^2 \le C\delta_n^2 s_n h_j \operatorname{Lip} f. \tag{4.clxxxi}$$

Since $h_j = h_n L^{-(n-j)}$, its sum is at most $C\delta_n^2 s_n\|f\|_{\sharp,n}$. Thus these near regular and source-gradient terms together have size $C\delta_n^2 s_n\|f\|_{\sharp,n}$ per final window unit. With the radii in eq. 4.clxvi, the prefactor is $\theta_n^{-1}(\log\theta_n)^{3p_0-q}$. The gain is obtained because the newly generated derivative member already has amplitude $\alpha_j^2 s_{j-1}$.

No field-independent far tail is included in eq. 4.clxxx–eq. 4.clxxxi. Such a tail cannot acquire a factor ρ_j^2 merely from a source derivative. Recent large-field terms, marked remainder windows and torus or hole windings still require their own ordinary source-disc bounds, domain comparisons or separately small-class estimates. Nor do the local implications in this section verify the nonlinear formation hypotheses for every history. They show exactly how the α^2 normalization and the source-gradient gain propagate once those ordinary local hypotheses and the finite pointed estimate hold. The formation interface and the marked alternatives. For the fixed window-first rule, the regular terms of eq. 4.clxxiii are the linear application of eq. 4.clviii–eq. 4.clix. The regular direction is the source derivative of its near member with its own coefficient, as in eq. 4.clxii; the defect is eq. 4.clxx. The common-background and common-base rule in eq. 4.cliii–eq. 4.cliv is kept while taking that derivative. The bare scalar direction is eq. 4.ci, whose $\alpha_k\delta_k = \alpha_k^2 s_k$ factor was obtained before the finite gas expansion.

For the regular near class the small physical radius of the complete field is essential. At age $a = k - j$, use the true ratio δ_k/α_j until the homogeneous window estimate has been applied. The complete background-plus-fluctuation datum, rather than just the increment, obeys that small-radius bound. The all-age half-disc admission in eq. 4.clxxx then permits the quadratic and cubic

gains for ratios less than one. Replacing that ratio by one before estimating the window would lose the desired source normalization. The full-radius amplification and its subsequent Schwarz factor are the ones proved in the window formation argument.

The vacuum-only defect terms use the quadratic window estimate without a scalar-action cancellation. Marked remainder and remote classes require a different bound on their actual source domain. One sufficient finite condition is joint holomorphy and the ordinary estimate

$$\sup_{\substack{|w|\|f\|_{\sharp,j}<r_0\\ P\ \text{admitted}}} |R_j^{wf}(X,P,z)| \le B_j e^{-\kappa d_j(X)} \quad\Longrightarrow\quad \|\dot R_j[f]\|_\kappa \le \frac{2B_j}{r_0}\|f\|_{\sharp,j}. \tag{4.clxxxii}$$

Here r_0 is an actually admitted source radius independent of X, P, z; it is not inferred from a real-source estimate. The norm here is the pointwise exponentially weighted member norm $\sup_{X,P,z} e^{\kappa d_j(X)}|\dot R_j[f](X,P,z)|$, not a rooted domain sum at that same exponent. Cauchy's formula on a circle of radius $r_0/(2\|f\|_{\sharp,j})$ proves the implication. The reference frame, source rule, cutoff and read domain remain fixed on that circle. If the remainder includes a history operation, the corresponding bound is needed in its complete kernel norm, with its inner Wilson weight; a bound at one read datum is insufficient.

There is no extra α_j^2 on the right of eq. 4.clxxxii. Any power or logarithmic loss in using that bound must be carried into the marked age sum. For example, if a later covariance calculation has a geometric volume cost L^{8a}, the elementary sufficient rarity bound is

$$q_a \le C\varepsilon_{\rm bad}\, q^a, \quad L^8 q < 1 \quad\Longrightarrow\quad \sum_{a\ge 0} L^{8a} q_a \le \frac{C\varepsilon_{\rm bad}}{1-L^8 q}. \tag{4.clxxxiii}$$

The geometric sum is immediate; the point is its actual weight and quantifiers. An unweighted small bad-class probability does not supply this age moment. A differentiated one-zone mass test does not supply it either. It is a separate undifferentiated estimate on the allowed classes.

Remote and wrapping terms whose bound is independent of the local field cannot be assigned an invented factor $(\delta_k/\alpha_j)^2$. They must either be excluded by an actual non-wrapping near chart or retained with their own fixed-disc and age estimate. Thus the source recurrence proved above has a concrete formation route under its map hypotheses, while its marked and remote alternatives remain separate finite estimates to verify.

4.5.6. *The old-origin Hessian on the larger run window.* This section proves a conditional ordinary estimate. Its inputs are the complex domains and first-response estimates of the actual background maps, the pointed quadratic cancellation, and the window formation rule. The desired Hessian estimate is not one of the inputs. In particular, an estimate on the Gaussian cutoff box alone is not used as an analytic continuation theorem. We construct the larger fluctuation domain from the unscaled constraint chart and the datum domains of the background maps.

The conclusion concerns the regular old-origin part of a step exponent. The conditional exterior-force estimate, boundary origins with stored fields, and the identification of a clean-class conditional measure are separate issues.

Physical and Gaussian coordinates. Fix a step from level k to level $k+1$. Write

$$g_k = \theta_k^{-1/2}, \qquad \alpha_i \asymp \theta_i^{-1/2}(\log\theta_i)^q, \qquad \mathfrak{b}_k \asymp (\log\theta_k)^p, \qquad \delta_k = g_k\mathfrak{b}_k. \tag{4.clxxxiv}$$

Here $q > p$, and α_i is the smaller of the usable physical radii in the datum, potential, curvature and current conditions. Their fixed ratios are included in the constants. A finite alteration of an index in α_i, as needed for adjacent input layers, has the same meaning. We assume the ordinary flow gives

$$\rho_i := \max\{1, C\alpha_k/\alpha_i\} \le C_\rho(1+k-i)^{1/2}, \qquad \sigma_i = L^{-(k-i)}, \qquad i \le k. \tag{4.clxxxv}$$

Constants depend on the fixed block and collar choices, but not on the number of old levels, the cutoff or the volume. In particular, $C_{\mathrm{a}} := \sup_{i\le k} \rho_i\sigma_i < \infty$.

The free Gaussian variable y_b has three real color coordinates at each nonpivot bond of the level-k lattice. The physical bond logarithm is of size $g_k y_b$. Thus a physical analytic radius α_k corresponds to a Gaussian radius of order α_k/g_k, rather than to α_k. For complex variables we use the Euclidean norm of the three complex components at a bond and its supremum over bonds.

Let I be the finite box of free bonds under consideration. Its outside free coordinates and other exterior data are fixed. Every real free coordinate appearing in the regular fields is bounded by $C_{\mathrm{w}}\mathfrak{b}_k$. The number of coordinates satisfies

$$m_I = 3\#I \le C(rL^{-a_*} + D)^4 \le C(r + D)^4. \tag{4.clxxxvi}$$

This count will not enter the localized estimate below. It is relevant to the weaker estimate available without spatial locality.

The primitive analytic inputs. We specify the domain inputs used in the proof. These are statements about assigned maps and their first responses, not bounds on the Hessian of an old activity.

For the actual one-step average, at its actual background $V^{\mathrm{bg}}(W)$, put

$$q_W(a) = \frac{1}{i}\log\Big[\mathcal{M}(e^{ia}V^{\mathrm{bg}}(W))W^{-1}\Big] = LQ_W a + \mathcal{R}_W(a). \tag{4.clxxxvii}$$

The logarithm is taken on its assigned local branch. The fixed-pivot construction supplies linear maps C_W and h_W with

$$LQ_W\mathsf{C}_W = 0, \qquad LQ_W h_W = 1, \qquad \|\mathsf{C}_W\|_{\infty\to\infty} + \|h_W\|_{\infty\to\infty} \le C_L. \tag{4.clxxxviii}$$

The map C_W is the pivot elimination map, not a Gaussian covariance. The maps in eq. 4.clxxxvii–eq. 4.clxxxviii are the ones used in the run. Uniformly on an unscaled physical ball $\|a\|_\infty < r_0$, the remainder is holomorphic and obeys

$$\|\mathcal{R}_W(a)\|_\infty \le C_0\|a\|_\infty^2, \qquad \|D\mathcal{R}_W(a)\|_{\infty\to\infty} \le C_0\|a\|_\infty. \tag{4.clxxxix}$$

Here r_0, C_0, C_L are independent of the box size. The same bounds, with fixed enlarged constants, apply to the assigned local charts on the independent fine-parameter discs $|s_\Delta| < e^{\bar\kappa}$. At physical parameters the local charts agree with the run chart by their restriction and completeness identities.

The ordinary background package supplies holomorphic maps on their declared datum balls and their declared core slices. The datum radii satisfy $r_{B,i} \ge c\alpha_i$. At zero fluctuation all substituted data and pairs have a fixed positive fraction ϵ_0 of room in these domains. This room includes the tower conditions, node representatives, current bounds, and the inner, outer and removed substitutions. These are local complex assertions; they do not assert the existence of a global Gaussian measure for independent currents.

We use the following precise first-response form of that package. Measure each defining datum or core displacement at old level i in units of its allowed radius. Along an admitted physical perturbation of supremum size u, its derivative in any of these normalized quantities is bounded by

$$C_R\sigma_i\alpha_i^{-1}u. \tag{4.cxc}$$

The bound holds throughout the declared complex domains, for all the fine parameters above. It is the integrated first-response and nonlinear-average estimate: the actual average, not its differential, is used to construct the datum. The constant C_R includes the fixed enlarged parameter discs and the chart derivative. For outer and removed derivatives there are additionally their assigned exponential distance factors. As usual, a compatible boundary comparison and the weighted Hölder response estimates are assumed for the actual box backgrounds.

Finally, the field maps are hereditary on active wall components. After the parameters outside a domain Y are set to zero, a local potential uses only the free coordinates in Y. A fixed collar can

instead be included in Y throughout; it changes the constants below. The number of domains of tree length in $[m, m+1)$ containing a fixed cube is at most $C_D e^{\kappa_D m}$, and

$$\operatorname{diam} Y \le C_M(1 + d_k(Y)). \tag{4.cxci}$$

The spatial rates have the strict reserves needed to sum these domains and the fixed polynomial diameter factors.

The actual chart on the larger ball. For clarity we give the contraction argument behind the radius claim. Put $z = g_k \mathsf{C}_W y$. The nonlinear correction is the solution of

$$d = \mathcal{R}_W(z - h_W d), \qquad a_W(y) = z - h_W d, \qquad V_W(y) = e^{i a_W(y)} V^{\mathrm{bg}}(W). \tag{4.cxcii}$$

Choose $r_1 > 0$ so small that $2r_1 < r_0$ and $4C_0 C_L r_1 < 1/2$. For $\|z\|_\infty \le r_1$, the right side maps the ball $\|d\|_\infty \le 4C_0\|z\|_\infty^2$ to itself. Indeed $\|z - h_W d\|_\infty \le 2\|z\|_\infty$, and eq. 4.clxxxix then gives that bound. Its Lipschitz constant in d is at most $2C_0 C_L r_1 < 1/2$. Iteration from zero therefore converges uniformly to the unique solution, including locally uniformly in all complex parameters. Uniform limits of the holomorphic iterates are holomorphic. Differentiating the fixed-point equation, or its uniformly convergent derivative iteration on a smaller ball, gives

$$\|a_W(y)\|_\infty \le C g_k \|y\|_\infty, \qquad \|D_y a_W(y)\|_{\infty\to\infty} \le C g_k. \tag{4.cxciii}$$

Moreover, $q_W(a_W(y)) = 0$, because $LQ_W z = 0$ and $LQ_W h_W d = d$. This is the actual constraint, with its nonlinear average. Uniqueness shows that this chart agrees on the operational cutoff box with the chart already used in the run.

There is consequently a fixed $c_* > 0$ for which all the old substitutions are defined and holomorphic on

$$\|y\|_\infty < R_k, \qquad R_k = c_* \alpha_k / g_k. \tag{4.cxciv}$$

Here and below fixed exterior coordinates may be retained with norm at most $C_{\mathrm{w}}\mathfrak{b}_k$. To prove the assertion, first make α_k small enough that eq. 4.cxciii stays in its physical chart. For any fixed complex y in eq. 4.cxciv, follow the segment ty, $0 \le t \le 1$. On the portion where a composition of assigned background maps is admitted, eq. 4.cxc and eq. 4.cxciii bound each normalized displacement by

$$C_R g_k \|y\|_\infty \sigma_i/\alpha_i \le C_R c_* \rho_i \sigma_i \le C_R c_* C_{\mathrm{a}}. \tag{4.cxcv}$$

Choose c_* so that the last expression is less than $\epsilon_0/4$. The segment cannot reach a domain boundary: every defining inequality still has at least half of its initial room. Atomic background maps are already given on those domains, so this is an inclusion argument for a composition of assigned holomorphic maps, not an assertion that a branch continues through an unknown singularity. The same argument gives the required joint holomorphy with the fine parameters. It also applies to local independent-current formulas without postulating an off-graph global Gaussian integral.

The window multiplier used to differentiate an inner direction can range on a fixed disc $|\nu| < c_1/c_*$, where c_1 is chosen from the same room estimates and $c_* < c_1/4$. In fact its normalized increment is bounded by $C_R|\nu| c_* \rho_i \sigma_i$. The unamplified part costs only $C_R c_* C_{\mathrm{a}}$; choose c_1 so that their sum still spends less than half the room. Thus this disc contains $\nu = 1$ and permits the window derivative at zero.

Since $q > p$, increasing the coupling floor gives $C_{\mathrm{w}}\mathfrak{b}_k < R_k/4$. Two coordinate Cauchy circles with radii cR_k, centered anywhere on the real product window, therefore fit in eq. 4.cxciv. There is no factor depending on m_I in this inclusion. No indicator function or cutoff is analytically continued. Only the activity functions are evaluated on the larger ball; the real measure, Gaussian scaling and all numerical choices of the run remain fixed.

An amplitude bound before the Gaussian-growth norm. Let the regular member at old level i have norm e_i, with $e_i \le E_0$. The norms include its infinite companion if one is required. Each pointed total has local gauge invariance, constant color invariance and the full site symmetry needed for the pointed Hessian theorem. At every old base point subtract its vacuum and its own extracted coefficient times its own tent action. The tent has unit quadrature; the action convention is $A(e^{iB}) = \frac{1}{2}|\mathrm{d}B|^2 + O(B^3)$. This is the regular part of the decomposition: its counterterms have been transferred to the running Wilson coefficient. A profile deficit is retained as a lag or boundary origin, rather than silently subtracted from the measure. The clean interior has no such deficit in the canonical decomposition with redrawn profiles. Thus the affine quadratic term cancels with coefficient one in that normalization. We do not replace the pointed object by a bulk convolution or assign an action coefficient to an individual domain.

We recall explicitly the value estimate supplied by this cancellation. Write $D_X = 2 + \mathrm{diam}_i X$. On an inner box background the affine part and its error have sizes bounded, with fixed powers of D_X, by

$$\alpha_k \sigma_i^2, \qquad \alpha_k \sigma_i^{2+\alpha_H} + r_{B,i}^{-1} \alpha_k^2 \sigma_i^4, \qquad 0 < \alpha_H \le 1. \tag{4.cxcvi}$$

These estimates concern the complete substituted field, not just its fluctuation increment. They hold on the whole disc just constructed. Second and third derivatives of a member cost $Ce_i\alpha_i^{-2}$ and $Ce_i\alpha_i^{-3}$, with its original tree decay. Its linear derivative at the trivial pair is zero by constant color invariance.

Set $T = CD_X^s \rho_i \sigma_i^2$. When T is small, Taylor's formula, the cancellation of the affine quadratic value on the pointed total, and $r_{B,i} \ge c\alpha_i$ bound the remaining terms by $Ce_i D_X^{s'}[\rho_i^2 \sigma_i^{4+\alpha_H} + \rho_i^3 \sigma_i^6]$. For example, the product of the affine part and its error, divided by α_i^2, gives exactly these two powers. Squares of the error and cubic terms are bounded by the same expression, since their normalized sizes are bounded by $C(T\sigma_i^{\alpha_H} + T^2)$ and CT^3. If T is not small, whole-core bounds for the member and its own action, and the comparison affine quadratic value, give $Ce_i(1+T^2) \le Ce_i C_T T^3$. The fixed powers of D_X are summable against the tree decay. A fixed finite set of young ages failing the central half-datum-ball test is also covered by the whole-core bound: their σ_i have a fixed positive lower bound. The separate remote-datum admission is retained. This is precisely the reason to use the ordinary full-radius ratio $\rho_i \ge 1$ here.

At one base point, after its domain sum, the bound is therefore

$$Ce_i \left[\rho_i^2 \sigma_i^{4+\alpha_H} + \rho_i^3 \sigma_i^6\right]. \tag{4.cxcvii}$$

A current window contains at most $C\sigma_i^{-4}$ old base points. Its value bound is at most $Ce_i\rho_i^3\sigma_i^{\alpha_H}$. Terms extending beyond that window retain an exponentially small tree-length tail. Outer and removed terms retain their actual response factors. Even the cruder amplitude $Ce_i\sigma_i^{-4}e^{-c/\sigma_i}$, when only a long-domain value bound is used, is bounded by $Ce_i\rho_i^3\sigma_i^{\alpha_H}$. This does not give such a tail a square of the actual small curvature; it is a full analytic-radius estimate.

It is important where the inner estimate is localized. At each old base point form one window function from the near pointed sum, its own action counterterm, and one common critical box map. This entire function has one fixed current-scale base, of uniformly bounded size. Only then apply the fine brackets of the window formation rule. Thus the cancellation in eq. 4.cxcvii occurs before a single common bracket. No sup norm of a sum is used to bound a sum of differently based bracket operators.

On the independent fine discs the bracket with m differenced cubes costs at most $(e^{\bar\kappa}-1)^{-m}$, with no factorial. The derivative at $\nu = 0$ costs the reciprocal of its fixed disc, hence only a fixed constant. For outer origins retaining their original base, split the old input rate into the domain-sum, long-tail and retained parts. If Y is the resulting current domain, the hull and rooting geometry gives $d_k(Y) \le C_h(d_i(X) + m + 1)$; for a bounded window base it gives $d_k(Y) \le C_h(m+1)$. Choose the retained rates and $\bar\kappa - 1$ larger than $C_h(\lambda + \varepsilon)$, after spending the old rooted entropy and diameter

powers. The remaining ε absorbs the polynomial number of window anchors at a fixed Y. This proves the following pointwise analytic bound for the actual chosen window filing:

$$|V^{\mathrm{old}}_{k,i}(Y;y)| \le Ce_i\omega_{k+1-i}e^{-\lambda d_k(Y)}, \qquad \|y\|_\infty < R_k, \quad \omega_{a+1} = C(1+a)^{3/2}L^{-\alpha_H a}. \tag{4.cxcviii}$$

The current origin $i = k$ uses its direct whole-core Cauchy bound and $\omega_1 = O(1)$; it needs no age improvement. The proof was carried out on the larger ball using a physical fluctuation amplitude at most $c_*\alpha_k$, rather than the tested amplitude δ_k. It does not use the final potential bound with a Gaussian-growth factor $1 + M^{-4}\sum_{b\subset Y}|y_b|^2$. Using that weaker envelope on a radius R_k would introduce R_k^2 and erase the desired Cauchy gain.

Let

$$\mathcal{E}_k = \sum_{i\le k}\omega_{k+1-i}e_i \le CE_0. \tag{4.cxcix}$$

Absolute convergence is uniform on every smaller ball in eq. 4.cxciv, by eq. 4.cxcviii. It justifies summing old levels before taking two coordinate derivatives. All estimates can first be made with finitely many old levels and on a finite torus. Their constants do not change in either limit.

Cauchy, rooted counting and the weighted precision gap. Write $P^{\mathrm{old}}_{k,I}(y) = \sum_Y\sum_{i\le k}V^{\mathrm{old}}_{k,i}(Y;y)$, with exterior variables fixed. Additive terms depending only on the exterior can be omitted. By two coordinate Cauchy formulas, including the factor 2! for a repeated coordinate, eq. 4.cxcviii gives

$$\left|\partial_{y_b^a}\partial_{y_{b'}^{a'}}\sum_{i\le k}V^{\mathrm{old}}_{k,i}(Y;y)\right| \le C\mathcal{E}_kR_k^{-2}e^{-\lambda d_k(Y)} \tag{4.cc}$$

throughout the real product window. The derivative is zero unless both bonds belong to the declared domain, including its fixed collar. For such a domain, $d(b,b') \le C_M(1+d_k(Y))$. Choose $\mu > 0$ so small that $\lambda - \mu C_M > \kappa_D$, retaining a strict gap. Root the domains at a cube containing b; the fixed number of possible root cubes costs only a constant. Then

$$\sum_{Y\ni b,b'}e^{-\lambda d_k(Y)} \le Ce^{-\mu d(b,b')}\sum_{m\ge 0}e^{-(\lambda-\mu C_M-\kappa_D)m} \le C'e^{-\mu d(b,b')}. \tag{4.cci}$$

Consequently the full old-activity Hessian, in the actual Gaussian coordinates, satisfies

$$\|D_bD_{b'}P^{\mathrm{old}}_{k,I}(y)\| \le C\mathcal{E}_k\left(\frac{g_k}{\alpha_k}\right)^2e^{-\mu d(b,b')} \le CE_0(\log\theta_k)^{-2q}e^{-\mu d(b,b')}. \tag{4.ccii}$$

Color matrix norms cost a fixed factor only. The count of bonds at distance in $[r, r+1)$ is at most $C(1+r)^3$. Thus for every $0 < \mu' < \mu$, both weighted row and column sums of the Hessian are at most $C\mathcal{E}_k(g_k/\alpha_k)^2$. In particular, Schur's inequality gives

$$\|T_\phi D^2P^{\mathrm{old}}_{k,I}(y)T_\phi^{-1}\|_{2\to 2} \le C\mathcal{E}_k(g_k/\alpha_k)^2, \qquad |\phi(b)-\phi(b')| \le \mu' d(b,b'), \tag{4.cciii}$$

where T_ϕ multiplies the three coordinates at b by $e^{\phi(b)}$. This estimate is uniform in I.

For completeness, suppose the actual free precision A, after the prescribed constraint and gauge fixing, has a gap $A \ge a_-\mathbf{1}$ and uniform exponentially summable entries. This is a separate free-background input, concerning the constrained pullback Hessian in the coordinates C_W, not the ambient curl Hessian. Its Dirichlet compression A_{OO} has the same gap. For small Lipschitz weights its conjugation difference has norm at most $C\mu'$. Hence the conjugated inverse of A_{OO} has norm at most $2/a_-$ when $C\mu' < a_-/2$, by the Neumann series. Applying this to $\phi(b) = \mu' d(b,b')$ bounds each inverse entry by $(2/a_-)e^{-\mu' d(b,b')}$. This proof is uniform in O. It follows by two exponentially summable convolutions that

$$K_I = ((A^{-1})_{II})^{-1} = A_{II} - A_{IO}A_{OO}^{-1}A_{OI}$$

has exponentially summable entries at a possibly smaller rate. Furthermore, $\langle v, K_Iv\rangle = \inf_w\langle(v,w), A(v,w)\rangle \ge a_-\|v\|^2$. Thus the inverse marginal covariance, with its actual Schur correction, retains the free gap. Its conjugation difference also has norm at most $C\mu'$: use

$|e^{\phi(b)-\phi(b')}-1| \le \mu' d(b,b') e^{\mu' d(b,b')}$ and the row and column sums. Choose μ' so that this norm is at most $a_-/4$. Then

$$\mathrm{Re}\langle v, T_\phi (K_I - D^2 P^{\mathrm{old}}_{k,I}) T_\phi^{-1} v\rangle \ge \left(\frac{3a_-}{4} - C\mathcal{E}_k (g_k/\alpha_k)^2\right) \|v\|^2. \tag{4.cciv}$$

For a sufficiently large coupling floor the old activities cost at most $a_-/4$, leaving a weighted gap of at least $a_-/2$. Other intrinsic or remainder Hessians must be charged separately. The reference precision is held fixed while differentiating in y; no derivative of a covariance with respect to y is introduced.

Remainders and the weaker finite-box alternative. A holomorphic aged remainder with no fixed color spectators has zero linear term at the trivial pair, but has no action counterterm. Its vacuum-only window bound has weight ρ_i^2 instead of ω_{k+1-i}. The same proof gives eq. 4.ccii with $\mathcal{E}_k$ augmented by $\sum_i \rho_i^2 r_i$, provided its actual maps have the same domains and locality. If $r_i \le C\theta_i^{-s}$, $s > 2$, and $\theta_i \ge \theta_k + c(k-i) - C_0$, use the actual running radii to bound $\rho_i^2 \le C\theta_i/\theta_k$. Indeed the squared radius ratio is bounded by this expression times $(\log\theta_k/\log\theta_i)^{2q}$, which stays bounded on the admitted flow. The maximum with one has the same bound. Thus

$$\sum_i \rho_i^2 r_i \le C\theta_k^{-1} \sum_{a\ge 0} (\theta_k + ca - C_0)^{1-s} \le C_s \theta_k^{1-s}. \tag{4.ccv}$$

For the last inequality use the integral comparison with $\theta_k - C_0 \ge \theta_k/2$. This optional conclusion does not cover a boundary term retaining stored color variables or a term for which only an integrated norm is known.

If only a bound on the whole finite-box analytic function is available, a useful but weaker statement remains. Suppose $|P(y)| \le CE_0(r+D)^A$ on a Gaussian polydisc of radius $c\alpha_k/[g_k(r+D)^B]$. The same coordinate Cauchy estimate and $m_I \le C(r+D)^4$ give

$$\|D^2 P\|_{2\to 2} \le CE_0 (r+D)^{A+2B+4} (g_k/\alpha_k)^2. \tag{4.ccvi}$$

Indeed each matrix entry has the bound without the last power $(r+D)^4$, and the row and column contain at most m_I entries. For a direct volume bound $A=4, B=0$, this is $CE_0(r+D)^8(\log\theta_k)^{-2q}$. When $r + D \le C(\log\theta_k)^{2p}$, it tends to zero if $q > 8p$. It preserves an unweighted gap. It does not imply eq. 4.cciii at a fixed positive spatial weight: conjugation could cost $e^{\mu' \operatorname{diam} I}$. The rooted localization in eq. 4.cxcviii–eq. 4.cci proves the stronger weighted conclusion; counting window coordinates alone would not suffice.

The old-activity Hessian estimate and its scope. Under the stated ordinary analytic map hypotheses and the reviewed pointed and window inputs, the old regular-activity contribution to the localized Hessian is bounded by $CE_0(\log\theta_k)^{-2q}$, uniformly over old ages and box sizes. The analytic radius is in the physical-to-Gaussian coordinate conversion in eq. 4.cxciv. A bare operational cutoff domain, or only a Gaussian-growth potential bound on that domain, would not prove it. The two required primitive verifications are the uniform unscaled pivot estimates in eq. 4.clxxxviii–eq. 4.clxxxix and the all-domain first-response and membership estimates in eq. 4.cxc, including towers and outer substitutions. They belong to the actual ordinary background analysis and have not been proved for the Yang–Mills maps merely by this deduction.

The statement has no automatic consequence for the change in force when exterior data are changed. For that one needs, separately, uniform estimates such as $\|D_b(P_e - P_{e_0})\| \le C\mathfrak{b}_k e^{-cd(b,O)}$ on the actual compatible exterior and stored data. A Hessian bound in the variables of I does not bound derivatives with respect to the exterior parameters. Nor does it identify a clean-class restriction with a Gaussian fibre kernel. Field-independent remote or holonomy bounds without the analytic domain assertion used above remain separate tails; they receive neither an invented curvature factor nor an unjustified Cauchy estimate.

An analytic criterion for the old exterior force. The larger fluctuation ball controls derivatives in its free coordinates. A useful further reduction states precisely what function-level locality would also control a change of exterior datum. This reduction concerns regular old members, not a conditional class probability or a boundary measure.

Let $O_{e,Y}(y)$ be the actual old-origin member on a fixed run window, where e is a compatible exterior datum. Assume both e and a comparison datum e_0 give admitted functions on the same full complex ball $\|y\|_\infty < R$, with the same local filing. Let O be the exterior region where they differ. Suppose the actual background/boundary comparison yields the amplitude difference

$$|O_{e,Y}(y) - O_{e_0,Y}(y)| \le \varepsilon_\partial e^{-\lambda d(Y)} e^{-c\,\mathrm{dist}(Y,O)} \quad (\|y\|_\infty < R). \tag{4.ccvii}$$

This is a uniform function bound on the entire analytic ball. A comparison on the real cutoff box alone is not this premise.

Assume the actual supports have diameter at most $C_h(1 + d(Y))$, their free-coordinate counts are at most $C_h(1 + d(Y))^q$, and the number containing a fixed coordinate with $m \le d(Y) < m + 1$ is at most $C_D e^{\kappa_D m}$. When b belongs to Y,

$$\mathrm{dist}(b, O) \le C_h(1 + d(Y)) + \mathrm{dist}(Y, O). \tag{4.ccviii}$$

Choose $0 < c' < c$, $c'' > 0$ and a strict $\eta > 0$ so that $\lambda - C_h(c' + c'') > \kappa_D + \eta$. Such choices exist when $\lambda > \kappa_D$. On $\|y\|_\infty < R/2$, coordinate Cauchy in the common larger ball gives

$$\left| D_b \sum_Y [O_{e,Y} - O_{e_0,Y}](y) \right| \le \frac{C\varepsilon_\partial}{R} e^{-c'\mathrm{dist}(b,O)}. \tag{4.ccix}$$

Indeed only supports containing b contribute. For each such support Cauchy costs $2/R$. Using eq. 4.ccviii, its exponential weight is at most $e^{c'C_h} e^{-(\lambda - c'C_h)d(Y)} e^{-c'\mathrm{dist}(b,O)}$. The rooted count is then a convergent geometric sum. The estimates are uniform in finite volume, so the absolutely convergent sum and its derivative have the same limit on every smaller ball.

Two coordinate derivatives, with the same reasoning, also give the weighted row bound

$$\sum_{b'} e^{c''\mathrm{dist}(b,b')} \left| D_b D_{b'} \sum_Y [O_{e,Y} - O_{e_0,Y}](y) \right| \le \frac{C\varepsilon_\partial}{R^2} e^{-c'\mathrm{dist}(b,O)}. \tag{4.ccx}$$

For coincident coordinates the second Cauchy estimate has the factor 2!; for different coordinates use two independent discs. Both are bounded by a fixed constant times R^{-2}. For a given Y, summing b' costs at most its polynomial coordinate count times $e^{c''C_h(1+d(Y))}$. The strict rate inequality above leaves $e^{-\eta d(Y)}$, which absorbs that polynomial. This proves the asserted row bound, with constants independent of the number of window variables.

For the run-window radius $R = c\alpha_k/g_k$, these are explicit Cauchy costs in that same radius. If only R/r^4 has been admitted, the costs become r^4/R and r^8/R^2; they are not discarded. The remaining model question for eq. 4.ccix is the actual common-domain amplitude comparison in eq. 4.ccvii, with its compatible exterior, stored fields, gauges and relative boundary data. The interior Hessian estimate alone does not furnish that comparison. Even this regular old-origin force bound would leave the other terms of a clean conditional exponent, its boundary contributions and its normalized class law to be identified.

4.5.7. *Finite histories and the local formation norm.* The local estimates above are conditional on all admitted stored and boundary data. A finite history operation is an additional integral, not an extra name for the local Gaussian functional. We retain its read variables and its inner Wilson weight explicitly.

Let ω range over the discrete finite history records. Write ξ for the stored variables integrated by this history operation and P for the remaining admitted read data. Suppose the operation has been expressed over one parameter-independent positive reference measure $d\mu_\omega(\xi)$. Its complex integrand is $K_\omega(\xi; P)$. If a source derivative also inserts a local function $A_\omega(\xi; P)$, the relevant

estimate is on the product $K_\omega A_\omega$. One cannot first replace K_ω by its partition function and then take a supremum of A_ω on different fibres.

For $c \geq 0$, fixed history volume v_ω, and fixed read cores $\mathcal{C}_\omega$, define

$$\|K\|_c = \sum_\omega \int^* d\mu_\omega(\xi)\, e^{cv_\omega} \sup_{P \in \mathcal{C}_\omega} |K_\omega(\xi; P)|. \tag{4.ccxi}$$

The upper integral permits a supremum whose measurability has not been established; the same core and reference operation are used on both sides of every estimate. If $M_\omega(\xi)$ is a common positive envelope and

$$\sup_{P \in \mathcal{C}_\omega} |K_\omega(\xi; P) A_\omega(\xi; P)| \leq M_\omega(\xi)\, \varepsilon e^{-\lambda d(X)}, \qquad \sum_\omega \int d\mu_\omega\, e^{cv_\omega} M_\omega \leq C_H, \tag{4.ccxii}$$

then the norm of the localized insertion is at most $C_H \varepsilon e^{-\lambda d(X)}$. This follows directly from monotonicity of the upper integral and the sum over records. It requires no exchange of a supremum and an integral.

The inner Wilson factor belongs inside K_ω. On a real fibre it may supply positive action suppression, while its complex continuation must be controlled by the kept precision and the actual action reserve. It is not replaced by Haar measure alone. The weighted history argument supplies a route to the envelope in eq. 4.ccxii; the unmarked Gaussian polymer bound, by itself, supplies only a local bound after the history has been fixed.

For a finite list of records and a finite-dimensional source parameter, one may derive derivatives under this operation as follows. Suppose each kernel is pointwise holomorphic on a source disc, the operations and read cores are fixed, and a jointly measurable common envelope bounds its field supremum on every smaller source circle. Cauchy's formula, Tonelli's theorem for that envelope, and dominated convergence then give the kernel derivative and its norm bound. For an infinite record sum one needs the corresponding summable envelope or Banach-norm holomorphy in eq. 4.ccxi. Pointwise partition holomorphy alone does not establish that assertion.

Thus the finite local formation proof and the history-mass proof have distinct conclusions. The former gives the derivative in a small potential direction, with the actual bond rooting and own counterterm. The latter must pay the norm over stored fields and the sum of history records. Their composition is justified by a common envelope such as eq. 4.ccxii, not by dropping the retained Wilson factor or replacing an integral of a supremum by a pointwise polymer estimate.

4.6. **The actual Gaussian mismatch and its zero coefficient.** The action weight and the reference gauge weight need not coincide. Their ratio contributes a Gaussian term of order $|\tau - 1|$, which can be much larger than g. This term has an exact total at a physical constrained-critical background. The argument uses the actual contour gauge and the complete Hessian on the nonlinear averaging fibre. It explains why this Gaussian term is retained separately in an absolute-radius formation estimate.

4.6.1. *The averaging fibre and its residual gauges.* Consider one step on a periodic four-dimensional lattice, with odd block size $L \geq 3$. Let n be the number of coarse sites. There are $L^4 n$ fine sites. The symmetric contour average $\mathcal{M}$ is the map in eq. 2.iv. Its means and logarithms are taken on their admitted small branches. Fix a coarse field W.

Write $\mathcal{S}(V)$ for the physical action being expanded on the fine-step field V. At the first step it is the Wilson action. At a homogeneous later step it is the actual effective background action $A(U_k(V))$. In the latter case its gauge covariance, differentiability, and the asserted critical background are hypotheses concerning that actual background; the algebra below does not construct that background.

Let V_0 be a constrained-critical point on $\mathcal{M}(V) = W$. Use the actual nonpivot chart

$$V(u) = e^{i\Phi(u)} V_0, \qquad \mathcal{M}(V(u)) = W, \qquad \Phi(0) = 0, \quad D\Phi(0) = C, \tag{4.ccxiii}$$

where $u \in E \cong \mathbb{R}^d$ is the list of free nonpivot colour coordinates. One three-colour pivot is eliminated for each coarse bond. Hence

$$d = 12(L^4 - 1)n. \tag{4.ccxiv}$$

The chart is assumed to cover a neighborhood of the critical point, with the actual branch fixed. No assertion about a large history chart is made here.

A residual site gauge is a function v equal to one at every coarse node. Gauge covariance of the contour formula gives $\mathcal{M}(V^v) = \mathcal{M}(V)$, so these gauges preserve the actual fibre, including its nonlinear constraints. Their infinitesimal parameters form

$$\mathfrak{h} = \{\lambda : \lambda(y) = 0 \text{ at every coarse node } y\}, \qquad r := \dim \mathfrak{h} = 3(L^4 - 1)n. \tag{4.ccxv}$$

For a site $x \in B(y)$, let $T_{y,x}(V)$ be the actual symmetric contour transport from the block node y to x. It obeys

$$T_{y,x}(V^v) = v(y)T_{y,x}(V)v(x)^{-1}. \tag{4.ccxvi}$$

Indeed every path has this endpoint transformation, and uniqueness of the admitted symmetric mean gives the same law for that mean. Choose the block-axial representative with $T_{y,x}(V_0) = 1$. Such a representative is obtained by the single residual gauge $v(x) = T_{y,x}(V_0)$, with $v(y) = 1$. Define the actual local gauge coordinate

$$\ell_x(V) = \frac{1}{i} \log T_{y,x}(V), \qquad x \neq y, \qquad \ell(V_0) = 0. \tag{4.ccxvii}$$

These contours lie within their blocks and use no pivot crossing a block interface.

Let $T : \mathfrak{h} \to E$ be the tangent to the residual gauge orbit in the free coordinates of eq. 4.ccxiii, and let $G = D_u \ell(V(u))|_0$. At $v_t(x) = e^{it\lambda(x)}$, eq. 4.ccxvi gives $T_{y,x}(V_0^{v_t}) = e^{-it\lambda(x)}$. Therefore the exact linear identity is

$$GT = -I_{\mathfrak{h}}. \tag{4.ccxviii}$$

It is independent of the depth of the homogeneous background and does not require an estimate for an inverse Hessian.

4.6.2. *The complete physical Hessian.* Put $S(u) = \mathcal{S}(V(u))$. Constrained criticality means $DS(0) = 0$. The physical action Hessian is

$$K_A = D_u^2 S(0). \tag{4.ccxix}$$

It contains the second derivative of the constraint chart. To make this explicit, write $q(a) = \frac{1}{i} \log[\mathcal{M}(e^{ia}V_0)W^{-1}]$, $P = Dq(0)$, and take the actual pivot right inverse h, with $Ph = 1$. Differentiating $q(\Phi(u)) = 0$ gives

$$D^2\Phi(0)[u, v] = -hD^2q(0)[Cu, Cv]. \tag{4.ccxx}$$

The ambient action gradient satisfies $D\mathcal{S}(0) = P^{\mathsf{T}}\mu$, since it annihilates $\ker P$. Thus

$$K_A[u, v] = D^2\mathcal{S}(0)[Cu, Cv] - \langle \mu, D^2q(0)[Cu, Cv] \rangle. \tag{4.ccxxi}$$

The second term is part of the action Hessian, rather than a small potential to be discarded before the Gaussian split.

Lemma 4.11 (Gauge null directions of the constrained Hessian)**.** The complete Hessian satisfies $K_A T = 0$. Let the quadratic reference gauge fixing be $K_G = G^{\mathsf{T}} a G$, where $a > 0$ on $\mathfrak{h}$. Then

$$E = \ker G \oplus \operatorname{ran} T, \qquad K_A \operatorname{ran} T = 0, \qquad K_G \ker G = 0. \tag{4.ccxxii}$$

The two summands need not be orthogonal in the original free Euclidean coordinates; they are orthogonal for both quadratic forms in the displayed sense. ∎

Proof. The chart transports the residual gauge action to a local action $u \mapsto h_\lambda(u)$ on the exact fibre. Gauge invariance gives $S(h_{t\lambda}(u)) = S(u)$. Differentiate first in t, then in a free direction v, at $t = 0, u = 0$. The term involving the derivative of the gauge tangent is multiplied by $DS(0) = 0$. The remaining term is $K_A[v, T\lambda] = 0$. This uses the Hessian of S, including eq. 4.ccxxi.

For any $u \in E$, write $u = (u + TGu) - TGu$. The first term lies in $\ker G$ by eq. 4.ccxviii; the second is a gauge tangent. If $T\lambda \in \ker G$, then $0 = GT\lambda = -\lambda$, so the sum is direct. The assertions about K_G follow from its Gram form. □

When V_0 is a real constrained minimum, $K_A \geq 0$. The reference Gaussian requires

$$K := K_A + K_G > 0. \tag{4.ccxxiii}$$

This nondegeneracy is retained explicitly. The gauge argument does not prove positivity on the physical sector $\ker G$. The actual reference gauge-fixing function has zero first derivative at V_0, because all its contour variables equal one. Its Hessian is exactly $G^{\mathsf{T}} a G$; no chart curvature term is missing from that gauge Hessian.

4.6.3. *The determinant and the compensating expectation.* Let $\tau = x/\theta$ with $\mathrm{Re}\,\tau > 0$, and retain the reference gauge weight θ. The complete quadratic exponent is

$$Q_\tau = \tau K_A + K_G, \qquad -\tfrac{1}{2} u^{\mathsf{T}} Q_\tau u = -\tfrac{\tau}{2} u^{\mathsf{T}} K u + \tfrac{\tau-1}{2} u^{\mathsf{T}} K_G u. \tag{4.ccxxiv}$$

All determinant roots and $\log \tau$ below are continued from $\tau = 1$ in the right half-plane.

Proposition 4.12 (The actual mismatch normalizer)**.** Under the preceding physical hypotheses,

$$\det Q_\tau = \tau^{d-r} \det K, \tag{4.ccxxv}$$

$$\int e^{-u^{\mathsf{T}} Q_\tau u/2}\, du = \tau^{-(d-r)/2} \int e^{-u^{\mathsf{T}} K u/2}\, du, \tag{4.ccxxvi}$$

$$\int \exp\left(\tfrac{\tau-1}{2} u^{\mathsf{T}} K_G u\right) d\mu_{(\tau K)^{-1}}(u) = \tau^{r/2}. \tag{4.ccxxvii}$$

Here $d\mu_{(\tau K)^{-1}}$ is the normalized full Gaussian on E. It has no fluctuation cutoff. The two normalizing contributions are separately $-\frac{d}{2}\log\tau$ and $\frac{r}{2}\log\tau$; they do not cancel. ■

Proof. Choose bases in the two sectors of eq. 4.ccxxii, and combine them into one invertible change of coordinates S, independent of τ. In these coordinates

$$S^{\mathsf{T}} K_A S = \begin{pmatrix} A & 0 \\ 0 & 0 \end{pmatrix}, \qquad S^{\mathsf{T}} K_G S = \begin{pmatrix} 0 & 0 \\ 0 & B \end{pmatrix}, \qquad A > 0,\ B > 0.$$

The dimensions are $d - r$ and r. The factors $(\det S)^2$ cancel in the determinant ratio, giving eq. 4.ccxxv. Real Gaussian integration gives eq. 4.ccxxvi for real $\tau > 0$. For complex τ in the right half-plane, $\mathrm{Re}\, Q_\tau$ is positive:

$$\mathrm{Re}\, Q_\tau = (\mathrm{Re}\,\tau) K_A + K_G \geq \min(\mathrm{Re}\,\tau, 1) K.$$

This gives absolute convergence and holomorphic integration locally uniformly in that half-plane, so the same identity continues there. Equivalently integrate the two displayed blocks directly. Normalizing the Gaussian with precision τK contributes $\tau^{d/2}$; multiplication by eq. 4.ccxxvi gives eq. 4.ccxxvii. □

Corollary 4.13 (The mismatch has zero physical coefficient)**.** Suppose the localized mismatch family $\mathbf{G}_\tau$ is the actual free-potential leg of the Gaussian expansion, so its sum on a complete physical pair is the logarithm of eq. 4.ccxxvii. Then

$$\sum_X \sum_{z \in X} \mathbf{G}_\tau(X, \mathbf{p}_W, z) = \tfrac{r}{2} \log \tau. \tag{4.ccxxviii}$$

This total is independent of W. When the local Hessians converge normally and use the actual physical response and pointing, their bulk polarization and coefficient satisfy

$$\Pi^{\mathbf{G}_\tau} = 0, \qquad b[\widehat{\mathbf{G}}_\tau] = 0. \tag{4.ccxxix}$$

■□

Proof. The right side of eq. 4.ccxxvii is positive at real $\tau > 0$. Hence the logarithm selected from that real value is $r \log \tau/2$, which gives the sum rule. Differentiate it twice along the physical background map. The normally convergent sum of local second derivatives equals the second derivative of the constant total. At the trivial pair a first derivative of a scalar gauge-invariant family vanishes by constant colour rotations. Thus the extra first-derivative term from differentiating the background map vanishes, and the second derivative is precisely the bulk polarization computed with its physical linear response. It is zero. The second-moment readout defining the coefficient therefore gives zero as well. Compatible finite-volume localizations pass this equality to the companion family by normal convergence; no estimate of an individual local summand by zero is asserted. □

The sum rule extends to admitted complex physical data by holomorphic continuation of the actual background map from its real domain. It does not make the total constant on the whole independent-current pair core. That core contains directions transverse to the physical background manifold.

4.6.4. *Two essential qualifications.* First, the nonlinear constraint term in eq. 4.ccxxi cannot be removed from this argument. Even on a circle $q(p) = |p|^2 - 1 = 0$, the invariant action $\mathcal{S}(p) = |p|^2$ is constant on the rotation orbit. Its constrained action Hessian is zero, while its ambient Hessian is $2I$. The constraint curvature subtracts exactly that tangent contribution. The same chain rule accounts for the gauge null directions on the averaging fibre.

Second, replacing the physical current by an independent current changes that constrained Hessian. For example take

$$K_A = \operatorname{diag}(1, 0), \qquad K_G = \operatorname{diag}(0, 1), \qquad \widetilde{K}_A = \operatorname{diag}(1, e).$$

The physical determinant has the power in eq. 4.ccxxv, while the changed form has $\det(\tau\widetilde{K}_A + K_G) = \tau(1 + \tau e)$. Its compensating expectation is

$$\tau^{1/2} \left(\frac{1+e}{1+\tau e} \right)^{1/2},$$

which depends on the defect e. This shows why the actual independent-current completion and its defect must remain in the local Gaussian family, even though its physical total has zero coupling coefficient.

Finally, inserting sharp fluctuation tests into eq. 4.ccxxvii changes the identity. The test contribution belongs to the cutoff leg of the non-Gaussian formation remainder. The exact Gaussian mismatch is defined before those tests are turned on.

4.7. **Absolute-radius formation for the first homogeneous step.** We prove an absolute-radius formation estimate for the first homogeneous Wilson step. The precision, contour gauge, nonlinear pivot chart, coarea density and sharp fluctuation cutoff are the actual ones. A local covariance construction below supplies the enlarged cube-parameter discs required by the local expansion. Thus no decoupling-domain assertion is assumed for this step. The construction does not extend a later nonlocal effective Hessian by treating it as a finite-range Wilson matrix.

4.7.1. *The range of fields and the exact completion.* Fix the odd block size L. Work on periodic lattices which admit the L-blocks and the localization grids chosen below; their side lengths are at least ten localization cubes. All constants can depend on L, the requested output rate and the fixed localization choices, and are uniform in the volume.

Group delta integrals here mean the regular coarea disintegration of the actual analytic averaging map. Fix a sufficiently small absolute ϵ_{reg} and restrict this disintegration to fields whose fine plaquettes in every double block are below that ceiling. The logarithms are the regular branches of the pivot construction. No property of an arbitrary Borel completion outside this regular set is used.

The actual first-step chart of § 3.7 solves

$$q_U(a) = \frac{1}{i}\log[\mathcal{M}(e^{ia}U)\mathcal{M}(U)^{-1}] = 0, \qquad a = \Phi_U(u), \qquad \Phi_U(u)|_{\mathrm{nonpivot}} = u. \tag{4.ccxxx}$$

Its unscaled free radius is $r_u = c_u L^{-9}$. Its linear part is C_U, and its nonlinear pivot values use only their defining double blocks. On a fixed smaller radius, $\|\Phi_U(u)\|_\infty \le C_L\|u\|_\infty$, and all local derivatives through the orders used below have uniform bounds depending only on L. These are the explicit joint chart estimates proved in that section, not estimates for an unspecified many-level constraint.

Here is a gauge-covariant current completion on the entire local tube used in this proof. Put $J_A(U) = DA_U(0)$, and define

$$S_{U,J}(u) = A(e^{i\Phi_U(u)}U) - A(U) + \langle J - J_A(U), \Phi_U(u)\rangle - \langle J, C_U u\rangle, \tag{4.ccxxxi}$$

$$G_U(u) = \sum_{x\neq y(x)} a_x \left[1 - \tfrac{1}{2}\,\mathrm{Tr}\{T_{y(x),x}(e^{i\Phi_U(u)}U)T_{y(x),x}(U)^{-1}\}\right], \qquad a_x = 1. \tag{4.ccxxxii}$$

These are the actual unit contour-gauge weights in canonical Gaussian units, held fixed as τ varies. The relative contour product is holomorphic and conjugates at the block node under a simultaneous gauge change. Its value at zero is one. It uses no crossing pivot bond. Consequently both expressions have zero linear part, and

$$K_A(U,J) = D^2 S_{U,J}(0), \qquad K_G(U) = D^2 G_U(0), \qquad K(U,J) = K_A(U,J) + K_G(U). \tag{4.ccxxxiii}$$

On the real block-axial locus this is exactly the first-step matrix in eq. 3.cxxx, with its nonlinear constraint curvature term. The relative gauge has the same Hessian there as the absolute contour gauge. Away from that locus eq. 4.ccxxxii specifies the completion; no equality with a differently defined completion is presumed.

Choose fixed positive ϵ_0, j_0 strictly inside the real smallness bounds of eq. 3.cxxx. At a real reference pair suppose

$$\sup_p |1 - \partial U(p)| < \epsilon_0, \qquad \|J\|_\infty < j_0. \tag{4.ccxxxiv}$$

A node-fixed unitary contour gauge makes U block axial. The relative completion is covariant under this change, so the actual first-step estimates give, in the free coordinates,

$$\gamma I \le K \le BI, \quad \mathrm{range}\, K \le R_K, \quad \|K\|_{\mathrm{Sch}} \le B_{\mathrm{Sch}}, \qquad \gamma > 0. \tag{4.ccxxxv}$$

Increase $R_K = C_L L$ so it also bounds the radius of the background and current variables read by each coefficient. The Schur norm is the maximum of the absolute row and column sums of the three-by-three colour blocks. These constants depend only on L and the chosen strict real ceilings.

For $\mathbf{U} = e^{iE}U$, $\mathbf{J} = J + Z$, the same finite local chart gives the explicit perturbation estimate

$$\|K(\mathbf{U},\mathbf{J}) - K(U,J)\|_{\mathrm{Sch}} \le C_L(\|E\|_\infty + \|Z\|_\infty). \tag{4.ccxxxvi}$$

For completeness the relative-gauge version has this estimate because it is a fixed finite product of the admitted means, inverses and logarithms. In local unitary frames its arguments lie in the joint chart of radius cL^{-5}; a coefficient reads at most C_L variables and has bounded derivatives there.

Summation over their bounded incidence gives the Schur estimate. Thus the radius is absolute, rather than divided by the number of lattice sites.

For $\tau = x/\theta$, let $Q_\tau = \tau K_A + K_G$. Taking $|\tau - 1|$ sufficiently small adds at most $C_L|\tau - 1|$ to eq. 4.ccxxxvi. We shrink all these radii explicitly in the construction below. They remain independent of $g = \theta^{-1/2}$.

At an actual real constrained-critical background, with $J = J_A(U)$ and $T_{y,x}(U) = 1$, one has

$$S_{U,J}(u) = A(e^{i\Phi_U(u)}U) - A(U), \qquad G_U(u) = \mathrm{GF}(e^{i\Phi_U(u)}U). \tag{4.ccxxxvii}$$

The final linear term in eq. 4.ccxxxi vanishes because $C_U^{\mathsf{T}} J_A(U) = 0$. At nonphysical independent currents it is an auxiliary completion, which was written explicitly to avoid an unaccounted term of order g^{-1} in the linear expansion.

4.7.2. *A local covariance construction from the actual gap.* We give the construction with Q_τ denoted by K_c, and its chosen real reference in eq. 4.ccxxxv by K_r. Choose a real $a \geq 2B$, and write

$$H_r = I - K_r/a, \quad H_c = I - K_c/a, \qquad r = 1 - \gamma/a < 1. \tag{4.ccxxxviii}$$

The spectrum of H_r lies in $[0, r]$. Finite propagation and Cauchy–Schwarz in each matrix row give

$$\|H_r^j\|_{\mathrm{Sch}} \leq C_L(1 + j)^2 r^j. \tag{4.ccxxxix}$$

Indeed a row of H_r^j has at most $C_L(1 + j)^4$ nonzero blocks, and its squared row norm is bounded by a fixed colour factor times r^{2j}. The column estimate is the same. This estimate retains the cancellations inside each matrix power.

We will also use the local version of the real gap. There is a fixed radius $R_{\mathrm{gap}} = C_L$, independent of volume and of the set D, with the following property. If the real pair is given and obeys the strict ceilings on the R_{gap}-neighborhood of D, its actual Dirichlet coefficient matrix $K_{r,D}$ on free bonds of D satisfies $\gamma I_D \leq K_{r,D} \leq B I_D$. To check this, repeat the partition-of-unity proof of eq. 3.cxxx for a field supported on D. Only the fixed-size frame patches meeting its support are used. Taking R_{gap} larger than their diameters and the coefficient margin makes all these patches available in the given data. Axialize the real reference by its internal means first; the relative completion makes this a unitary change of the free coordinates. The subsequent block-constant frames, IMS error and flat comparison are then precisely those in that proof. No extension of a real field through the holes of D or across its exterior is required.

The estimate eq. 4.ccxxxix concerns one common real pair. The rooted activity norm below takes each local coefficient's data supremum before summing its endpoints and carriers. We retain a positive majorant for that stronger norm. For an entry of the already combined power, the same local compression and its spectral gap give $\|(H_r^j)(b, b')\| \leq r^j$, uniformly over the real data on its complete carrier. There are at most $C_L(1 + j)^4$ possible endpoints in a row or column. Put

$$p_j^+ = C_L(1 + j)^4 r^j, \qquad P_*^+ = \sum_{j \geq 0} p_j^+ < \infty. \tag{4.ccxl}$$

These are sums of coefficientwise local-data suprema. The smaller polynomial in eq. 4.ccxxxix cannot be used after moving separate suprema through the endpoint sum.

Fix a desired cube-parameter radius $S > 2$. Choose an integer m, to be made large, and put

$$T = H_c^m. \tag{4.ccxli}$$

One entry of T depends only on the matrix coefficients within distance $(m + 1)R_K$ of its two endpoints. Put $R_c = (m + 1)R_K + R_{\mathrm{gap}}$. Assign it the symmetric carrier consisting of both radius-R_c balls and all localization cubes they meet. Choose the fine cube size $M = M(m)$ to be the smallest power of L at least $16R_c$. Then $16R_c \leq M < 16LR_c$, so it still grows only linearly in m, is odd, and is compatible with the centered grids and power-of-L tori. For a root set W, its guard $W^\sharp$ is the union of all coarse cubes containing a fine cube at fine-cube wall distance at most

eight from a cube incident to W. This definition preserves unions and is used in every restriction and factorization below. Every short prefix H_c^j, $j < m$, starting at a root bond, together with its real-gap data collar, is contained in that root guard. The number c_s of coarse cubes in a short-step carrier is then bounded independently of m, volume and field.

Set $\eta_m^+ = p_m^+$. We also need a positive bound for the finite complex perturbation. For each actual finite-range coefficient, take the supremum of its norm over its common local real-reference and complex-pair domain. The bounded number of coefficients meeting a bond, and the finite local chart estimate eq. 4.ccxxxvi, give a fixed positive Schur envelope B_+ for both K_r and K_c on an initial smaller tube, and a difference envelope of Schur norm

$$\delta_K^+ \le C_L(\|E\|_\infty + \|Z\|_\infty + |\tau - 1|).$$

These envelopes take the supremum separately for each raw entry. They use only its full finite carrier. Define $C_H = 1 + B_+/a$. The telescoping polynomial identity, with these positive entry envelopes multiplied and summed, gives for every fixed $j \ge 1$

$$\|\mathbf{H_c^j} - \mathbf{H_r^j}\|_{\mathrm{Sch,sup}} \le \Delta_j^+ := (\delta_K^+/a) j C_H^{j-1}. \tag{4.ccxlii}$$

Set $\Delta_0^+ = 0$. Here the left side means the positive word majorant after taking each local coefficient supremum. Thus the estimate is stronger than a Schur bound at one common pair. Choose the fixed absolute tube and τ disc small enough that $\Delta_m^+ \le r^m$ and

$$\sum_{j=1}^{m-1} \Delta_j^+ \le r^m. \tag{4.ccxliii}$$

Both are quantitative finite inequalities, imposed after m, a, B_+ have been fixed. Their radii are positive and independent of g, volume and the number of sites.

For the combined power, the real entry bound and the positive difference envelope give a coefficientwise Schur majorant at most $p_j^+ + \Delta_j^+$. In particular the short step has bound $2\eta_m^+$, and the sum of all complex prefixes has bound $P_*^+ + 1$. The sum of their difference envelopes is at most $r^m \le \eta_m^+$. These bounds may be used before every carrier sum even when different coefficients are evaluated at different admitted local data.

Attach one parameter s_Δ to each coarse cube. Multiply an entire combined entry $T(b, b')$ by $\prod_{\Delta \in \mathrm{car}(b,b')} s_\Delta$, and call the resulting matrix T_s. We combine the polynomial entry before inserting this parameter, rather than separating its mutually cancelling fine paths. For $|s_\Delta| < S$,

$$\|T_s\|_{\mathrm{Sch}} \le 2S^{c_s}\eta_m^+ =: q_m^+. \tag{4.ccxliv}$$

All its coefficients are holomorphic local functions of the actual pair. Its carrier contains every background variable used by the entry.

Let $c_j = 4^{-j}\binom{2j}{j}$, the coefficients of $(1-z)^{-1/2}$. For a finite root set of free bonds W, hold the parameters at one on its fixed guard $W^\sharp$, and set

$$R_W(s) = a^{-1/2}\chi_W \sum_{j=0}^{m-1} H_c^j \sum_{k \ge 0} c_{km+j} T_s^k. \tag{4.ccxlv}$$

The prefix is local inside the root guard. The tail is a chain of the short-step carriers. Since $0 < c_j \le 1$, the positive prefix bound $P_*^+ + 1$ and eq. 4.ccxliv show that this series converges in Schur norm as soon as $q_m^+ < 1$.

At all parameters equal to one, grouping the absolutely convergent binomial series by j mod m gives

$$R_W(1) = \chi_W K_c^{-1/2}, \qquad D_W(s) := R_W(s) R_W(s)^{\mathsf{T}}, \qquad D_W(1) = \chi_W K_c^{-1} \chi_W^{\mathsf{T}}. \tag{4.ccxlvi}$$

Transposition is bilinear; no conjugation is inserted in this analytic covariance. The binomial identity is legitimate in the convergent coefficient algebra. In particular its square is K_c^{-1}, and its transpose is itself before the cube parameters are inserted.

Define the real short-prefix reference

$$R_{0,r} = a^{-1/2} \sum_{j<m} c_j H_r^j, \qquad D_{0,W} = \chi_W R_{0,r}^2 \chi_W^{\mathsf{T}}.$$

Since $H_r \geq 0$,

$$a^{-1} I_W \leq D_{0,W} \leq \gamma^{-1} I_W. \tag{4.ccxlvii}$$

Its definition uses only the fixed guard of W. Equations eq. 4.ccxliii and eq. 4.ccxlv give, uniformly on all the enlarged parameter discs,

$$\|R_W(s) - \chi_W R_{0,r}\|_{2\to 2} \leq a^{-1/2} \left[\eta_m^+ + (P_*^+ + 1) \frac{q_m^+}{1 - q_m^+} \right] =: \zeta_m^+. \tag{4.ccxlviii}$$

Consequently $\|D_W(s) - D_{0,W}\| \leq C_{a,\gamma} \zeta_m^+ + (\zeta_m^+)^2$, independently of the local and auxiliary dimensions. As $m \to \infty$, this tends to zero exponentially, while $M(m)$ grows only linearly. We may therefore choose m so large that

$$q_m^+ < 1/4, \qquad C_{a,\gamma} \zeta_m^+ + (\zeta_m^+)^2 \leq c_* (LM(m))^{-4}. \tag{4.ccxlix}$$

Here c_* is any prescribed small Gaussian comparison constant. The order is: fix the desired rates and S; choose m and $M(m)$; then choose the absolute tube and τ disc by eq. 4.ccxlii–eq. 4.ccxliii.

Proposition 4.14 (Admitted local Gaussians for the actual first step)**.** On the resulting fixed absolute tube, the functions

$$\mathcal{J}_W(s)[F] = \int_{\mathbb{R}^{3\#W}} F(b)\, d\mu_{D_W(s)}(b) \tag{4.ccl}$$

are normalized holomorphic local Gaussian functionals for $|s_\Delta| < S$. They obey the local Gaussian comparison of Prop. 4.7, with perturbation at most $c_*(LM)^{-4}$ and with $\Gamma = 0$. At complete physical data and $s = 1$, they are the actual marginals of the first-step Gaussian with precision Q_τ. When parameters vanish outside a union Z containing $W^\sharp$, they read no pair data outside Z, and they factor over the wall components of Z. ■

Proof. The covariance is symmetric and within the bound eq. 4.ccxlix of the real positive matrix $D_{0,W}$. In particular its real part is uniformly positive after decreasing c_*. The Gaussian integral and its determinant branch are therefore defined on the whole indicated polydisc, are normalized, and are holomorphic with measurable sharp functions allowed in F. Apply Prop. 4.7 with $C = D_W$, $C_0 = D_{0,W}$, $\Gamma = \Gamma_0 = 0$. Only $3\#W$ coordinates occur in this comparison. The possibly much larger column space of R_W is not charged as a Gaussian dimension. Completeness is eq. 4.ccxlvi.

If parameters outside Z are zero, each surviving short step has its full carrier in Z. Every prefix from a root in W is already in its guard. Thus every coefficient and intermediate column used by that row lies in the same wall component as the root. A short-step carrier is a connected cube union containing both endpoints; it cannot join two different components without reading a zero parameter. Prefix carriers are connected and lie in the guard. Rows rooted in different components therefore have disjoint column supports. Their bilinear covariance blocks are zero, proving Gaussian factorization. The same description proves dependence only on pair data in Z and the required hereditary restriction identity for the fixed root support and its held guard: computing from the restricted pair in Z agrees with any larger ambient computation whose parameters are zero outside Z. At complete parameters the usual nested marginal identities follow from eq. 4.ccxlvi. □

This is a localization of the actual covariance, fixed once for all tori in the admitted class. It need not equal another walk expansion term by term. Its full Gaussian marginals, nonlinear integration variables, and complete physical integral are exactly the original ones.

The estimates and local recipes hold also for pairs given only on the output domain. To see the domain point explicitly, retain only entries whose full carrier is contained in that domain. If a retained entry has first endpoint b, the real data on its radius-R_c ball are present. Compress the actual matrix to the radius-mR_K ball about b. The preceding local gap applies to this compression. The row at b of its m-th H power is the same polynomial row as the uncompressed one: none of its length-m paths can leave that ball. This proves the pointwise estimate eq. 4.ccxxxix for that entire common-data row before any inadmissible entries are deleted. For coefficientwise local-data suprema, apply the same compression to each entry separately and count its possible endpoints; this gives eq. 4.ccxl. The positive finite-range perturbation envelopes give eq. 4.ccxlii on these local domains as well. Deleting entries can only decrease either positive majorant, and symmetry gives the corresponding column bounds. For the root prefix and $D_{0,W}$, use one common Dirichlet compression to the mR_K-neighborhood of W; its needed real-data collar is inside $W^\sharp$. This preserves eq. 4.ccxlvii. Thus the local estimates are on the actual local pair domains with these collars, rather than only on restrictions of globally extendible real fields.

The same construction localizes the Gaussian logarithms. For the actual matrix K_c, the identity

$$\log K_c = (\log a)I - \sum_{\ell\ge 1} H_c^\ell/\ell \tag{4.ccli}$$

converges in Schur norm after grouping $\ell = km + j$, $0 \le j < m$, and omitting $\ell = 0$. Its diagonal trace at a bond is expanded as the finite prefix H_c^j followed by k actual short steps. The carrier is the union of their full carriers. It is connected and has tree length at most $C_0 + c_s k$. Multiplication by $e^{\kappa d_c(X)}$ therefore costs at most $e^{\kappa C_0} e^{\kappa c_s k}$. Choose S and m above with this additional rate reserve. Each word is bounded by the product of the positive prefix and short-step envelopes before taking the supremum on its own union carrier. Summing those positive words proves that the coefficientwise absolute rooted sum is bounded by

$$C \sum_{j<m} (p_j^+ + \Delta_j^+) \sum_{k\ge 0} (2\eta_m^+ e^{\kappa c_s})^k \le C(P_*^+ + 1),$$

with the finitely many $k = 0, j > 0$ terms included. This proves locality and an absolute, volume-independent rooted norm for the actual Gaussian log normalizer. The value $\log J_U(0)$ adds its finite local pivot terms and fixed numerical powers; its nonconstant part has the same type of bound by the joint pivot chart.

Use the same localization on a τ disc four times larger than the disc retained in the conclusion. Applying it to $-\frac{1}{2}\log\det Q_\tau + \frac{1}{2}\log\det K + \frac{d}{2}\log\tau$ gives the mismatch family. Its terms vanish at $\tau = 1$, and the Cauchy bound in this actual larger disc proves their rooted bound $C|\tau - 1|$. Its physical total remains exactly eq. 4.ccxxviii. The construction does not classify that term as a g-small vertex.

The Gaussian normalizer is pointed at each diagonal free bond in eq. 4.ccli; each zero-field pivot factor is pointed at that pivot. Colour traces are invariant under the local adjoint frames. Their midpoint tents give the pointed normalizer, with the same rate reserve.

For the mismatch use its actual gauge-quadratic interpolation, which also fixes its bond density:

$$\begin{aligned} Q_{\tau,u} &= \tau K - u(\tau - 1)K_G, \qquad 0 \le u \le 1, \\ g_{\tau,b}(P) &= \frac{\tau - 1}{2} \int_0^1 \mathrm{tr}[K_G Q_{\tau,u}^{-1}](b,b)\, du. \end{aligned} \tag{4.cclii}$$

Indeed $Q_{\tau,0} = \tau K$ and $Q_{\tau,1} = Q_\tau$. Differentiating its Gaussian determinant gives $\sum_b g_{\tau,b} = \mathcal{G}_\tau$, with the same normalization as above. The integrand is the expectation of the actual insertion $(\tau - 1)B(b) \cdot (K_G B)(b)/2$. All $Q_{\tau,u}$ stay in the same admitted local tube after a fixed decrease of the retained τ disc. Their inverse series uses $a^{-1}\sum_{\ell\ge 0} H_{\tau,u}^\ell$, grouped by the same short powers. Marking its one finite-range K_G factor preserves the carrier bound. Hence eq. 4.cclii has local

pointed terms of norm $C|\tau-1|$. This identifies the pointing by the defining interpolation, including in the noncommuting curved case.

4.7.3. *The actual coarea density and the intrinsic vertices.* Write $g=\theta^{-1/2}$, $\mathfrak{b}=A_1(\log\theta)^p\geq 1$, and keep the cutoff $\chi=\prod_b \mathbf{1}_{\{|B(b)|<\mathfrak{b}\}}$ fixed at this real reference. Choose g so small that

$$16C_L g\mathfrak{b}<r_u. \tag{4.ccliii}$$

Every argument $\Phi_U(tgB)$, $|t|\leq 4$, and every local old-member substitution below then lies in the actual unscaled graph chart. Cube parameters do not change these local graphs: their complete double-block support is kept in each selected potential's guard. They change the local Gaussian functional outside that guard by the construction just proved.

Let p_c be the three pivot coordinates of row c. Eliminating the exact constraint in these coordinates gives the relative density

$$J_U(u)=\prod_b j(\Phi_U(u)(b))\prod_c \det[D_{p_c}q_U(\Phi_U(u))]^{-1}\,,\qquad j(a)=\left(\frac{\sin\sqrt{a\cdot a}}{\sqrt{a\cdot a}}\right)^2. \tag{4.ccliv}$$

The factor g^d and the fixed Haar and gauge normalizers are independent of B. We use the raw logarithmic constraint q_U throughout. A per-length constraint would require its compensating factor L^{-3} for every coarse bond; it must not be inserted a second time into the present raw convention. At real arguments the pivot determinant has its positive identity sign. Its reciprocal in eq. 4.ccliv is the holomorphic continuation, with no complex absolute determinant. Each pivot factor reads only its double block.

On the uniform unscaled radius, the logarithm of each factor of $J_U(u)/J_U(0)$ is holomorphic, vanishes at zero and has derivative bounded by C_L. For the pivot factor this follows by differentiating $-\operatorname{Tr}\log[D_pq(u)(D_pq(0))^{-1}]$, using the actual pivot lower bound and joint chart radius. For Haar it follows from eq. 4.dlvii. Hence its local logarithmic vertices satisfy a linear bound $C_Lg\sum_{b\in S}|B(b)|$ on their fixed supports.

Subtract the full quadratic parts, and define

$$\begin{aligned}P_g^A(B)&=-g^{-2}\{S_{U,J}(gB)-\tfrac12 g^2B^{\mathsf T}K_AB\},\\ P_g^G(B)&=-g^{-2}\{G_U(gB)-\tfrac12 g^2B^{\mathsf T}K_GB\},\\ P_g^J(B)&=\log[J_U(gB)/J_U(0)].\end{aligned} \tag{4.cclv}$$

Every Wilson plaquette, relative contour gauge term and current-completion term is a holomorphic function of a fixed finite list of free coordinates, on an unscaled radius. Its first three derivatives are uniformly bounded there by the actual chart estimates. Taylor's integral formula consequently gives, for each such local term,

$$|g^{-2}R_3(gB)|\leq C_Lg\left(\sum_{b\in S}|B(b)|\right)^3\leq C_Lg\mathfrak{b}\sum_{b\in S}|B(b)|^2. \tag{4.cclvi}$$

The second inequality uses the fixed bound on $\#S$ and the actual cutoff $|B(b)|\leq\mathfrak{b}$. The coefficients are uniform on the absolute external pair tube, not just at $U=1$. The current-completion correction is included before this Taylor expansion. The same estimates, with a fixed increase in C_L, hold on nested complex fluctuation boxes $|B_b^a|<\nu(1+\mathfrak{b})$, for a fixed $1<\nu<9/8$, and on their fixed radial margins. The factor sixteen in eq. 4.ccliii leaves this room for the independent-bond pointing construction.

Group these terms into their actual fine localization cube carriers, enlarged by the fixed double-block collar. For $Q_Y(B)=1+M^{-4}\sum_{b\subset Y}|B(b)|^2$, the finite support and incidence counts give

$$|V_g^{\mathrm{int}}(Y;P,B)|\leq C_{L,M}g\mathfrak{b}\,e^{-\lambda_V d_f(Y)}Q_Y(B),\qquad V_g^{\mathrm{int}}=\tau P_g^A+P_g^G+P_g^J. \tag{4.cclvii}$$

Indeed each elementary support meets a bounded number of fine cubes, so its exponential carrier cost is fixed; a fine cube contains $O(M^4)$ elementary terms, and a free coordinate enters only C_L of them. All these finite factors are included in $C_{L,M}$. The same bound holds for $|\tau-1|$ on its fixed admitted disc.

4.7.4. *Admitted old functions and ordinary source profiles.* Let a local input $S_{\mathrm{old}}=\sum_X f_X$ be holomorphic on fixed pair balls of radii $a_{H,U},a_{H,J}>0$ around the indicated field and current, with bounds B_X and

$$\sup_b \sum_{X\ni b} e^{\lambda_H d_f(X)} B_X \le H_0. \tag{4.cclviii}$$

Use the same physical input function before and after the chart substitution. To include its current argument, define the following explicit pair map:

$$\begin{aligned} U_P(u) &= e^{i\Phi_U(u)}U, \\ \Psi_P(u) &= \big(U_P(u), J + J_A(U_P(u)) - J_A(U)\big), \qquad P=(U,J). \end{aligned} \tag{4.cclix}$$

The fine Wilson gradient reads only its adjacent plaquettes. Its local derivative is uniformly bounded on these fixed unscaled tubes. Hence $\|J_A(U_P(u))-J_A(U)\|_\infty \le C_L\|u\|_\infty$. This is the actual gradient variation, rather than a current held fixed during a physical field variation. The map is jointly gauge covariant, equals P at zero, and at a physical pair maps exactly to $(U_P(u), J_A(U_P(u)))$. Put $a_H=\min(a_{H,U},a_{H,J})$, and require $16C_L g\mathfrak{b}<a_H$ as well as eq. 4.ccliii. The exact old potential is

$$V_X^{\mathrm{old}}(B) = f_X(\Psi_P(gB)) - f_X(P). \tag{4.cclx}$$

Its second value stays in the carried background action. The local substitution reads the fixed double-block enlargement of X, including the adjacent plaquettes needed for its current arguments. The analytic path $t\mapsto f_X(\Psi_P(tgB))$ is admitted up to $|t|<c\min(r_u,a_H)/(g\mathfrak{b})$. The one-variable Cauchy difference on that actual path gives

$$|V_X^{\mathrm{old}}(B)| \le C_L \frac{g\mathfrak{b}}{\min(r_u,a_H)} B_X.$$

The enlargement of a domain has at most a fixed multiple of its tree length plus one. Choose λ_H larger than that multiple of λ_V, with a strict incidence/entropy reserve. Refiling by that enlargement and summing eq. 4.cclviii then gives the actual potential budget

$$\|V^{\mathrm{old}}\|_{\lambda_V} \le C_{L,M,a_H} H_0 g\mathfrak{b}. \tag{4.cclxi}$$

All input origins with the same carrier are summed before this estimate; their number is not counted as a number of independent Gaussian variables or potential types.

This includes the ordinary profile presentation of a Wilson source $\sum_p w(p)a_p$, with w on fixed complex coefficient discs. Each term is a finite local holomorphic word, and eq. 4.cclviii holds with $H_0\le C\|w\|_\infty$. The Gaussian, chart, reference gauge weight and sharp cutoff stay fixed as this source is varied. A constant-shift presentation which instead changes τ uses its separate Gaussian mismatch and numerical factor.

4.7.5. *The three output families and the exact first-step law.* Let $\mathcal{N}^\circ$ be the localization just constructed of the vacuum-subtracted coarea and Gaussian normalizer at $\tau=1$:

$$\mathcal{N}^\circ(P) = \log\frac{J_U(0)}{J_1(0)} - \frac{1}{2}\log\frac{\det K(U,J)}{\det K(1,0)}. \tag{4.cclxii}$$

Its vacuum factors stay in the exact numerical normalization. Let $\mathcal{G}_\tau$ be the free Gaussian mismatch defined before cutoffs, as in Prop. 4.12. Define the last family from the actual normalized integral

$$\mathcal{F}_g(P) = \log\int \chi(B)\exp\{V_g^{\mathrm{int}}(P,B)+V^{\mathrm{old}}(P,B)\}\,d\mu_{Q_\tau^{-1}}(B). \tag{4.cclxiii}$$

This is a definition of the output, not an assumed bound.

Proposition 4.15 (Actual first-step absolute-radius formation)**.** Choose the rates and localization sizes as above. There is a coupling floor θ_*, independent of volume, such that eq. 4.cclxiii is nonzero and has an actual union-filed logarithm $F_g(X,P)$ on the full fixed absolute pair tube. Its terms satisfy

$$|F_g(X,P)| \le C\left[(1+H_0)g\mathfrak{b} + e^{-c\mathfrak{b}^2}\right] e^{-\kappa d_c(X)}. \tag{4.cclxiv}$$

The same estimate, after a fixed decrease of the spatial rate, holds for the constructed bond-rooted pointing and its midpoint tent sum. The constants include the fixed absolute radii, but contain no inverse power of g. The output splits into the actual Gaussian family, the Gaussian mismatch, and this remainder. In particular $F_g = O(g(\log\theta)^p)$. ■

Proof. The preceding construction supplies every Gaussian matrix, enlarged coarse-parameter disc, normalization, hereditary restriction and wall factorization used in the unmarked local expansion of § 4.5. The local coordinate set for an index is taken to contain all free bonds of its full fine support Z_0, not merely the bonds on which its integrand changes. Thus background supports of the selected potentials, including a background factor constant along the fibre, lie in the held guard as well. Adding these integrated coordinates does not change a Gaussian expectation of that integrand. The local coordinate count is at most $C(LM)^4\#Z$ for a polymer Z. There is no auxiliary-volume factor. The potentials are the literal local functions in eq. 4.cclv and eq. 4.cclx, with their actual cutoff supports. Equations eq. 4.cclvii and eq. 4.cclxi give $a_g \le C(1+H_0)g\mathfrak{b}$.

Apply the proved finite Mayer, cutoff and coarse interpolation estimates to these data. Their activity bound has amplitude $C(a_g + p_*)$, where $p_* \le C(LM)^4 e^{-c\mathfrak{b}^2}$. The rooted connected-cluster bound and union filing then give eq. 4.cclxiv. All its numerical smallness conditions hold after increasing θ_*, because $g\mathfrak{b} \to 0$ and $e^{-c\mathfrak{b}^2} \to 0$. This uses that $A_1(\log\theta)^p$ tends to infinity; choose $p > 1/2$, so its cutoff tail is also $O(g\mathfrak{b})$.

The Jacobian and old functions are rooted along $B \mapsto tB$. For the cubic action and gauge remainders use precisely the normalized path $t^{-2}P_g^{A,G}(tB)$, with the covariant shares and independent bond derivatives of eq. 4.cxxvii. In particular the bond insertion includes the derivative of t^{-2}; it is not the unnormalized Euler insertion. The admitted chart has a fixed radial margin by eq. 4.ccliii. The order-three vanishing and the local unscaled derivative estimates used in eq. 4.cclvi, followed by eq. 4.cxxx, give the rooted budgets with the same $g\mathfrak{b}$ factor, uniformly down to $t = 0$. The cutoff leg is the actual moving-threshold boundary term of eq. 4.cxxxix. It supplies its Gaussian tail and retains its bond root. Thus the previously proved rooted expansion applies to these literal legs; no pointing is inferred merely from an unpointed norm. Summing their midpoint tents costs a polynomial domain factor, absorbed by the reserved rate. □

Here is the exact physical normalization. Let U be the actual first-step constrained-critical background, in its block-axial representative. In this formula $S_{\mathrm{old}}(U)$ denotes the physical restriction $S_{\mathrm{old}}(U, J_A(U))$. Apart from the external coarse indicator, the bare small-field integral equals

$$e^{-xA(U)+S_{\mathrm{old}}(U)}\, C_{\mathrm{num}}(\theta) g^d J_U(0)(2\pi)^{d/2}(\det K)^{-1/2}\tau^{-d/2}\exp\{\mathcal{G}_\tau + \mathcal{F}_g\}. \tag{4.cclxv}$$

More explicitly, let n_f, n_c be the numbers of positive fine and coarse bonds, and let $n_s = N_f - N_c$ be the number of node-fixed gauge sites. In the raw convention of eq. 4.ccxxx,

$$C_{\mathrm{num}}(\theta) = \sigma_0^{n_f - n_c} z(\theta, \varepsilon_\theta)^{-n_s}, \qquad d = 3(n_f - n_c), \tag{4.cclxvi}$$

where σ_0 is Haar density at zero and z is the normalized group integral of the single-site contour gauge with its retained test. Indeed the fine Haar densities contribute $\sigma_0^{n_f}$, and each coarse group delta, written in raw logarithms, contributes σ_0^{-1}. At the trivial field the raw pivot derivative is $L^{-3}I_3$, so $J_1(0) = L^{9n_c}$. Equivalently one may use the per-length pivot derivative $L^{-4}I_3$, its factor L^{12n_c}, and the delta conversion L^{-3n_c}; their product is the same. Equation eq. 4.ccliv proves the coordinate identity; the centered action and gauge agree with the physical ones by eq. 4.ccxxxvii.

The quadratic normalization is Prop. 4.12. Every factor depending on U is included, in particular $J_U(0)$.

The first-step formation budget can therefore be closed in the prescribed order. The construction gives constants C_N, C_G, C_F, independent of the allowed old-input size N_*, such that

$$\|\mathbf{N}^\circ\|_+ \le C_N, \qquad \|\mathbf{G}_\tau\|_+ \le C_G|\tau-1|, \qquad \|\mathbf{F}_g\|_+ \le C_F\{(1+N_*)g\mathfrak{b} + e^{-c\mathfrak{b}^2}\}.$$

Choose $E_0 \ge 2C_N$, then the old-input ceiling N_*; decrease $|\tau-1|$ so that its term is at most $E_0/4$; finally increase the coupling floor so that the last term is at most $E_0/4$. This gives $\|\mathbf{N}^\circ + \mathbf{G}_\tau + \mathbf{F}_g\|_+ \le E_0$ for the proved first-step range, without putting E_0 or N_* into the preceding Gaussian or nonlinear chart choices.

Corollary 4.16 (Ordinary source jets in the proved first-step range)**.** Insert the literal profile $\sum_p w(p)a_p$ on the fixed source ball $\|w\|_\infty < \rho$. For $\|w\|_\infty \le \rho/2$, $n \ge 1$, and arbitrary profiles $h_1, \dots, h_n$,

$$|D_w^n F_g(X; w)[h_1, \dots, h_n]| \le C_\rho g\mathfrak{b}\, n!(2e/\rho)^n e^{-\kappa d_c(X)} \prod_{i=1}^n \|h_i\|_\infty. \tag{4.cclxvii}$$

The same estimate holds for the constructed pointing with its reserved spatial rate. Only the source plaquette vertices whose complete carriers are filed inside X occur in that derivative. ■□

Proof. The source potential is the actual admitted old difference already considered; its norm on the full source ball is at most $C\rho g\mathfrak{b}$. All Gaussian, chart and cutoff arguments stay fixed. The Mayer integrals and convergent cluster sum are therefore holomorphic in these source coefficients, with eq. 4.cclxiv uniformly on that ball. For nonzero h_i, use the independent complex directions $w + \sum_i z_i h_i$ on $|z_i| < \rho/(2n\|h_i\|_\infty)$. They lie in the admitted source ball. The multivariate Cauchy formula bounds the mixed derivative by $C_\rho g\mathfrak{b}(2n/\rho)^n \prod_i \|h_i\|_\infty e^{-\kappa d_c(X)}$. Use $n^n \le e^n n!$. A zero direction gives zero. The same argument applies to the analytic rooted terms. Their source support is literal: an activity filed inside X uses only selected potential carriers inside X, and its cluster union stays there. No source variable outside that set is read. □

4.7.6. *Physical tests and the largest proved range.* The preceding fixed absolute domain is the analytic domain of the filed functions. It is not the support of every original external small-field indicator. We first check that this regular coarea fibre contains exactly the graph used above on the free fluctuation box. Every middle pivot belongs to an elementary plaquette whose other three bonds are free; choose a fixed perpendicular direction. Odd $L \ge 3$ keeps every other middle pivot out of that plaquette. Let V be in the regular coarea set, with average $W = \mathcal{M}(U)$, and with its free bond logarithms relative to U at most $\delta = g\mathfrak{b}$. Solving that plaquette product for its pivot bond, and subtracting the corresponding expression for U, gives

$$\max_{\text{pivots}} \|V(b)U(b)^{-1} - I\| \le 2\epsilon_{\mathrm{reg}} + C\delta. \tag{4.cclxviii}$$

Here the other three factors are unitary and their differences are at most $C\delta$; the two plaquette products differ by at most $2\epsilon_{\mathrm{reg}}$. These estimates are unchanged by their left and right transports. The pivot fixed-point map has derivative at most $C_L\|a\|_\infty$ in a fixed full-field ball $r_p = c_p L^{-5}$, as follows from its quadratic constraint remainder and pivot inverse. Choose ϵ_{reg} so small that eq. 4.cclxviii puts all full logarithms in that uniqueness ball, and then take δ below its fixed small floor. The equation $q_U(a) = 0$, with its fixed free values, has exactly the chart solution there. Thus $V = e^{i\Phi_U(gB)}U$ and its pivot values obey the sharper $C_L g\mathfrak{b}$ bound. Conversely the graph stays in the regular coarea set when the background curvature is below $\epsilon_{\mathrm{reg}}/2$ and $g\mathfrak{b}$ is small enough. This proves the full change of variables on the stated regular fibre, rather than just an injective parametrization of a subset.

For the homogeneous tame operator itself, take real coarse data with $\|1 - \partial W\|_\infty < \epsilon_W$, where the fixed absolute $\epsilon_W > 0$ is small enough for § 3.8 and eq. 4.ccxxxiv. No shrinking curvature

condition is needed for that operator. Its additional tests are the contour-gauge tests at threshold $\varepsilon_\theta = A_0 g(\log\theta)^p$. The background contour means are exactly one, and those means read only internal free bonds. The product/mean derivative estimate therefore gives their deviations at most $C_L g\mathfrak{b}$, independently of the background curvature. Choose $A_0 > 2C_L A_1$. These indicators are then identically one. The nonpivot fluctuation field in eq. 4.ccxxx is exactly gB, so its prescribed test is exactly χ. This proves eq. 4.cclxv on the fixed absolute physical background range.

If this factor is used in a history with extra plaquette indicators, a sufficient common-test range is smaller. Namely require $\|1-\partial W\|_\infty < c_L\varepsilon_\theta$. The actual background fine curvature is then at most $C_L c_L \varepsilon_\theta$, and the graph changes fine plaquettes by at most $C_L g\mathfrak{b}$. Taking c_L and A_1/A_0 sufficiently small puts their sum below half the indicated thresholds. Those additional tests are identically one on the same box. Their identity has not been asserted on the larger absolute physical range.

Any such coarse external indicator remains outside this formula. It cannot be analytically continued as an indicator on a fixed absolute ball: a fixed nonzero real curvature eventually exceeds $A_0 g(\log\theta)^p$. The absolute-radius output is instead the analytic extension of the displayed fluctuation formula, with that external indicator factored out. The physical background continuation in the first-step theorem supplies its composition on a fixed sufficiently small complex coarse-datum ball. Its current is $J_A(U(W))$, so it lies in the physical completion just used. Source profiles vary on their independent fixed discs while the tests keep their real reference values.

The proof covers this actual first bare homogeneous step, arbitrary compatible volume and real flat holonomy, and its specified absolute complex tube. For a later step the effective action $A(U_k(V))$ is nonlocal. Its Hessian does not have the finite propagation used in eq. 4.ccxxxix and the short-step carrier construction. Extending this result to all homogeneous levels requires a proved localized effective-precision expansion and the corresponding unscaled nonlinear response domains. Those are the earliest additional operator and domain inputs; they are not replaced by assuming the desired activity norm.

4.8. **Connected trees for the actual homogeneous effective action.** The homogeneous background of Prop. 3.183 has an expansion whose spatial rate is independent of its Taylor order. We derive it from the actual Wilson and averaging equations. This supplies local analytic terms for $S_k(V) = A(U_k(V))$; localization by a single large ball would not give the connected carriers below.

The coarse spacing is one and $h = L^{-k}$. Use the parallel frame of the fixed flat reference W_0, and coarse coordinates $V_B = e^{iB}V_0$. Fine pairings use h^4 times counting measure. The constants in this section are independent of h, compatible volume and flat holonomy. The localization size, chosen after a requested rate, is allowed to enter them. No independent fine-current core or hereditary nonlinear tower is asserted.

Gauge invariance holds for the complete physical sum S_k. Its individual fixed-reference Taylor terms need not be gauge invariant. An application requiring individually invariant core members needs a gauge-covariant localization in addition to the analytic filing proved here.

4.8.1. *The actual cell equation and its analytic vertices.* Write $x = (A,\omega)$, with the strong norm $\|A\|_{X_\alpha} + \|\omega\|_\infty$ of eq. 3.mccxxiii. The actual equation is

$$x = \mathcal{L}_0^{-1}\{\iota B + \mathcal{R}_h(x)\}, \qquad \mathcal{R}_h(A,\omega) = \begin{pmatrix} -N_h(A) + (q_h'(A) - Q)^\sharp\omega \\ -[q_h(A) - QA] \end{pmatrix}. \tag{4.cclxix}$$

Here $\iota B = (0,B)$, not a fine point-mass insertion. Each component in the first row is an actual fine forcing with the physical density appropriate to $\sharp$. The second row is a coarse bond field. In particular $\mathcal{R}_h(0) = D\mathcal{R}_h(0) = 0$.

Choose a smooth partition $\sum_y \chi_y = 1$ on physical unit cells, with a fixed support enlargement and uniformly bounded derivatives through order three. Sample it on the fine lattice. The discrete

product rule, including the local Hölder difference, gives

$$\|\chi_y A\|_{X_\alpha} \le C\|A\|_{X_\alpha(\mathrm{star}\, y)}. \tag{4.cclxx}$$

Indeed $D(\chi A) = (D\chi)A + \chi(\cdot+h)DA$; one further difference uses only bounded $\chi, D\chi, D^2\chi$, A, DA and the local Hölder seminorm of DA. All distances are physical, so there is no negative power of h in this multiplication bound.

Let $E_y x$ consist of $\chi_y A$ and the coarse multiplier components assigned to cell y. Then $x = \sum_y E_y x$, with bounded local overlap. Let I_z inject the fine forcing on cell z and its assigned coarse forcing. The fine input norm here is L^∞, so characteristic cell restriction of that forcing needs no derivative. The actual block propagator

$$\mathcal{G}_{yz} = E_y \mathcal{L}_0^{-1} I_z \tag{4.cclxxi}$$

satisfies

$$\|\mathcal{G}_{yz}\| \le C_G e^{-s_0 d(y,z)}, \qquad G_s := \sup_y \sum_z e^{s d(y,z)} \|\mathcal{G}_{yz}\| < \infty \quad (0 < s < s_0). \tag{4.cclxxii}$$

This follows directly from the weighted joint inverse Prop. 3.182, with the weight centered on the input cell. The constants include the fixed support of E_y. The inverse retains both the field and the multiplier.

There is a fixed physical radius $R_0 = C_L$ such that the output $\mathcal{R}_{h,z}$ reads only the components $E_y x$ with $d(y,z) \le R_0$. This assertion concerns the actual nonlinear functions in eq. 4.cclxix. For the Wilson term it follows from its fine plaquette stencil and its exact normal-coordinate differential. The factor h in that differential cancels the possible h^{-1} from a second fine difference, as in eq. 3.mcclxv. For q_h, the successive carrier radii are bounded by $C_L \sum_{j<k} hL^j \le C_L$. In its physical transpose only coarse rows whose carriers meet the output fine bond occur. The fixed-leg column density Ch^4 in eq. 3.mcclviii cancels the h^{-4} in $\sharp$. Thus the same locality and uniform norm statement holds for $(q_h' - Q)^\sharp \omega$.

On a fixed local strong ball the resulting Taylor expansion is

$$\mathcal{R}_{h,z}(x) = \sum_{m\ge 2} \sum_{y_1,\dots,y_m \in \mathcal{N}(z)} T_{h;z;y_1\dots y_m}[x_{y_1}, \dots, x_{y_m}], \tag{4.cclxxiii}$$

where $\mathcal{N}(z) = \{y : d(y,z) \le R_0\}$. The coefficient includes $1/m!$. Uniform Banach Cauchy differentiation on the larger admitted local ball, followed by polarization, gives

$$\sum_{y_1,\dots,y_m \in \mathcal{N}(z)} \|T_{h;z;y_1\dots y_m}\| \le C_R r_0^{2-m}. \tag{4.cclxxiv}$$

To see the constants explicitly, the number of possible cells in each slot is at most $D_0 = \#\mathcal{N}(z)$, independent of h. The norm of $m!^{-1} D^m \mathcal{R}$ is at most $C(e/r)^m$ on a smaller ball. Absorb D_0^m, the localization multiplication bound and the fixed two-component choices into r_0. No fine-coordinate count is made. This proves eq. 4.cclxxiv from the actual local residual, rather than postulating an analytic vertex family for the desired output.

4.8.2. *The rooted expansion and its connected carriers.* Substitute eq. 4.cclxxiii into eq. 4.cclxix repeatedly. A leaf is the actual coarse input $B(c)$ propagated by $\mathcal{G}$. An internal vertex has arity $m \ge 2$, coefficient T_h, and an outgoing propagator. Order its children in their Taylor slots. The resulting ordered rooted trees are exactly the formal substitution expansion; the Taylor factorial is already in T_h and must not be inserted again.

Assign a carrier to each term as follows. An edge $\mathcal{G}_{yz}$ is carried by a fixed coordinate-order shortest unit-cell path from y to z. A local vertex is carried by its radius-R_0 cell star, including the short paths to all its input components. The root support and leaf coarse bonds are included.

The resulting carrier is a connected cube union containing every input value read by the term. Its physical tree length is bounded by

$$\ell(\mathcal{T}) \le C_0 \sum_{\text{propagator edges } e} (1 + d_e) + C_1 \#\mathcal{T}. \tag{4.cclxxv}$$

All local stars have fixed size, so C_0, C_1 are independent of arities, mesh and depth.

Choose a positive t so small that the propagator distance cost in eq. 4.cclxxv uses at most $s_0/2$ of its decay. The remaining constant per edge and per input slot is absorbed by a fixed decrease of r_0 and increase of G_s, C_R. With these modified constants, the absolute sum of trees rooted at one cell, charged by $e^{t\ell(\mathcal{T})}$, is bounded by the small solution of

$$U = G_*\|B\|_\infty + G_* C_* \frac{U^2}{1 - U/r_*}. \tag{4.cclxxvi}$$

For example choose $u_* < r_*/4$ and $8G_*C_*u_* < 1$, and then $G_*\rho_* < u_*/4$. The right side maps $[0, u_*/2]$ into itself and is contractive there. Its solution is at most $2G_*\|B\|_\infty$ for $\|B\|_\infty < \rho_*$.

This scalar estimate bounds the actual tree sum: at a fixed root sum each outgoing propagator over its endpoint using eq. 4.cclxxii; then sum its local child-cell choices using eq. 4.cclxxiv; finally repeat from its children. The resulting recursion is exactly dominated by eq. 4.cclxxvi. All sums are absolute. A tree with n leaves has at most $n - 1$ internal vertices, since every internal arity is at least two. Hence its bounded-star and zero-length-edge costs introduce only a fixed exponential per leaf, already included in that majorant.

The summed tree series solves the actual fixed point equation and lies in the uniqueness ball of Prop. 3.183. It therefore equals its constructed background. The spatial rate t has not been divided by the number of leaves.

For a torus, expand each flat propagator in its lifted, twisted infinite-lattice entries. These entries have the same exponential cell bound. Their absolutely convergent periodization solves the periodic joint system; uniqueness identifies it with eq. 4.cclxxi. This can also be obtained by taking the local limit of its uniformly exponentially bounded finite-volume inverse and then periodizing. The nonlocal linear site projector is included in that inverse, not in a purported local nonlinear vertex. Each lifted propagator is given its path on the cover before projection to the torus. Summing its endpoint and period image is the single infinite-lattice sum in eq. 4.cclxxii. Thus the carrier and entropy bounds are uniform in volume and flat twists, including wrapping trees.

4.8.3. *The actual Wilson action on these backgrounds.* Let $a_{h,z}(A)$ be the sum of the actual fine plaquette actions assigned to physical cell z, each plaquette assigned once. The exact plaquette logarithm has the form $U_A(p) = e^{ih^2 F_p(A)}$, with $\|F\|_\infty \le C(\|DA\|_\infty + \|A\|_\infty^2)$. Hence on a fixed local strong ball

$$|a_{h,z}(A)| \le C\|A\|^2_{X_\alpha(\text{star } z)}. \tag{4.cclxxvii}$$

Indeed each plaquette contributes at most $Ch^4\|F\|^2$, and the number assigned to one physical cell is at most Ch^{-4}. The same bound holds on the complex ball by the analytic cosine estimate, without a real part. The local action has no constant or linear Taylor coefficient.

Expand this actual cell action in its local strong variables, and substitute the convergent background trees in every slot. The outer action vertex has arity at least two. Its Banach Cauchy coefficients have the same form of bound as eq. 4.cclxxiv. Consequently, on a smaller fixed ball, the sum of resulting action trees rooted at z satisfies

$$\sum_{\mathcal{T} \text{ rooted at } z} e^{t\ell(\mathcal{T})} \sup_{\|B\|_\infty < \rho} |s_{h,\mathcal{T}}(B)| \le C\rho^2, \qquad 0 < \rho \le \rho_*/2. \tag{4.cclxxviii}$$

The literal fine gauge of the homogeneous background preserves Wilson action exactly. Therefore this series is the actual effective action $S_k(V_B)$, rather than the action of an approximate or separately chosen lift.

Fix any desired $\kappa > 0$. Choose an odd localization size M, a power of L, large enough that a path of length d meets at most $C(1 + d/M)$ localization cubes and $C\kappa/M < t/4$. For each action tree file its full carrier into its actual union X of these cubes. Constants per tree edge cost $e^{C\kappa}$ and are absorbed by a further fixed decrease of ρ_*, since the number of edges is bounded by a fixed multiple of its leaves. Write the resulting local function as $s_{k,M}(X; B_X)$.

Proposition 4.17 (Uniform local analytic effective action)**.** There is a fixed positive ρ_κ, independent of homogeneous depth and compatible volume, such that on $\|B\|_\infty < \rho_\kappa$

$$S_k(e^{iB}V_0) = \sum_X s_{k,M}(X; B_X), \qquad \sup_Q \sum_{X \ni Q} e^{\kappa d_M(X)} \sup_{\|B\|_\infty < \rho} |s_{k,M}(X; B_X)| \le C_M \rho^2 \tag{4.cclxxix}$$

for $0 < \rho \le \rho_\kappa$. Each term is holomorphic only in its indicated coarse bond coordinates and is zero to order two at the flat datum. The representation is formed from the actual fixed-point coefficients and their connected propagator carriers. ■

Proof. Only incidence at a cube different from the outer action root needs an additional check. If the carrier reaches that cube, its charged length is at least the physical distance from the action root to that cube, up to a fixed cell margin. Reserve half the exponential weight in eq. 4.cclxxviii to pay this distance. Summing action roots then costs at most $C \sum_z e^{-ctd(z,Q)} \le C_M$, including the $O(M^4)$ possible roots inside Q. The remaining weight pays $e^{\kappa d_M(X)}$ and the fixed tree costs just described. This proves the bound. Absolute normal convergence proves holomorphy and the sum identity. Every leaf is an actual input coarse bond in the filed carrier, so the indicated local coordinate dependence is literal. Each action tree has at least two leaves. Its zero of order two survives filing. □

4.8.4. *Marked leaves and the actual effective Hessian.* Taylor coefficients can be marked before filing. Fix a coarse bond b and mark one leaf there. Transfer the root to that leaf by reserving an exponential weight for the path to the action root. Sum the remaining root positions as in the preceding proof. Marking a second leaf at b' charges its distance to b by the same connected tree. The number of ordered choices of marked leaves is at most $n(n-1)$ at order n; its polynomial factor is summable on a fixed smaller analytic ball. Since each coarse cell has a fixed finite number of bond and colour coordinates, these are absolute kernel sums, not only multilinear operator-norm estimates.

In particular the actual Hessian admits a local symmetric family $H_{k,X}(B)$, obtained by differentiating the filed action terms and, if necessary, symmetrizing each carrier term. For a fixed smaller rate and radius,

$$\begin{aligned} S_k''(B) &= \sum_X H_{k,X}(B), \\ \sup_b \sum_{X \ni b} e^{\kappa d_M(X)} \sum_{b'} \|H_{k,X}(B)(b, b')\| &\le C_M, \\ \sup_b \sum_{X \ni b} e^{\kappa d_M(X)} \sum_{b'} \|[H_{k,X}(B) - H_{k,X}(0)](b, b')\| &\le C_M \|B\|_\infty. \end{aligned} \tag{4.cclxxx}$$

All rows and field variables read by a term lie in its full carrier. The column estimates are identical by symmetry. More finely one can keep the physical tree length in these estimates, with a fixed positive rate, by reserving it before passing to the M-grid.

This conclusion uses the all-order rooted expansion of the actual residual. Fixed-order max-distance response estimates alone would not justify the absolute marked-leaf sums or the unaltered spatial rate here.

4.9. **Absolute-radius formation at homogeneous depth.** We now use the actual effective-action expansion of Prop. 4.17. The external variables in this section are coarse bond logarithms in its fixed ball about a specified flat reference. This proves a homogeneous physical range and its local analytic extension in those coordinates. Independent fine-current cores and proper-region background towers are separate domains. Choose the frozen flat coarse reference V_0 in its outer block-axial representative, so its actual internal contour means are one. Every flat holonomy class has such a representative: the node-fixed gauge $T_{y,x}(V_0)$ sets those means to one and preserves the next coarse field. This is a fixed reference choice before the Taylor expansion. Consequently the later axializing gauge of a nearby field is small in that same fixed coordinate ball. A parallel-frame calculation alone would not replace this condition on the actual absolute contour gauge. The norms below are analytic spatial and pointing bounds. The fixed-reference filing does not establish individual gauge invariance of its terms, so it does not by itself give the termwise PH marginal cancellation or transport of older gauge-invariant core families. The torus periods are divisible by the chosen localization sizes and exceed ten such cubes. The estimates are uniform on this compatible volume class.

4.9.1. *The uniform flat fluctuation gap.* Let Q_h be the actual flat straight row in eq. 3.mccxxiv, with $h = 1/n$. Its coarse curl is an actual positive surface average of the fine curl:

$$\begin{aligned}(\mathrm{d}_c Q_h a)_{\mu\nu}(y) &= h^6 \sum_{x\in B(y)} \sum_{r,s=0}^{n-1} (\mathrm{d}_h a)_{\mu\nu}(x + rhe_\mu + she_\nu) \\ &=: (T_h d_h a)_{\mu\nu}(y), \qquad \|T_h F\|_2 \le \|F\|_{2,h}.\end{aligned} \tag{4.cclxxxi}$$

The identity follows by telescoping the difference of the two straight rows. The sum of its positive weights in one coarse row is $h^6 n^6 = 1$. A fixed fine plaquette has exactly n^2 possible choices of (r, s); for each choice its starting point belongs to exactly one block. Thus its column sum is $h^6 n^2 = h^4$. Jensen's inequality proves the contraction, with the physical fine measure. Parallel unitary transports in a flat reference preserve this argument, including arbitrary flat twists.

Let $\mathcal{H}_k = S_k''(0)$. The derivative of the actual background at zero minimizes the flat curl energy subject to $Q_h a = v$. Indeed its physical stationarity after removal of the gauge penalty is $\mathrm{d}_h^\sharp \mathrm{d}_h a = Q_h^\sharp \omega$, so the energy cross term against any other lift with the same row value is zero. The literal fine gauge does not change that energy. Equation eq. 4.cclxxxi and the smooth exact row seed Lem. 3.180 consequently give

$$\|\mathrm{d}_c v\|_2^2 \le \langle v, \mathcal{H}_k v\rangle = \inf_{Q_h a = v} \|\mathrm{d}_h a\|_{2,h}^2 \le C\|v\|_2^2. \tag{4.cclxxxii}$$

For the upper bound insert its exact lift $E_Q v$, whose physical H^1 energy is bounded uniformly in h. No inverse of a coarse point-mass readout is used.

Let C_0 be the actual one-step pivot inclusion at the coarse flat field, using the plain outer average and its middle pivots. Let $K_{G,0}$ be its actual contour-gauge quadratic form. Therefore

$$K_{k,0} := C_0^{\mathsf{T}} \mathcal{H}_k C_0 + K_{G,0} \ge C_0^{\mathsf{T}} \mathrm{d}_c^\sharp \mathrm{d}_c C_0 + K_{G,0} \ge \gamma_0 I, \qquad \|K_{k,0}\| \le B_0. \tag{4.cclxxxiii}$$

The last lower bound is the proved actual first flat precision gap; the outer constraint here has not been replaced by the straight row. The bounds on $C_0, K_{G,0}$ depend only on L. Thus γ_0, B_0 are independent of the inner homogeneous depth.

4.9.2. *The complete nonlinear effective precision.* For a coarse background $V = e^{iB_0} V_0$ inside a fixed smaller ball, let $V(u) = e^{i\Phi_V(u)} V$ be the actual one-step outer pivot graph. All its unscaled radii and support bounds are those already used in § 4.7. Define the centered composed action

$$\begin{aligned}\mathscr{S}_{k,V}(u) &= S_k(V(u)) - S_k(V) - D_u[S_k(V(u))]_{u=0} u, \\ K_{A,k}(B_0) &= D^2 \mathscr{S}_{k,V}(0), \qquad K_k(B_0) = K_{A,k}(B_0) + K_G(V).\end{aligned} \tag{4.cclxxxiv}$$

Use the explicit relative contour gauge of eq. 4.ccxxxii for its auxiliary extension. At an actual axial constrained-critical V, the subtracted linear functional is zero, so this is precisely the physical fluctuation action.

The composition in eq. 4.cclxxxiv includes both inner response terms in D^2S_k and the outer constraint-curvature term $DS_k\,D^2\Phi_V$. To control it, substitute the finite local holomorphic map

$$B(u) = i^{-1}\log[V(u)V_0^{-1}]$$

in the actual action trees. Its coefficients have a fixed physical star and uniform Cauchy bounds depending only on L. The marked-leaf proof of eq. 4.cclxxx therefore gives a symmetric local operator family $K_{k,X}(B_0)$, with every matrix endpoint and every background input in its carrier. For a fixed $t_0 > 0$, its absolute physical-length Schur sums obey

$$\begin{aligned} K_k(B_0) &= \sum_X K_{k,X}(B_0), \\ \sup_b \sum_{X\ni b} e^{t_0\ell(X)} \sum_{b'} \|K_{k,X}(B_0)(b,b')\| &\le C_K, \\ \sup_b \sum_{X\ni b} e^{t_0\ell(X)} \sum_{b'} \|[K_{k,X}(B_0) - K_{k,X}(0)](b,b')\| &\le C_K\|B_0\|_\infty. \end{aligned} \tag{4.cclxxxv}$$

Here X is retained as a connected physical unit-cell carrier, before the larger filing grid is introduced. Retain its lifted cover tree as a tag, and use its charged length as $\ell(X)$; tags with the same cubical union can be combined after the norm sum. This also retains winding lengths before projection. The transpose column sums satisfy the same bounds. Local contour gauge terms are included as additional fixed-star terms.

These inequalities follow from the actual tree coefficients, not from a hypothesis on the desired precision. A marked second derivative contributes at most a polynomial in its leaf number; summability follows on the smaller ball. The first-derivative factor in the outer curvature term vanishes at the flat field and is $O(\|B_0\|)$. Thus after decreasing the fixed real ball,

$$\gamma I \le K_k(B_0) \le BI \tag{4.cclxxxvi}$$

uniformly in depth. Complex differences have the corresponding Schur Lipschitz bound on a fixed smaller ball. The same carrier estimates hold for $Q_{k,\tau} = \tau K_{A,k} + K_G$, for τ in a fixed disc about one.

4.9.3. *Admitting cube parameters for the nonlocal precision.* We construct the local Gaussians rather than declaring the nonlocal matrix finite-range. Set $H = I - Q_{k,\tau}/a$, with $a \ge 2B$. The identity has a one-cell carrier. Take the actual carrier expansion induced by eq. 4.cclxxxv, and write

$$H = H_{\le R} + H_{>R}, \qquad H_{\le R} = \sum_{\ell(X)\le R} H_X. \tag{4.cclxxxvii}$$

Every entry of $H_{\le R}$ reads only fields within radius $R + C_L$ of its endpoints and has that finite matrix range. For real data symmetrize each carrier term if necessary. Its tail has Schur norm at most Ce^{-t_0R}. For large R, eq. 4.cclxxxvi therefore implies

$$0 \le H_{\le R} \le r'I, \qquad r' = 1 - \gamma/(2a) < 1. \tag{4.cclxxxviii}$$

The lower bound uses $I - Q/a \ge I/2$ and a tail smaller than $1/4$. All constants are uniform.

Fix the requested coarse parameter radius $S > 2$. For a connected physical carrier, round it to localization cubes of side M. The geometric covering-tree bound gives

$$S^{\#X_M} \le S^{C_0}\exp\{C_0(\log S)\ell(X)/M\}.$$

Choose M large enough that the rate in this exponent is below $t_0/4$. In the operator-family norm charging this cube weight, eq. 4.cclxxxv then gives constants $C_H, c > 0$ such that

$$\|H\|_{\mathrm{car}},\ \|H_{\le R}\|_{\mathrm{car}} \le C_H, \qquad \|H_{>R}\|_{\mathrm{car}} \le C_H e^{-cR}. \tag{4.cclxxxix}$$

The norm is the maximum absolute row/column sum of all its carrier terms, with the displayed weight. Operator composition files into the union of two carriers sharing their intermediate bond. Thus these unions are connected, their weights are submultiplicative, and this norm is submultiplicative as well.

The Gaussian parameters themselves are placed on the coarse LM-cube grid of the UM expansion. The displayed M-cube carrier weight is stronger than the needed LM-cube weight. On the fixed held root guard use $\widehat{s}_\Delta = 1$, and use $\widehat{s}_\Delta = s_\Delta$ elsewhere in every carrier weight below.

Choose an integer m, and then $R = Dm$, where the fixed D is large enough that $cD > 2\log(1 + C_H) + 2$. Use the exact identities

$$\begin{aligned} H^m &= (H_{\le R})^m + E_m, \\ E_j &= H^j - (H_{\le R})^j = \sum_{i=0}^{j-1} (H_{\le R})^i H_{>R} H^{j-1-i}. \end{aligned} \tag{4.ccxc}$$

The second line defines an actual filed carrier series. It gives, simultaneously for $j \le m$,

$$\|E_j\|_{\mathrm{car}} \le j C_H^j e^{-cR}. \tag{4.ccxci}$$

Combine all paths inside the entries of $(H_{\le R})^m$ before assigning their parameters. At one common real background the Hilbert-row estimate of eq. 4.ccxxxix gives a pointwise Schur bound with the factor $(1+m(R+C_L))^2$. For a local coefficient family, take the supremum separately for each entry over its full real read set. Denote the maximum of this row sum and its transpose column sum by $\|\cdot\|_{\mathrm{Sch},+}$. The appropriate bound is

$$\|(H_{\le R})^m\|_{\mathrm{Sch},+} \le C(1 + m(R + C_L))^4 (r')^m. \tag{4.ccxcii}$$

Indeed each matrix entry is at most $(r')^m$ by eq. 4.cclxxxviii, and a row has at most $C(1 + m(R + C_L))^4$ possible endpoints. Every permitted local real read set extends by zero relative to V_0 to admitted global real data. Thus the entry estimate remains valid when its supremum is taken independently of the other entries. A supremum outside the whole row sum would not establish this bound.

For the uncombined families H_X, their tails and the words defining E_j, use the sums of individual carrier suprema on a common larger complex ball. The positive Taylor-tree majorants proving eq. 4.cclxxviii and eq. 4.cclxxx give precisely these stronger bounds. Their products are bounded by the positive products of those majorants. Thus C_H in eq. 4.cclxxxix and eq. 4.ccxci can be chosen for these norms as well.

Take M to be the smallest power of L at least $C_L m(R + C_L)$. The combined near entries then have connected ball carriers meeting a bounded number of M-cubes. Their cube weights cost only S^{C_L}. Weight the already filed E_m terms individually by their full carriers, and weight each combined near entry by its full ball carrier. Denote their sum by T_s, symmetrizing its carrier terms if needed. At $s = 1$, $T_1 = H^m$ exactly. On all independent $|s_\Delta| < S$,

$$\|T_s\|_{\mathrm{Sch}} \le C S^{C_L} (1 + m(R + C_L))^4 (r')^m + m C_H^m e^{-cR} =: q_m \longrightarrow 0. \tag{4.ccxciii}$$

Here $M = O_L(m^2)$. Its appearance in the volume budget is polynomial, whereas both terms on the right decrease exponentially.

For each prefix $j < m$, similarly put $A_{j,s} = (H_{\le R})^j + (E_j)_s$. Only the near prefix is left unweighted; its row from a root is contained in the fixed held root guard. The tail prefix is weighted by its actual full carriers. Choose the guard to contain every radius-$m(R + C_L)$ root ball,

using the same fixed eight-cell collar convention as before, with constants increased once. With $c_\ell = 4^{-\ell}\binom{2\ell}{\ell}$, define

$$R_W(s) = a^{-1/2}\chi_W \sum_{j<m} A_{j,s} \sum_{v\ge 0} c_{vm+j} T_s^v, \qquad D_W(s) = R_W(s)R_W(s)^{\mathsf{T}}. \tag{4.ccxciv}$$

At complete parameters this is exactly $\chi_W Q_{k,\tau}^{-1/2}$, by the grouped binomial identity. Thus its covariance is the actual Gaussian marginal. Every prefix-tail and short-step carrier contains its endpoints and every external coordinate read by that coefficient. Zero outside a wall domain therefore gives literal local dependence and wall factorization, with fixed-root heredity.

For the real comparison use $R_{0,r} = a^{-1/2}\sum_{j<m} c_j (H_{\le R,r})^j$. Its compression has covariance at least $a^{-1}I$, by eq. 4.cclxxxviii. The sum of the Schur norms of its prefixes is at most a polynomial in R. Equations eq. 4.ccxci and eq. 4.ccxciii therefore make $D_W(s)$ uniformly $o(M^{-4})$-close to that real covariance by increasing m. Finally shrink the fixed complex coarse-field and τ balls, after m, R, M have been fixed. To justify this step coefficientwise, let δ_H^+ be the positive carrier bound for the difference between the complex near matrix and the matrix at its real data. Nested-ball Cauchy estimates on the actual Taylor-tree majorants give $\delta_H^+ \le C\delta$, where δ is the tube size. A positive word expansion of the telescoping identity gives, for $1 \le j \le m$,

$$\Delta_j^+ \le j C_H^{j-1} \delta_H^+.$$

This is the same finite-power estimate as eq. 4.ccxlii; enlarge $C_H \ge 1$ once if necessary. Choose the tube so that $\sum_{j=1}^m \Delta_j^+ \le (r')^m$. This pays the whole prefix sum and the m-th power perturbation. Increasing the fixed constant in eq. 4.ccxciii absorbs the latter term, and the covariance comparison remains $o(M^{-4})$. No bound polynomial in m for this coefficientwise perturbation is required. These radii are positive and independent of depth and coupling. Local data in this coarse product ball extend by zero relative to V_0, so no extra curvature-extension premise is needed. This proves the local Gaussian comparison, enlarged independent cube discs and exact structural identities needed by the homogeneous unmarked expansion for the actual nonlocal effective precision.

4.9.4. *The actual intrinsic and ordinary-source vertices.* Fix $g = \theta^{-1/2}$ and $\mathfrak{b} = A_1(\log\theta)^p$, with $p > 1/2$. Keep the real product cutoff $\chi(B) = \prod_b \mathbf{1}_{|B(b)|<\mathfrak{b}}$ fixed throughout. Take θ so large that $16C_L g\mathfrak{b}$ is less than both the outer pivot radius and the margin in the actual coarse-data ball just proved. Then $V(gB)$, its normalized radial paths and the needed complex fluctuation boxes all remain in that ball. In particular $U_k(V(gB))$ is the actual admitted homogeneous background on the entire box; its existence has not been replaced by an activity-norm assumption.

Compose each of the actual action terms in eq. 4.cclxxix with the outer graph. Subtract its constant, linear and quadratic Taylor terms in u, before summing. The global linear sum is the centering term in eq. 4.cclxxxiv, and the global quadratic sum is the complete $K_{A,k}$. Each composed member is holomorphic on a fixed ℓ^∞ free-coordinate ball and reads only the fixed chart collar of its filed carrier. If its admitted bound is B_X, directional Cauchy Taylor remainder gives

$$|g^{-2}R_{3,X}(gB)| \le CB_X g \max_{b\in X^+} |B(b)|^3 \le CB_X g\mathfrak{b} \sum_{b\in X^+} |B(b)|^2. \tag{4.ccxcv}$$

The first inequality includes the fixed analytic-radius cost; the maximum is over its actual chart support. The second inequality is valid on the kept cutoff and on its fixed complex margin after a fixed change of constants. Thus the actual Gaussian-growth potential norm has amplitude $C_M g\mathfrak{b}$, uniformly in depth. No derivative count proportional to the fine lattice size is present.

The outer relative contour gauge, Haar and pivot coarea factors are the literal one-step factors of eq. 4.ccxxxii and eq. 4.ccliv, on the present coarse lattice. Their supports and unscaled derivative bounds depend only on L, so their intrinsic remainders have the same amplitude. The zero-field coarea value $J_V(0)$ stays in the Gaussian normalizer.

There is an actual all-depth ordinary source class in this range. Take fine plaquette profiles $w(p)$, with $\|w\|_\infty < \rho_w$ on independent fixed coefficient discs, and put

$$H_{k,w}(V) = \sum_{p>0} w(p) a_p(U_k(V)). \tag{4.ccxcvi}$$

Its unit-cell action bound is $C\rho_w \|A\|^2_{X_\alpha}$, by the same h^4 plaquette count as eq. 4.cclxxvii. Apply the actual action-tree construction with these weights at its outer action vertices. It produces a genuinely local analytic coarse-source family with norm $C_M\rho_w$, uniformly in depth and in the number of fine plaquettes. The literal fine gauge preserves each plaquette trace separately, so this family represents precisely eq. 4.ccxcvi.

Its interaction is the exact difference $H_{k,w}(V(gB)) - H_{k,w}(V)$. Cauchy differentiation on the already admitted coarse-data margin gives its potential amplitude $C_M\rho_w g\mathfrak{b}$. The background, Gaussian, gauge weight and sharp cutoff have not been moved when inserting this ordinary source. Additional inputs already supplied as local holomorphic coarse-data families with incidence norm H_0 obey the same difference bound $C_M H_0 g\mathfrak{b}$. This last optional statement does not assert that arbitrary older fine-core families have already been transported into that class.

4.9.5. *The formed homogeneous families and their physical range.*

Proposition 4.18 (Actual homogeneous formation near a flat reference)**.** There are fixed positive coarse-data and τ radii and a coupling floor, independent of homogeneous depth and compatible volume, for which the actual regular homogeneous step with action xS_k, contour-gauge weight θ and the ordinary sources eq. 4.ccxcvi has an analytic filed decomposition $\mathbf{N}^\circ_k + \mathbf{G}_{k,\tau} + \mathbf{F}_k$. For every fixed requested output rate its constructed pointing satisfies

$$\|\mathbf{N}^\circ_k\|_+ \le C_N, \qquad \|\mathbf{G}_{k,\tau}\|_+ \le C_G|\tau - 1|, \qquad \|\mathbf{F}_k\|_+ \le C_F\{(1 + \rho_w + H_0)g\mathfrak{b} + e^{-c\mathfrak{b}^2}\}. \tag{4.ccxcvii}$$

Here $H_0 = 0$ unless the optional already filed coarse-input class is used. The constants are independent of depth. The normalizer and mismatch are retained as Gaussian terms, not counted in $\mathbf{F}_k$. ■

Proof. The local covariance construction eq. 4.ccxciv supplies all enlarged cube discs, Gaussian comparison, normalization, fixed-support heredity and wall factorization needed in the actual UM expansion. In each functional take all free bonds of its full fine support, so its held guard also contains any background inputs constant along that fibre. Its scalar dimension is at most $C(LM)^4 \# Z$. The comparison error can be chosen below $c_*(LM)^{-4}$, without an auxiliary-volume factor.

The actual interaction estimates just proved give the UM potential budget $C_M(1 + \rho_w + H_0)g\mathfrak{b}$. The unchanged sharp cutoff gives the Gaussian tail $Ce^{-c\mathfrak{b}^2}$. The already proved finite Mayer, connected cluster and union-filing theorems therefore give the stated $\mathbf{F}_k$ bound. The normalized cubic, ordinary radial and moving- threshold pointings are exactly those used in the first-step proof; their analytic margins and budgets are now uniform in depth.

For the Gaussian normalizer, use the actual carrier expansion of $\log Q$, grouping $\log Q = (\log a)I - \sum_{j<m,v\ge 0,vm+j>0} H^j(H^m)^v/(vm+j)$. The near combined powers and the filed tails have precisely the summable cube weights proved above. Root the trace at its actual diagonal bond and add the local zero-field pivot terms. This proves the $\mathbf{N}^\circ_k$ bound after vacuum subtraction. The same construction on a larger τ disc gives the mismatch bound; its pointing is its actual resolvent insertion as in eq. 4.cclii. □

The actual source functions are holomorphic on independent fixed fine profile discs. The same argument as Cor. 4.16 therefore gives

$$|D^n_w F_k(X; w)[h_1, \dots, h_n]| \le Cg\mathfrak{b}\, n!(2e/\rho_w)^n e^{-\kappa d_c(X)} \prod_j \|h_j\|_\infty$$

on the half-radius source ball, with the reserved rate for pointed terms. There is no factor counting fine plaquettes or source profiles in this bound.

4.9.6. *The actual nested physical step.* To identify the complete physical step, take $W = e^{iB_+}V_{0,+}$, where $V_{0,+} = M(V_0)$ and $\|B_+\|_\infty$ is sufficiently small, and form its actual depth-$k+1$ background $U_+(W)$. Choose the flat fine extensions compatibly at the two depths, so the intermediate flat reference is the partial average of that same flat fine field. The partial averaging recursion and its raw bound eq. 3.mcclvi put $V = M^k U_+(W)$ in the coarse-data ball above. Its node-fixed one-step axial gauge is also there after a fixed decrease of the outer radius. The required gauge extension is the bounded local node extension from the homogeneous background construction. More explicitly, truncating that recursion at its intermediate spacing $1/L$ gives $\|a_k\|_\infty + \|v_k - I\|_\infty \le C_L\|B_+\|_\infty/L$. On rescaling this spacing to one, the fine potential is A/L and its first difference is DA/L^2. The one-step axial node values have size $C_L\|B_+\|_\infty$; their actual smooth fine extension has the same bound in the required strong gauge norm. Thus the intermediate field and its axial representative remain within $C_L\|B_+\|_\infty$ of the fixed strong orbit chart, uniformly in k.

This intermediate field is an actual constrained-critical point for S_k under $M(V) = W$. Indeed every fine variation with $D(M^k)\delta U = 0$ also has $D(M^{k+1})\delta U = 0$. Thus $U_+(W)$ is critical on its M^k-fibre. Both it and the constructed $U_k(V)$ are in the fixed strong regularity class, after rescaling the intermediate coarse spacing by the fixed factor L. Orbit uniqueness in Prop. 3.183 identifies their actions. To check outer stationarity, lift any admitted curve $V(t)$ with $M(V(t)) = W$ by its actual background $U_k(V(t))$. Then $M^{k+1}U_k(V(t)) = W$ exactly. At $t = 0$ its background is the same critical orbit as $U_+(W)$, so $\partial_t A(U_k(V(t)))|_{t=0} = 0$. This proves that $DS_k(V)$ annihilates the outer constraint tangent. The linear centering in eq. 4.cclxxxiv therefore vanishes physically.

On $|B| < \mathfrak{b}$, the actual $V(gB)$ stays in the same fixed coarse-data ball, so all inner backgrounds exist on one admitted chart. The outer regular-fibre anchor, coarea density and contour-gauge test removal are the literal one-step proofs already given; their constants do not involve k. The exact physical normalization is therefore eq. 4.cclxv with $A(U)$ replaced by $S_k(V)$, the present complete precision, and its actual zero-field pivot factor. At these critical axial pairs gauge invariance of the actual effective action supplies the orbit-null action sector. Thus the physical mismatch total is again $(r/2)\log\tau$, with the explicit numerical $\tau^{-d/2}$ retained separately.

This physical range is a fixed bond ball about a frozen flat reference. Extra history plaquette indicators still require their own threshold margin. The proof does not extend the local functions across arbitrary flat-reference changes, to all curvature-only fields, to independent fine currents, or to proper-region and history towers. Those conclusions are not prerequisites for the homogeneous near-flat step proved here.

4.10. **Gauge invariance of the complete homogeneous pointing.** The fixed-reference Taylor terms in Prop. 4.17 need not be individually gauge invariant. A complete physical pointed density can nevertheless be constructed invariantly: specify its insertions at the original fine plaquettes before making the Taylor-tree filing. This distinction is needed for its quadratic Ward identity. The result below concerns the homogeneous near-flat range already proved, with the literal fine plaquette sources and no untransported older fine-core inputs. Here V is the input coarse background of that one-step integral. The actual output datum W enters through the critical intermediate background $V = p_k(W)$, considered explicitly below.

4.10.1. *Invariant functions before filing.* For each original fine plaquette put

$$f_{k,p}(V) = a_p(U_k(V)), \qquad f_{k,p;V}(u) = f_{k,p}(e^{i\Phi_V(u)}V). \tag{4.ccxcviii}$$

These are the actual functions, before decomposition into connected carriers. For every sufficiently small coarse site gauge g whose two data lie in the admitted ball, the literal node extension and

orbit uniqueness of Prop. 3.183 give

$$f_{k,p}(V^g) = f_{k,p}(V). \tag{4.ccxcix}$$

Indeed a fine gauge with those node values takes the critical field to the same regular orbit as $U_k(V^g)$. A fine gauge leaves the trace of each plaquette, at its fixed position p, unchanged. This is an assertion about the nonlocal function $f_{k,p}$, not its local Taylor pieces.

Write $(O_g u)(b) = \mathrm{Ad}(g(b_-))u(b)$ on outer free bonds. The actual pivot equation, its relative coarse logarithm and its free-identity convention give

$$\Phi_{V^g}(O_g u) = O_g \Phi_V(u), \qquad f_{k,p;V^g}(O_g u) = f_{k,p;V}(u). \tag{4.ccc}$$

The first identity follows by covariance and uniqueness of the same small pivot graph. At real unitary g, O_g is a real block-orthogonal map on the actual integration space. It preserves each retained cutoff.

Let $R_{3,p;V}(u)$ be the third-order remainder of $f_{k,p;V}$, subtracting its own constant, linear and quadratic jets. Each homogeneous jet transforms under the same linear map O_g. Consequently $R_{3,p;V^g}(O_g u) = R_{3,p;V}(u)$. This gives invariant cubic remainders before their carrier expansion.

The other functions have the same property directly. Every relative contour-gauge trace conjugates at its node. The Haar density is a function of the invariant colour pairing of Φ. A pivot matrix transforms on its two sides by adjoint matrices of determinant one; its determinant ratio and chosen logarithm are invariant. The ordinary source $\sum_p w(p) f_{k,p}$ is invariant with its fine profile held fixed.

4.10.2. *The actual normalization shares and insertions.* For each fine plaquette p, choose nonnegative fixed numbers $\vartheta_{p,b}$ on outer free bonds with

$$\sum_b \vartheta_{p,b} = 1, \qquad \vartheta_{p,b} = 0 \quad \text{if } d(\mathrm{mid}\, p, \mathrm{mid}\, b) > C_L. \tag{4.ccci}$$

One choice is equal shares on the nearest free-bond midpoints. Their distance is uniformly bounded because each outer L-block contains free bonds. This choice is covariant under the geometric symmetries preserving the actual pivot pattern. It is independent of the field and its Taylor-carrier presentation.

Put $P_{p,V}(B) = -\tau g^{-2} R_{3,p;V}(gB)$. The normalized intrinsic interpolation and its actual bond insertion are

$$\begin{aligned} P_{p,V;t}(B) &= t^{-2} P_{p,V}(tB), \\ a_{p,t,b}(V;B) &= t^{-2} B(b) \cdot D_b P_{p,V}(tB) - 2\vartheta_{p,b} t^{-3} P_{p,V}(tB). \end{aligned} \tag{4.cccii}$$

The shares are specified at the original plaquette, before any carrier filing. For independent parameters the defining function is

$$\left(\sum_b \vartheta_{p,b} t_b\right)^{-2} P_{p,V}((t_b B(b))_b).$$

Its derivative at $t_b = t$ is exactly the displayed insertion. Thus its sum over b is the derivative of the normalized diagonal path, including its normalization term. Nonnegative shares keep the denominator at least $t/2$ on $\max_b |t_b - t| < ct$, $c < 1/2$. All the field arguments remain in the proved common chart.

Equation eq. 4.ccc and invariance of the colour pairing show, for every bond separately,

$$a_{p,t,b}(V^g; O_g B) = a_{p,t,b}(V;B). \tag{4.ccciii}$$

The same construction is applied to the original relative gauge remainders with shares on their fixed local free supports. The Haar, pivot and ordinary-source legs use their ordinary radial insertions $B(b) \cdot D_b V(tB)$, which satisfy the same identity.

There is a uniform rooted bound for these actual insertions. Retain each p as the outer action-tree tag. Its local analytic bound is Ch^4, before summing the fine plaquettes. The proof of eq. 4.ccxcv then gives its intrinsic amplitude $Ch^4 g\mathfrak{b}$. A derivative rooted at b marks a leaf in that actual tree. The exponential root-transfer estimate sums these terms over the plaquette's physical cell positions. The normalization root in eq. 4.cccii is within C_L of p by eq. 4.ccci. It has the same carrier budget. Finally there are $O(h^{-4})$ fine plaquettes per physical cell, cancelling their h^4 bound. The order-three radial vanishings and eq. 4.cxxx therefore give the same $Cg\mathfrak{b}$ integrable rooted norm as the homogeneous formation theorem, with a fixed rate reserve. This step uses the absolute marked-tree sums, rather than differentiating only an unpointed output estimate.

4.10.3. *Invariant normalized expectations.* The complete precision of the actual composed action and relative contour gauge transforms on the shared domain as $Q_\tau(V^g) = O_g Q_\tau(V) O_g^{\mathsf{T}}$. For real unitary gauges, Gaussian change of variables by O_g, the fixed product cutoff and eq. 4.ccciii therefore give invariance of each normalized bond insertion expectation. Every interpolation partition function is zero-free in the ordinary cluster domain proved above. Its canonical logarithm and expectation are thus unambiguous there. The identities are holomorphic in the external data and extend on their common complex domain.

The cutoff leg is invariant as well. Its one-bond moving threshold and its boundary surface measure depend only on $|B(b)|$, which the real orthogonal map $O_g(b)$ preserves. Its rooted Gaussian tail estimate is the already proved one. The free mismatch leg has its actual density $(\tau - 1)\int \mathrm{tr}(K_G Q_{\tau,u}^{-1})(b,b)du/2$; the diagonal colour trace is invariant.

Let $\mathcal{E}_b^F(V)$ be the integral of the cutoff and interaction insertions just specified. The exact path identities give $\sum_b \mathcal{E}_b^F = \mathcal{F}_k$. Use the fixed midpoint tents for the output base point:

$$F_{k,z}^{\mathrm{phys}}(V) = \sum_b h_z(\mathrm{mid}\, b)\mathcal{E}_b^F(V). \tag{4.ccciv}$$

The tents h_z are on the outer output-node lattice, of spacing L in the present input units. After rescaling, the same z is the output unit-lattice basepoint in the composition below. This complete physical density is gauge invariant. Its local analytic filing obtained from the actual insertions has the uniform bound $Cg\mathfrak{b}$ of eq. 4.ccxcvii. The individual filed functions still need not be gauge invariant.

Proposition 4.19 (The physical quadratic Ward identity)**.** At a trivial flat reference, the complete density eq. 4.ccciv has zero first derivative in coarse bond logarithms. Its quadratic kernel annihilates a coarse gradient in either argument:

$$D^2 F_{k,z}^{\mathrm{phys}}(0)[\mathrm{d}_c\lambda, a] = 0. \tag{4.cccv}$$

Its second spatial moments are bounded by $Cg\mathfrak{b}$, uniformly in homogeneous depth. ■

Proof. A constant colour conjugation fixes the trivial field. An invariant linear functional in one adjoint colour is zero, so $DF_{k,z}^{\mathrm{phys}}(0) = 0$. Differentiate the proved local gauge identity in a small gauge parameter and then in the field. The linear gauge variation at zero is $\mathrm{d}_c\lambda$. The nonlinear variation multiplies the vanished first derivative. This proves eq. 4.cccv; symmetry gives the second argument. One may first use finite-support gauges. The exponential marked-tree bounds then extend the identity to the stated finite-moment class.

The filed insertion bounds are holomorphic on a fixed external coarse-coordinate ball. Two Cauchy derivatives cost its fixed inverse radius squared. A carrier has at most $C(LM)^4(1 + d_c(X))$ outer coarse bond coordinates. Summing all derivative pairs and multiplying by their squared spatial distances therefore costs only a fixed polynomial in $d_c(X)$, with an M-dependent constant and no fine depth factor. The reserved spatial rate makes that polynomial summable. Thus the second moments have the asserted $g\mathfrak{b}$ bound. In particular an affine curvature probe may be inserted in this quadratic kernel by its absolutely convergent spatial moments. □

4.10.4. *Composition with the actual critical background.* Let $p_k(W)$ be the intermediate coarse field $M^k U_{k+1}(W)$, in its actual one-step axial gauge, as constructed in the physical-range argument above. Define the complete output density, now in output coarse units, by

$$\mathscr{F}_{k,z}(W) = F_{k,z}^{\mathrm{phys}}(p_k(W)). \tag{4.cccvi}$$

This is the density for the actual output datum W. Gauge invariance makes it independent of the admitted intermediate representative.

Corollary 4.20 (Physical homogeneous marginal bound)**.** At the trivial flat reference and zero ordinary profile, the complete output densities eq. 4.cccvi retain the quadratic Ward identity and the uniform rooted second-moment bound $Cg\mathfrak{b}$. Their infinite-lattice companion has the physical Yang–Mills quadratic coefficient

$$|b_k^{\mathrm{phys}}| \le Cg\mathfrak{b}, \tag{4.cccvii}$$

with the Wilson normalization of eq. 4.i. This coefficient belongs to the complete physical pointed density. ■□

Proof. The map p_k is analytic on the fixed output ball. Its actual first response $H_k = Dp_k(I)$, written in potential coordinates, has uniform exponential row and column moments. Indeed it is the localized response eq. 3.mccxcv followed by a partial actual average and its local axial gauge. Each partial row has bounded physical carrier and bounded directional norm by eq. 3.mcclvi. There are only L^4 intermediate cells per output cell. Thus summing its responses costs a fixed L factor, not a fine-depth factor.

Write $\mathcal{K}_{k,z}$ for the quadratic kernel already proved for $F_{k,z}^{\mathrm{phys}}$. The first jet vanishes, so the second-order chain rule is exactly

$$D^2\mathscr{F}_{k,z}(I)[a,b] = \mathcal{K}_{k,z}[H_k a, H_k b]. \tag{4.cccviii}$$

No $D^2 p_k$ term remains. The kernel moments on the right are bounded by composing the two exponentially localized responses. For example the squared distance of an output bond from z is bounded by a constant times the squared distance to its intermediate bond plus that intermediate bond's squared distance from z. Sum the former with the exponential response moment and the latter with the rooted moment of $\mathcal{K}_{k,z}$. This is the pointed root-transfer bound and retains $Cg\mathfrak{b}$.

If W is changed by a sufficiently small output site gauge, actual orbit covariance of U_{k+1} shows that the two intermediate fields are gauge equivalent, with the prescribed output node values. The proved invariance of $F_{k,z}^{\mathrm{phys}}$ therefore makes $\mathscr{F}_{k,z}$ invariant. Its first jet is zero and the same differentiated gauge identity gives the output Ward identity.

We check the physical affine normalization using the actual successive map. By eq. 5.clxxvi, its first response to an affine output field of constant curl is the intermediate affine potential modulo a lattice gradient. That identity follows from the actual nesting in § 4.9.6, the full Wilson affine response, and then its literal partial mean. The literal and straightened means are kept distinct; their frame correction is an intermediate gradient. The vanished first jet removes the nonlinear response, and the Ward identity removes both gradient legs. Thus eq. 5.clxxvii applies to this complete invariant density. Its physical Wilson normalization is unchanged by the intermediate change of units.

The original plaquette functions, the nearest-midpoint shares and the midpoint tents are covariant under translations and the full hypercubic group, including reflections. Orbit uniqueness preserves this covariance in the complete composed density. The quadratic tensor classification eq. 4.xviii–eq. 4.xix therefore applies to this invariant kernel with its proved moments. It is applied to the complete kernel, using the Ward and symmetry identities just established; no termwise invariant-core hypothesis is inferred from its Taylor filing. The extractor is a fixed linear second-moment functional, so the bound in eq. 4.cccvii follows from the composed moment bound. Absolute

lifted-carrier and cluster convergence gives the infinite-lattice companion as the limit of compatible tori, with these derivatives and moments. □

The quadratic identity belongs to the complete invariant density. It is not applied separately to the fixed-flat Taylor terms. A termwise invariant core family, an older-family transport theorem or a full fine-current marginal identification still requires its corresponding additional argument.

4.11. **An even-coupling improvement of the intrinsic formation bound.** The first absolute formation estimate uses the size of the cubic fluctuation vertex. The normalized integral has an additional cancellation: changing the sign of the fluctuation coupling can be compensated by changing the sign of every Gaussian variable. We use that exact symmetry before estimating the resulting local activities. It improves their intrinsic smallness by one power of the coupling.

Keep the homogeneous law and its actual Gaussian structure from Prop. 4.18. In this subsection the cutoff radius $\mathfrak{b}$ is fixed independently of a complex parameter g. The parameters τ, the external background and any admitted ordinary coarse input are also held fixed. Only at the end do we set $g = \theta^{-1/2}$ and $\mathfrak{b} = A_1(\log\theta)^p$. The explicit numerical Jacobian and Gaussian normalizer have already been factored as in eq. 4.cclxv; their logarithms are not included in the intrinsic function considered here.

4.11.1. *The analytic deformation at zero coupling.* Write the exact normalized fluctuation integral in the form

$$\mathcal{Z}(g;V,H,\mathfrak{b}) = \int \chi_{\mathfrak{b}}(B) e^{P(g;V,H,B)}\, d\mu_{Q_\tau(V)^{-1}}(B), \qquad \mathcal{F}(g) = \log \mathcal{Z}(g). \tag{4.cccix}$$

The Haar and pivot ratio in P is the actual one. The action and relative gauge sectors are their exact centred functions minus their quadratic Gaussian parts. The ordinary input is $H(V(gB)) - H(V)$. The free coordinate graph $V(u)$ and all precision localizations are independent of g.

Every divided remainder in this formula is analytic at $g = 0$. For example a centred action remainder of order three has the convergent expansion

$$g^{-2} R_3(gB) = \sum_{n\geq 3} \frac{g^{n-2}}{n!} D^n R_3(0)[B,\dots,B].$$

The ordinary density and source terms are analytic functions of gB, with their constant values subtracted. Thus $P(0;V,H,B) = 0$. The cutoff is a fixed real even function of each $B(b)$.

The absolute formation proof remains valid on the complex disc

$$|g| < r_g = c_*/\mathfrak{b}. \tag{4.cccx}$$

Here $c_* > 0$ is fixed below all intrinsic-vertex and analytic-chart ceilings. Its proof estimates the vertices by $C|g|\mathfrak{b}$; positivity of g was not used. All Gaussian covariances are held fixed on their already admitted complex background domain. The cluster series is therefore a holomorphic, zero-free logarithm on this disc, with the same fixed spatial rate reserve. This gives holomorphy in the norm of the local activity family, rather than only pointwise finite-volume holomorphy.

At zero coupling,

$$\mathcal{F}(0) = \log \mu_{Q_\tau(V)^{-1}}(\chi_{\mathfrak{b}}).$$

Its actual wall expansion is exponentially small in $\mathfrak{b}^2$. With a fixed slightly smaller spatial rate, its unpointed and canonical pointed norms are bounded by

$$Ce^{-c\mathfrak{b}^2}. \tag{4.cccxi}$$

Polynomial wall factors have been absorbed by decreasing c. This is the wall estimate of the formation proof, and does not bound a whole-volume cutoff probability away from zero.

4.11.2. *Exact sign symmetry of the filed functions.* The exact integrand satisfies

$$P(-g;V,H,-B)=P(g;V,H,B). \tag{4.cccxii}$$

Indeed every occurrence of the actual group field has argument gB, which is unchanged. A prefactor g^{-2} is also unchanged. The subtracted quadratic Gaussian form is even in B. The ordinary input depends on the same group field, and the Haar and pivot functions have that same argument. The even Gaussian density and cutoff therefore give

$$\mathcal{F}(-g)=\mathcal{F}(g). \tag{4.cccxiii}$$

The equality uses the zero-free branch through $g=0$, so there is no undetermined logarithm constant.

We need this identity for the local family, where an arbitrary refiling could obscure cancellation. Use the actual Taylor and carrier filing of the homogeneous formation theorem. That filing commutes with the involution $(g,B)\mapsto(-g,-B)$: each Taylor monomial keeps its degree in g and its degree in the fluctuation variables, and its carrier is independent of their signs. An intrinsic degree-n monomial has the factor $g^{n-2}B^n$, whose sign is $(-1)^{2n-2}=1$. An ordinary degree-n term has g^nB^n, also with sign one.

Mayer exponentiation, multiplication, the fixed Gaussian weakening, connected extraction and union filing all commute with this involution. Any partial Gaussian integral has the same symmetry under negation of all its Gaussian coordinates. Consequently every resulting filed activity can be chosen even in g. This statement concerns sign parity; it does not assert gauge invariance of individual fixed-reference terms.

The canonical bond pointings have the same parity. For an intrinsic plaquette function $P_g(B)$, its normalized insertion is

$$t^{-2}B(b)\cdot D_bP_g(tB)-2\vartheta_{p,b}t^{-3}P_g(tB).$$

Equation eq. 4.cccxii changes both the vector and its derivative sign in the first term; the second term is unchanged. Ordinary radial insertions satisfy the same identity. A moving cutoff threshold and its surface measure are even in $B(b)$. Thus the actual pointed expectation, its integral in the interpolation parameter, and its carrier filing are even as well.

4.11.3. *The improved absolute bound.*

Proposition 4.21 (Quadratic intrinsic formation smallness)**.** Let $\mathbf{F}(g)$ denote the actual unpointed or canonical pointed homogeneous intrinsic activity family, with the spatial rate just fixed. For $|g|\le c_*/(2\mathfrak{b})$,

$$\|\mathbf{F}(g)\|\le C\{\,|g|^2\mathfrak{b}^2+e^{-c\mathfrak{b}^2}\,\}. \tag{4.cccxiv}$$

The constants are independent of the inner fine depth and volume. The same statement holds on the smaller fixed external and ordinary source discs of the formation theorem. ■

Proof. The activity-valued function $\mathbf{F}(g)-\mathbf{F}(0)$ is holomorphic and even on eq. 4.cccx. On a fixed slightly smaller concentric disc its norm is bounded by a constant, since the original estimate is $C|g|\mathfrak{b}$ plus the wall tail. Use the Cauchy circle of radius $R=3r_g/4$. For the stated $|g|\le r_g/2$, $|g|/R\le 2/3$.

Its Taylor coefficients of odd order vanish, and its constant coefficient is zero. Cauchy's estimate in the activity norm gives

$$\|\mathbf{F}(g)-\mathbf{F}(0)\|\le C\sum_{n\ge1}(|g|/R)^{2n}\le C|g|^2\mathfrak{b}^2.$$

Add eq. 4.cccxi. The same proof applies to each pointed norm because the preceding parity argument held before those norms were estimated. □

For the physical choice $g = \theta^{-1/2}$, $\mathfrak{b} = A_1(\log\theta)^p$, $p > 1/2$, this reads

$$\|\mathbf{F}\| \le C\theta^{-1}(\log\theta)^{2p} + C\exp[-c(\log\theta)^{2p}]. \tag{4.cccxv}$$

The tail is smaller than any fixed inverse power of θ after increasing its threshold, because $2p > 1$. This is a stronger bound than estimating the cubic vertex alone. It is still a bound on the specified homogeneous model.

Two external field derivatives cost a fixed inverse radius squared. The reserved spatial rate absorbs their coordinate incidence and second spatial moments, exactly as in Prop. 4.19. For zero ordinary profile, or an input already proved to satisfy the same complete physical gauge identities and the Euclidean symmetries required for a scalar coefficient in Cor. 4.20, that complete physical quadratic coefficient consequently satisfies

$$|b_k^{\mathrm{phys}}| \le C\{\theta^{-1}(\log\theta)^{2p} + e^{-c(\log\theta)^{2p}}\}. \tag{4.cccxvi}$$

This uses the complete invariant pointed density and its actual critical substitution. It is not a coefficient readout from separate noninvariant Taylor pieces.

4.11.4. *The first nonzero fluctuation coefficient.* The same argument identifies the algebraic coefficient without a numerical two-loop claim. Write the actual exponent as

$$P(g;B) = gP_1(B) + g^2P_2(B) + O(g^3).$$

Then P_1 is odd and P_2 is even. Let $\langle\cdot\rangle_\chi$ be the normalized Gaussian expectation with its retained even cutoff. Expansion of the normalized integral gives

$$\mathcal{F}(g) = \mathcal{F}(0) + g^2\left\{\langle P_2\rangle_\chi + \tfrac{1}{2}\langle P_1; P_1\rangle_\chi\right\} + O(g^4). \tag{4.cccxvii}$$

Here the semicolon is the connected two-variable expectation. Its subtracted product is zero because $\langle P_1\rangle_\chi = 0$. The $O(g^4)$ is in the smaller activity norm, bounded by $C|g|^4\mathfrak{b}^4$.

For precision, let $\mathscr{S}_V(u)$ be the complete centred composed action on the actual pivot graph, and let $\mathscr{G}_V(u)$ be the actual relative contour gauge. Their quadratic parts are the two parts of $Q_\tau(V)$. Let $\mathscr{H}_V(u) = H(V(u))$ and $\mathscr{J}_V(u) = \log J_V(u)$. All derivatives below are at zero. The two polynomials in eq. 4.cccxvii are

$$\begin{aligned} P_1(B) &= -\frac{\tau}{6}D^3\mathscr{S}_V[B^3] - \frac{1}{6}D^3\mathscr{G}_V[B^3] + D\mathscr{J}_V[B] + D\mathscr{H}_V[B], \\ P_2(B) &= -\frac{\tau}{24}D^4\mathscr{S}_V[B^4] - \frac{1}{24}D^4\mathscr{G}_V[B^4] + \frac{1}{2}D^2\mathscr{J}_V[B^2] + \frac{1}{2}D^2\mathscr{H}_V[B^2]. \end{aligned} \tag{4.cccxviii}$$

Repeated arguments are denoted by B^n. In particular the action vertices contain derivatives of the nonlinear pivot constraint; the relative gauge vertices are those of the literal trace gauge. Neither can be replaced by an ambient unconstrained action or a squared logarithmic gauge.

Without the cutoff, eq. 4.cccxvii is evaluated by Gaussian pairings. Each contribution of $\langle P_1; P_1\rangle$ has a line joining the two vertices: their separate odd expectations vanish. Thus its connected carrier is rooted without a second volume factor. The cutoff correction has the already proved wall smallness. Equation eq. 4.cccxvii therefore specifies the next fluctuation coefficient as an actual connected expression, but does not assign it a universal numerical beta-function value.

4.12. **Gaussian comparison for the classical-pullback homogeneous law.** We compare the actual regular homogeneous one-step measure with its quadratic Gaussian reference at the trivial flat background. The observables are fine Wilson plaquettes evaluated on the classical background $U_k(V)$. Their quadratic parts are resummed into the Gaussian precision. The source derivatives are then rooted at their original fine plaquettes. This gives an error proportional to source support mass, rather than the whole lattice volume.

This measure is a classical-pullback one-step model. It does not include an arbitrary older-core Gibbs weight, history conditioning or independent fine quantum fluctuations. The Gaussian

observables below are quadratic functions of a Gaussian field; their joint law need not itself be a multivariate Gaussian.

4.12.1. *The actual normalized fibre measure.* Fix the compatible periodic geometry of Prop. 4.18, inner depth k, and $h = L^{-k}$. Let τ be real in the proved fixed interval about one, and put $g = \theta^{-1/2}$, $\mathfrak{b} = A_1(\log\theta)^p$, $p > 1/2$. Work on the regular coarea branch of the actual outer fibre $M(V) = 1$. The background is exactly one. Its actual graph is

$$V(gB) = e^{i\Phi_1(gB)}, \qquad \Phi_1(gB)|_{\text{free}} = gB, \qquad \chi(B) = \prod_b \mathbf{1}_{|B(b)|<\mathfrak{b}}. \tag{4.cccxix}$$

The entire regular fibre on this free box is this graph, by the proved pivot anchor and uniqueness. The contour-gauge indicators equal one there. Their reference weights, the gauge normalizers and the real box remain fixed as sources vary.

Let $J_1(u)$ be the literal Haar and raw pivot coarea density in eq. 4.ccliv. The normalized law $\nu_{k,g}$ is the pullback to B of

$$\frac{1}{Z_{k,g}} \mathbf{1}_{\text{retained tests}}(V) e^{-\tau S_k(V)/g^2 - \mathrm{GF}(V)/g^2} \delta_G(M(V))\, dV. \tag{4.cccxx}$$

The delta denotes the stated regular Haar coarea disintegration. All field-independent gauge, Haar and g^d factors cancel in this normalized measure; no determinant depending on a source is discarded.

Write $K_0 = Q_{k,\tau} = \tau K_{A,k}(0) + K_G(1)$, $C_0 = K_0^{-1}$, and $\mu_0 = \mu_{C_0}$. For this subsection only, write C for the free-to-full pivot tangent $D\Phi_1(0)$, to distinguish it from the covariance C_0. Define the exact remainder

$$P_g(B) = -g^{-2}\left\{\tau S_k(V(gB)) + \mathrm{GF}(V(gB)) - \tfrac{1}{2} g^2 B^{\mathsf{T}} K_0 B\right\} + \log \frac{J_1(gB)}{J_1(0)}. \tag{4.cccxxi}$$

There is no linear term: the flat action, contour gauge and their first derivatives vanish. Consequently the literal normalized identity is

$$d\nu_{k,g}(B) = \frac{\chi(B) e^{P_g(B)}}{\mathcal{Z}_g(0)}\, d\mu_0(B), \qquad \mathcal{Z}_g(0) = \mu_0[\chi e^{P_g}] > 0. \tag{4.cccxxii}$$

The preceding formation proof supplies the actual local vertices of P_g, with norm $Cg\mathfrak{b}$, and the complete admitted Gaussian structure. All constants are uniform in k, h and compatible volume.

4.12.2. *Actual quadratic source operators.* For a fine plaquette p, put $f_{k,p}(V) = a_p(U_k(V))$. It has value and first derivative zero at one. Let $\mathcal{H}_k$ be the actual linear fine background response in physical potential units. Its literal gauge correction is a gradient and does not change its linear curvature. Define

$$\mathcal{D}_{k,p} B = (\mathrm{d}_h \mathcal{H}_k \mathsf{C} B)(p).$$

The fine Wilson normalization then gives

$$\frac{1}{2} D^2[f_{k,p}(V(u))]_{u=0}[B,B] = B^{\mathsf{T}} A_p B, \qquad A_p = \frac{h^4}{2} \mathcal{D}_{k,p}^{\mathsf{T}} \mathcal{D}_{k,p}. \tag{4.cccxxiii}$$

The nonlinear outer chart contributes no extra quadratic term, because $Df_{k,p}(1) = 0$. The second derivative of the inner background is likewise multiplied by the vanished first fine plaquette variation. The remaining jet is exactly the displayed linear-curvature Gram matrix.

The actual weighted strong response eq. 3.mccxcv gives exponentially summable coarse bond kernels for $\mathcal{D}_{k,p}$. In particular, for a fixed $s > 0$,

$$\sum_{b,b'} e^{s(d(b,p)+d(b',p))} \|A_p(b,b')\| \le C h^4. \tag{4.cccxxiv}$$

Keep the original p and its two propagator paths as its carrier tag. This is an actual source-rooted operator family: each carrier contains p and its matrix endpoints. The same bound holds

with a fixed connected-carrier exponential weight, by the marked-tree construction. There is no fine-coordinate dimension factor in eq. 4.cccxxiv.

For profiles w_i, $1 \le i \le r \le 4$, with $\|w_i\|_\infty \le 1$, put

$$\begin{aligned} H_i(V) &= \sum_p w_i(p) f_{k,p}(V), \quad X_i(B) = g^{-2} H_i(V(gB)), \\ A_i &= \sum_p w_i(p) A_p, \qquad\qquad Q_i(B) = B^{\mathsf T} A_i B. \end{aligned} \tag{4.cccxxv}$$

Equivalently $Q_i = \frac{1}{2} H_i''(1)[\mathsf{C}B, \mathsf{C}B]$. Summing eq. 4.cccxxiv over fine plaquettes near a fixed coarse bond cancels the physical h^4 with their $O(h^{-4})$ density. It proves a uniform weighted Schur bound $\|A_i\|_{\mathrm{Sch,s}} \le C$. Summing its absolute entries instead gives $\|A_i\|_{\mathrm{tr}} \le C h^4 \sum_p |w_i(p)|$.

The exact source remainder is

$$R_{p,g}(B) = g^{-2} f_{k,p}(V(gB)) - B^{\mathsf T} A_p B, \qquad X_i = Q_i + R_{i,g}, \quad R_{i,g} = \sum_p w_i(p) R_{p,g}. \tag{4.cccxxvi}$$

Retaining its original fine tag in the action-tree proof gives a rooted potential norm at most $C h^4 g\mathfrak{b}$ for each $R_{p,g}$, with a fixed reserve in the carrier rate. Its zero of order three follows from the own value, first jet and quadratic subtraction. Its chart is the same fixed admitted chart as eq. 4.cccxix. Thus the large factor g^{-2} in the observable has been treated by its actual Taylor decomposition; it is not inserted into a bounded- source theorem as an old coefficient.

4.12.3. *Exact quadratic resummation.* For $t = (t_1, \dots, t_r)$, define

$$K_t = K_0 - 2 \sum_i t_i A_i, \qquad C_t = K_t^{-1}, \qquad \mu_t = \mu_{C_t}, \qquad R_g(t) = \sum_i t_i R_{i,g}. \tag{4.cccxxvii}$$

The uniform Schur bounds and the actual gap of K_0 give a fixed complex polydisc $|t_i| < 4\rho$ on which the real part of K_t is positive and its actual carrier norms are uniform. Decrease ρ further, if necessary, in the near/tail and combined-power construction of eq. 4.ccxciv. It supplies precisely the local Gaussian structures for every K_t, including enlarged independent cube discs, normalization and walls. The radius $\rho > 0$ is independent of h, k, g, volume and profiles satisfying the displayed supremum bound. At most four profiles are used, so no shrinking radius in their number is hidden here.

Let

$$\mathcal{Z}_g(t) = \mu_t[\chi e^{P_g + R_g(t)}], \qquad E_g(t) = \log \mathcal{Z}_g(t), \qquad L_G(t) = -\frac{1}{2} \log\det\left(I - 2C_0 \sum_i t_i A_i \right). \tag{4.cccxxviii}$$

Choose the determinant branch zero at $t = 0$, and the cluster-log branch for E_g. The actual nonlinear source vertices remain of norm $C g\mathfrak{b}$ on this disc. Formation therefore makes $\mathcal{Z}_g(t)$ zero-free. Gaussian completion, with all its normalizers retained, proves

$$\log \mathbb{E}_{\nu_{k,g}} e^{\sum_i t_i X_i} = L_G(t) + E_g(t) - E_g(0), \qquad \log \mathbb{E}_{\mu_0} e^{\sum_i t_i Q_i} = L_G(t). \tag{4.cccxxix}$$

The determinant here is essential. It is the source-dependent ratio of the normalized Gaussians before the residual interaction is expanded.

4.12.4. *Source-rooted differentiation of the actual expansion.* We prove a source-mass bound, not an unpointed error times the volume. Introduce independent fine coefficients ζ_p, with $K_\zeta = K_0 - 2\sum_p \zeta_p A_p$ and source remainder $\sum_p \zeta_p R_{p,g}$. The preceding argument is uniform on a fixed product ball $\|\zeta\|_\infty < \zeta_*$: the uniform Schur bound uses the h^4 density sum already proved. At each filed carrier combine the fine-plaquette contributions into one source-potential type. Keep p as the mark when differentiating. The type count is then uniform in the fine mesh. Choose the retained ρ

so that $16\rho < \zeta_*$; the four-profile polydisc is then inside this product ball. For each original fine plaquette, the complete covariance has the exact derivative

$$\partial_{\zeta_p} C_\zeta = 2C_\zeta A_p C_\zeta. \tag{4.cccxxx}$$

Its source tag and its h^4 mass are retained in every term. At complete parameters the exact normalized differentiation identity is

$$\partial_{\zeta_p} E_g = \left\langle R_{p,g} + B^{\mathsf{T}} A_p B \right\rangle_{g,\zeta} - \mathrm{Tr}(C_\zeta A_p),$$

where the brackets have density $\mathcal{Z}_g(\zeta)^{-1}\chi e^{P_g + \sum_q \zeta_q R_{q,g}}\, d\mu_\zeta$. Thus the Gaussian quadratic normalizer is subtracted exactly.

This tag can also be retained through the local covariance construction. Truncate by the full connected carrier, including the original p, both matrix endpoints and their propagator paths. A term with nearby matrix endpoints and a distant source root belongs to the long-carrier tail. Endpoint distance alone does not define this truncation. Symmetrize each real carrier contribution under transpose, retaining its p tag. The source-rooted exponential entry bound above and the physical h^4 density sum give a uniformly small Schur tail. Thus the short-carrier real precision differs from the full gapped precision by that small tail; the near-power spectral argument still applies. More explicitly, reserve two copies of a small length weight in the tagged source family. Since its carrier joins b to p, the tail then obeys

$$\sum_{b',\,\gamma:\ell(X_\gamma)>R} \|A_{p,\gamma}(b,b')\| \le Ch^4 e^{-cR} e^{-cd(b,p)}.$$

Summing p uses $h^4 \sum_p e^{-cd(b,p)} \le C$, so the full source tail has Schur norm Ce^{-cR}, uniformly on the source product ball. Transposition gives the column estimate. In this full-carrier algebra, differentiating a near power inserts exactly one $2A_p/a$; differentiating its tail telescoping formula does the same. For example

$$\partial_{\zeta_p} H^m_{\le R} = \sum_{j<m} H^j_{\le R}(2A_{p,\le R}/a) H^{m-1-j}_{\le R}.$$

Its full combined ball carrier contains the original p. The global absolute entry sum of that marked matrix is Ch^4, with constants allowed to depend on the fixed m, R, M. For products, this follows from $\|UE_pV\|_{\mathrm{entry},1} \le \|U\|_{\mathrm{Sch}} \|E_p\|_{\mathrm{entry},1} \|V\|_{\mathrm{Sch}}$. The marked geometric series costs $\sum_{v\ge1} vq^{v-1} < \infty$. The prefix derivatives have the same estimate. Consequently the filed local covariance $D_{W,Z}$, with root coordinate set W, held root guard, and all cube parameters zero outside its wall domain Z, has a source derivative $\dot D_{W,Z,p}$ with

$$\|\dot D_{W,Z,p}\|_{\mathrm{entry},1} \le Ch^4, \qquad \|D^{-1}_{W,Z}\| \le C, \tag{4.cccxxxi}$$

uniformly on the full coarse parameter discs. If the local wall domain does not contain the source root p, this derivative is zero: every retained carrier contains that root. The same statements hold for the explicit source-potential derivative $R_{p,g}$.

At complete parameters the actual covariance restriction instead has derivative

$$\partial_{\zeta_p}(\chi_W C_\zeta \chi_W^{\mathsf{T}}) = 2\chi_W C_\zeta A_p C_\zeta \chi_W^{\mathsf{T}},$$

which can be nonzero for a source outside W. The vanishing above concerns the filed $D_{W,Z}$ for $p \notin Z$; it does not assert vanishing of this complete restriction for $p \notin W$.

Here the entry norm is the sum of colour-block norms. It bounds trace norm up to the fixed colour factor. Thus the derivative of the normalized marginal Gaussian density is its density times

$$\frac{1}{2}\{B^{\mathsf{T}} D^{-1}_{W,Z} \dot D_{W,Z,p} D^{-1}_{W,Z} B - \mathrm{Tr}(D^{-1}_{W,Z} \dot D_{W,Z,p})\}, \tag{4.cccxxxii}$$

whose absolute value is at most $Ch^4(1+|B|^2)$. There is no factor equal to the local or exterior Gaussian dimension in this bound. Its expectation against the normalized constant functional is exactly zero. In particular an empty selection cannot contribute a source-dependent vacuum activity.

Use a fixed small extra Gaussian tilt $\delta \asymp (LM)^{-4}$ to bound $1+|B|^2 \le C_\delta e^{\delta|B|^2}$. The Gaussian comparison charge is then only a fixed constant per polymer cube, absorbed by the reserved spatial rate and cube-Cauchy radius. It retains the same small amplitude as the selected integrand: every nonempty selection has either an actual remainder potential of size $Cg\mathfrak{b}$ or a failed-cutoff tail of size $Ce^{-c\mathfrak{b}^2}$. Polynomial boundary factors can be absorbed by a fixed decrease of c. Differentiating a potential instead inserts the actual $R_{p,g}$, whose norm is already $Ch^4 g\mathfrak{b}$. Apply the proved inserted-potential estimate to that literal norm.

It follows, by the same finite Mayer and coarse-interpolation formulas, that the actual activity derivative with its source root satisfies

$$|\partial_{\zeta_p} H_g(Z;\zeta)| \le Ch^4\eta(g)e^{-\lambda d_c(Z)}\mathbf{1}_{\{p\in Z\}}, \qquad \eta(g) = g\mathfrak{b} + e^{-c\mathfrak{b}^2}. \tag{4.cccxxxiii}$$

Membership includes the fixed assigned carrier collar. A fixed boundary multiplicity is absorbed in C. The extra tilt used above is chosen in the ordinary Gaussian margin before the final spatial rates; it does not depend on g, h, k or source support.

Differentiate the convergent connected-cluster logarithm. Mark the differentiated activity and retain its original p. The rooted cluster theorem bounds all polymers attached to it. Summing its own polymers containing the fixed coarse cube of p uses their reserved exponential rate. Hence

$$|\partial_{\zeta_p} E_g(\zeta)| \le Ch^4\eta(g). \tag{4.cccxxxiv}$$

This is the source-rooted argument; the estimate is not obtained by first bounding $|E_g|$ by a volume term and then differentiating.

For $\zeta_p = \sum_i t_i w_i(p)$, eq. 4.cccxxxiv therefore proves

$$|\partial_{t_i} E_g(t)| \le C\eta(g)h^4 \sum_p |w_i(p)|. \tag{4.cccxxxv}$$

Integrating on the straight path from zero to t also gives

$$|E_g(t) - E_g(0)| \le C\eta(g)\sum_i |t_i| h^4 \sum_p |w_i(p)|.$$

4.12.5. *Cumulants and their Gaussian leading terms.*

Proposition 4.22 (Uniform comparison for classical-pullback observables)**.** For $1 \le n \le 4$ and the profiles of eq. 4.cccxxv,

$$\left|\kappa_{\nu_{k,g}}(X_{i_1},\dots,X_{i_n}) - \kappa_{\mu_0}(Q_{i_1},\dots,Q_{i_n})\right| \le C_n\eta(g)\, m_h(w), \qquad m_h(w) = h^4\sum_{p,i}|w_i(p)|. \tag{4.cccxxxvi}$$

The constants and the analytic source disc are independent of homogeneous depth, mesh, volume and source support. For the unscaled actual observables $H_i(V)$, the corresponding error is $C_n g^{2n}\eta(g)m_h(w)$. ∎

Proof. Use the exact normalized identity eq. 4.cccxxix. Bound one source derivative of its error by eq. 4.cccxxxv. The remaining at most three derivatives follow from Cauchy on the fixed larger source disc. Repeated indices give only their fixed factorials. This proves eq. 4.cccxxxvi. Finally $H_i = g^2 X_i$ exactly, so multilinearity of cumulants gives the factor g^{2n}. □

4.12.6. *The source-rooted even-coupling refinement.* Keep the physical retained threshold $\mathfrak{b}$ fixed and replace the coupling in the remainder by an auxiliary complex γ. In particular $R_{p,\gamma}(B) = \gamma^{-2} f_{k,p}(V(\gamma B)) - B^{\mathsf{T}} A_p B$, with its removable value at zero. Write $E_{\gamma,\mathfrak{b}}(\zeta)$ for the resulting logarithm. The Gaussian precision K_ζ, the profiles and the real cutoff are held fixed. The divided remainders have removable values at $\gamma = 0$. The actual chart and local potential bounds hold on $|\gamma| < c_*/\mathfrak{b}$, with c_* fixed below their uniform ceilings, exactly as in eq. 4.cccx. This is an analytic deformation of the retained-cutoff integral; it makes no change to the original real tests at the physical value $\gamma = g$.

The source-rooted proof above therefore holds throughout that disc, with

$$|\partial_{\zeta_p} E_{\gamma,\mathfrak{b}}| \le C h^4 \{|\gamma|\mathfrak{b} + e^{-c\mathfrak{b}^2}\}.$$

Its h^4 tag is unchanged. At zero coupling only failed-cutoff activities remain, so $|\partial_{\zeta_p} E_{0,\mathfrak{b}}| \le C h^4 e^{-c\mathfrak{b}^2}$.

Moreover the actual source remainders satisfy $R_{p,-\gamma}(-B) = R_{p,\gamma}(B)$. The Gaussian, cutoff and the matrix construction are independent of γ. The exact sign argument of eq. 4.cccxii thus applies with every original source tag retained. The chosen cluster logarithm, and its ζ_p derivative, are even in γ. Subtract the zero-coupling derivative. This holomorphic function has a double zero at the origin. Cauchy on a fixed smaller concentric circle, followed by the order-two Schwarz bound, gives

$$|\partial_{\zeta_p} E_{g,\mathfrak{b}}| \le C h^4 \eta_2(g), \qquad \eta_2(g) = (g\mathfrak{b})^2 + e^{-c\mathfrak{b}^2}, \qquad g\mathfrak{b} < c_*/4. \tag{4.cccxxxvii}$$

This step uses the uniform source-rooted bound, so it retains h^4 rather than introducing a whole-volume factor. Profile summation and the same fixed source-disc Cauchy argument show that the log-MGF comparison and eq. 4.cccxxxvi hold with η_2 in place of η. The unscaled observables retain their exact factor g^{2n}. The preceding η estimate is its weaker corollary when $g\mathfrak{b} < 1$.

For clarity the leading Gaussian law is entirely explicit:

$$\begin{aligned} \mathbb{E}_{\mu_0} Q_i &= \operatorname{Tr}(C_0 A_i), \\ \operatorname{Cov}_{\mu_0}(Q_i, Q_j) &= 2 \operatorname{Tr}(C_0 A_i C_0 A_j), \\ L_G(t) &= \sum_{n \ge 1} \frac{2^{n-1}}{n} \operatorname{Tr}\left[\left(C_0 \sum_i t_i A_i\right)^n\right]. \end{aligned} \tag{4.cccxxxviii}$$

Equivalently, the actual linear fine-curvature covariance is $\Gamma_k(p,q) = \mathcal{D}_{k,p} C_0 \mathcal{D}_{k,q}^{\mathsf{T}}$. The first two observable formulas are

$$\mathbb{E} Q_i = \frac{h^4}{2} \sum_p w_i(p) \operatorname{Tr} \Gamma_k(p,p), \quad \operatorname{Cov}(Q_i, Q_j) = \frac{h^8}{2} \sum_{p,q} w_i(p) w_j(q) \operatorname{Tr}[\Gamma_k(p,q)\Gamma_k(q,p)].$$

Thus a mixed Gaussian quadratic cumulant is $\frac{2^{n-1}}{n} \sum_{\sigma \in S_n} \operatorname{Tr}(C_0 A_{i_{\sigma(1)}} C_0 A_{i_{\sigma(2)}} \cdots C_0 A_{i_{\sigma(n)}})$. For coincident observables this is $2^{n-1}(n-1)! \operatorname{Tr}[(C_0 A_i)^n]$. These are quadratic Gaussian cumulants, including their generally nonzero higher orders.

Since $p > 1/2$, $\eta_2(g) \to 0$ and the cutoff term is eventually $O((g\mathfrak{b})^2)$. The log-MGF and cumulant errors tend to zero whenever $\eta_2(g) m_h(w) \to 0$, including bounded source masses and masses growing by a fixed power of $\log(1/g)$. Their reference is the actual depth- k quadratic Gaussian law. All bounds retain the actual constraint, Haar/coarea density and fixed tests of this concrete classical-pullback model.

4.13. **Symmetry of the cutoff fibre integral.** The cutoff is imposed in free bond coordinates. Its lattice symmetry therefore requires more than symmetry of the group average. For the middle pivots used here, an isometry permutes the free bonds and acts orthogonally on their colour coordinates. We prove this and the covariance of the resulting integral.

Let $L = 2m + 1$, and use the centered blocks and the pivot policy of § 3.3. For a positive coarse bond $c = (y, y + Le_\mu)$, its pivot is

$$b_0(c) = (y + me_\mu, y + (m + 1)e_\mu). \tag{4.cccxxxix}$$

Write Π for these bonds and E for their complement among positive bonds, with all three colour coordinates on each bond. A real fluctuation cutoff in this subsection means

$$\chi_{\mathfrak{b}}(B) = \prod_{b \in E} \mathbf{1}_{\{\langle B(b), B(b)\rangle < \mathfrak{b}^2\}}. \tag{4.cccxl}$$

Thus each factor is a colour ball. Complex polydiscs used for estimates are separate analytic domains.

Let $\mathsf{r}(x) = Rx + a$, where R is a signed permutation matrix and a is a coarse lattice translation. On oriented bonds define $(\mathsf{r}U)(\mathsf{r}b) = U(b)$. We consider isometries between compatible tori, or of the infinite lattice. On a cubic torus this includes the full hypercubic group.

Lemma 4.23 (The action on free coordinates)**.** The isometry preserves the pivot set, with positive orientations restored. For a background U, define the linear map r_U on bond coordinates as follows. Let b^{r} be the positive representative of the image unoriented bond, and let $\varepsilon_{\mathsf{r}}(b)$ be its image orientation sign. Put

$$(\mathsf{r}_U a)(b^{\mathsf{r}}) = \begin{cases} a(b), & \varepsilon_{\mathsf{r}}(b) = 1, \\ -\operatorname{Ad}(U(b)^{-1})a(b), & \varepsilon_{\mathsf{r}}(b) = -1. \end{cases} \tag{4.cccxli}$$

Then

$$\mathsf{r}(e^{ia}U) = e^{i\mathsf{r}_U a}\mathsf{r}U. \tag{4.cccxlii}$$

For real U, r_U permutes bonds and acts by an orthogonal matrix on each colour space. Its restrictions $\mathsf{r}_U^E, \mathsf{r}_U^\Pi$ are well defined, and $\chi_{\mathfrak{b}}(\mathsf{r}_U^E B) = \chi_{\mathfrak{b}}(B)$. ■

Proof. If $Re_\mu = e_\nu$, the image of eq. 4.cccxxxix is the middle pivot of the image coarse bond. If $Re_\mu = -e_\nu$, the new positive coarse bond starts at $\mathsf{r}y - Le_\nu$. Its middle pivot has endpoints $\mathsf{r}y - (m + 1)e_\nu, \mathsf{r}y - me_\nu$, the reversed endpoints of the image pivot. Thus Π, and hence E, are preserved.

On a reversed bond,

$$(e^{ia(b)}U(b))^{-1} = U(b)^{-1}e^{-ia(b)} = e^{-i\operatorname{Ad}(U(b)^{-1})a(b)}U(b)^{-1}.$$

This proves eq. 4.cccxlii. For real U, its adjoint action preserves the colour pairing; the minus sign also preserves it. The product cutoff is therefore unchanged. The same assertion would not follow for a box in fixed individual colour components. □

Lemma 4.24 (Covariance of the mean and graph)**.** The actual one-step mean satisfies $\mathcal{M}(\mathsf{r}U) = \mathsf{r}\mathcal{M}(U)$. For its admitted graph,

$$\Phi_{\mathsf{r}U}(\mathsf{r}_U^E u) = \mathsf{r}_U \Phi_U(u). \tag{4.cccxliii}$$

The identity is holomorphic wherever both graph arguments lie in the joint chart. ■

Proof. The isometry sends the coordinate-order path multiset from y to x to the one from $\mathsf{r}y$ to $\mathsf{r}x$, preserving its weights. The internal implicit mean therefore has the same covariance, by uniqueness.

The outer operation is the exponential of the average of closed logarithms, followed by multiplication by the central path. It also respects reversal. To check this directly, write its central transport as C and its closed inputs as Z_x, so $\mathcal{M}(U)(c) = e^{\overline{\log Z}}C$. For the reversed coarse bond the closed inputs are $C^{-1}Z_x^{-1}C$. Their average logarithm is $-\operatorname{Ad}(C^{-1})\overline{\log Z}$; multiplication by C^{-1} gives $(e^{\overline{\log Z}}C)^{-1}$. This uses the actual outer operation.

Put $W = \mathcal{M}(U)$. The relative raw constraint q_U transforms as

$$q_{\mathsf{r}U}(\mathsf{r}_U a) = \mathsf{r}_W q_U(a).$$

For a reversed coarse bond this is $-\operatorname{Ad}(W(c)^{-1})q_U(a)(c)$; it follows by conjugating the inverse relative coarse product before taking its admitted logarithm. The right side of eq. 4.cccxliii thus solves the transformed constraint with the transformed free values. Its small-graph uniqueness proves the identity for real data. Joint analyticity extends it on the common complex chart. □

Proposition 4.25 (Covariance of the regular transfer)**.** Use the actual regular coarea component, unit contour-gauge weights, the middle pivots eq. 4.cccxxxix, and the cutoff eq. 4.cccxl. Assume the action and input pointings are covariant under r. Then the transfer and its complete pointings are covariant under r. This applies to the canonical homogeneous step with action S_j, and to an ordinary input with the same covariance. In particular the scalar quadratic readout is available for that model on the infinite companion. ■

Proof. For the physical background action, reflecting a critical orbit gives a critical orbit with reflected datum. The strong norm, regularity bounds and averaging constraint are preserved. Orbit uniqueness in Prop. 3.183 identifies the two orbits. Each original plaquette trace, and hence S_j, has the required covariance. Any difference between chosen literal representatives is a node-fixed gauge and is removed at the level of the complete function.

For a fixed real background, use $u' = \mathsf{r}_U^E u$ as free coordinates. This is an orthogonal change with absolute determinant one. Equation eq. 4.cccxliii maps the graph and the product colour balls exactly. Regular plaquette bounds and the coarea fibre are preserved.

The coordinate coarea factor is preserved as well. Its pivot derivative transforms by r_W on its rows and $(\mathsf{r}_U^{\Pi})^{-1}$ on its columns. For each reversed coarse row the corresponding pivot is also reversed: the two factors of determinant minus one cancel. Their adjoint factors have determinant one. Row and pivot permutations cancel in the same way. The reciprocal pivot determinant on its identity branch is therefore unchanged. The Haar density $j(a)$ depends only on the invariant colour pairing. Consequently the full coarea density in eq. 4.ccliv is carried to itself.

The internal transports and their reference products are permuted by the isometry. Their relative contour trace, tame test and unit-weight sum are unchanged. The centered action and its full quadratic Hessian transform by the same free orthogonal map. Thus the Gaussian precision transforms as $K' = \mathsf{r}_U^E K(\mathsf{r}_U^E)^{-1}$, and its normalized real Gaussian measure is carried to the new one. This proves covariance of the integral, including its actual cutoff, Haar factor, pivot factor and numerical Gaussian normalization.

The block axial choice also commutes with the isometry. If $s_U(x) = T_{y,x}(U)$ and $s_U(y) = 1$, then $s_{\mathsf{r}U}(\mathsf{r}x) = s_U(x)$. Hence $(\mathsf{r}U)^{s_{\mathsf{r}U}} = \mathsf{r}(U^{s_U})$. This uses the symmetric contour mean, not a choice of one ordered axial path.

For the pointings, choose their insertions before carrier filing. Original plaquettes and old anchors are permuted, and midpoint tents are covariant. On a reversed free bond, the vector and its derivative are contracted by the same orthogonal map, so the radial and normalized cubic insertions are preserved. The cutoff surface and its colour surface measure are also preserved. For a Gaussian trace, each diagonal colour block is conjugated and its free bond is permuted. The pivot normalizer factors have the covariance already proved. Normalized expectations and their interpolation integrals therefore give covariant complete pointed functions.

The real identities extend to the admitted complex external-field domain by holomorphy. This extension does not change real integration contours by a complex orthogonal map. The auxiliary localization grid need not be preserved by every translation; it files an already defined complete pointing and does not change its sum. Its individual pieces need not have the full covariance. □

4.14. **Physical transport of homogeneous invariant densities.** The subtraction appropriate to a classical pullback is a multiple of its actual effective action. We prove a local analytic irrelevance estimate for the remaining complete physical density. The proof uses the literal intermediate mean, including its node frames. Its localized analytic representatives are not required to be separately gauge invariant.

We work on the fixed coarse bond ball about the trivial flat field, with compatible periodic volumes, and on its infinite lattice companion. All assertions about the companion concern normally convergent pointed analytic functions. They do not require an infinite volume probability measure. Fix $0 < \beta < \alpha < 1$. Constants below may depend on L, α, β, a fixed analytic input radius, and the localization size. They are independent of the two depths and the compatible volume.

4.14.1. *Literal intermediate coordinates.* Use final coarse spacing one. For $0 \le s \le k$ put

$$h = L^{-k}, \qquad \xi = hL^s = L^{s-k}, \qquad W = e^{iw}, \qquad U_k(W) = e^{ih\widehat{A}_k(w)}.$$

Here U_k is the literal critical representative of Prop. 3.183. Define

$$V_{s,k}(W) = M^s U_k(W), \qquad B_{\xi,b}(w) = \frac{1}{i} \log V_{s,k}(W)(b). \tag{4.cccxliv}$$

The bond b on the left is indexed in old coarse units; its physical midpoint in final units is ξm_b. The logarithm will be shown to stay in its actual chart. This definition does not replace M^s by the straightened linear average.

We first isolate a bound for the actual mean acting on an arbitrary small fine field. Write

$$\mathscr{P}_{h,s}(A) = \frac{1}{i} \log M^s(e^{ihA}).$$

For a homogeneous polynomial row, its absolute row norm is the sum over its fine input bonds of the norms of its colour multilinear coefficients. Ordered coefficients include their Taylor factorial once.

Lemma 4.26 (Absolute rows of the full plain mean)**.** There are $c, C > 0$ such that the degree m row coefficient $T^{(m)}_{h,s;b}$ of $\mathscr{P}_{h,s}$ satisfies

$$\sum_{b_1,\dots,b_m} \|T^{(m)}_{h,s;b;b_1\dots b_m}\| \le C^m \xi^m, \qquad m \ge 1. \tag{4.cccxlv}$$

Its fine inputs lie within physical distance $C_L\xi$ of the output bond. On $\|A\|_\infty < c$,

$$\|D\mathscr{P}_{h,s}(A)\|_{\mathrm{row}} \le C\xi, \qquad \|D^2\mathscr{P}_{h,s}(A)\|_{\mathrm{row}} \le C\xi^2. \tag{4.cccxlvi}$$

The same conclusions, with zero constant term, hold for the logarithm of the node frame in the partial factorization. For the row assertion alone C, c can be chosen uniformly over $L \ge 3$, as in eq. 3.mcccv; the nonlinear fixed-leg estimate has the different dependence proved in Prop. 3.187. ■

Proof. Use the exact recursion and factorization eq. 3.mccliii–eq. 3.mccliv, stopped at s. The one-step stencil is finite for fixed L. Its actual analytic chart therefore gives absolute Taylor row bounds K_L^m for the terms of degree $m \ge 2$. The derivative of the straightened row at zero must first be combined: its row norm is exactly L, by eq. 3.mcclv. Taking the absolute values of its separate contour and node-frame contributions before this cancellation would give an incorrect depth factor.

The positive formal series majorizing the raw angle rows can consequently be chosen to satisfy

$$b_0(z) = hz, \qquad b_{t+1}(z) = Lb_t(z) + \frac{K_L^2 b_t(z)^2}{1 - K_L b_t(z)}. \tag{4.cccxlvii}$$

Increasing K_L also majorizes the zero-constant one-step node increment by $K_L b_t/(1 - K_L b_t)$. Let $\xi_t = hL^t$, and evaluate these positive series at $z = c_0/\xi$. A first-exit argument gives

$$b_t(z) \le 2\xi_t z \quad (0 \le t \le s), \qquad \sum_{t<s} \xi_t \le \frac{\xi}{L-1}.$$

Indeed, below this bound the quotient $b_{t+1}/(Lb_t)$ is at most $1 + C_L b_t$. The product of these quotients is at most $\exp(C_L z \sum_{t<s} \xi_t)$, less than two when c_0 is fixed sufficiently small. All inputs then stay strictly in the one-step analytic chart.

The product defining v_s, and the product in reverse order defining v_s^{-1}, have positive row majorants bounded by

$$\prod_{t<s}(1-K_L b_t(z))^{-1}.$$

They differ from one by at most $C_L c_0$. Apply the convergent exponential and logarithm series to the exact product

$$M^s(e^{ihA})(b) = v_s(b_-)\, e^{ia_s(b)}\, v_s(b_+)^{-1}.$$

Its zero-constant absolute logarithm majorant at $z = c_0/\xi$ is at most $C_L c_0$. Positivity of the majorant gives the coefficient bound $C_L c_0^{1-m}\xi^m$, which implies eq. 4.cccxlv. This is an absolute coefficient sum over fine inputs; it is stronger than a Cauchy bound for a function of an unspecified number of fine coordinates.

The one-step support enlargement at stage t has physical size at most $C_L\xi_t$. Its total size is at most $C_L\sum_{t<s}\xi_t \le C_L\xi$. Differentiating the absolutely convergent majorant on a fixed smaller supremum ball proves eq. 4.cccxlvi. The proof for $\log v_s$ uses the same product majorant. Restriction of a node row to a coarser node set does not increase any of these row sums. □

The literal representative also has a uniform connected expansion. This step is needed because the action trees can use a mean-slice representative by gauge invariance, whereas the intermediate field in eq. 4.cccxliv uses the literal one.

Lemma 4.27 (Connected expansion of the literal field)**.** On a fixed coarse ball, $\widehat{A}_k(w)$ has uniform strong-cell norm $C\|w\|_\infty$ and an analytic connected-tree family rooted at each output fine cell, with a fixed positive physical length rate. After choosing M large enough for a requested cube rate and decreasing the field radius, its rooted M-cube norm is at most Cr on $\|w\|_\infty < r$. The same family bound holds for the entire field vector on one localization cube, with its maximum strong-cell norm. For a fixed requested rate its amplitude constant can be chosen independent of M and L, with an allowed radius that may depend on L. ■

Proof. The mean-slice field $A_k(w)$ has the strong-cell trees of eq. 4.cclxix and eq. 4.cclxxii. The prescribed literal field is eq. 3.mcclxxxiv. Its node function $v_h(A)$ reads only a fixed physical star: the support sum in the preceding proof is bounded at full spacing one. That proof also gives its uniform analytic supremum bounds on a fine supremum ball.

The actual extension E_n in eq. 3.mcclxxxii is local and bounded from coarse supremum norm to Y_α. Hence $\lambda(A) = E_n(i^{-1}\log v_h(A))$ is a local analytic map into Y_α with norm $C\|A\|_\infty$. A fixed physical star contains only a fixed number of strong cell slots. Banach Cauchy in those slots gives coefficients C^m; it does not introduce the number of fine sites.

Finally use the uniformly analytic finite-gauge map eq. 3.mcclxxxiii. Its apparent h^{-1} is removed before expanding by writing $\lambda(x+he_\mu) = \lambda(x) + hD_\mu\lambda(x)$. The logarithm of the remaining product vanishes at $h=0$, so division by h is analytic and bounded in the stated strong cell norms. Substitution of the field trees into these local analytic maps attaches fixed physical stars and vertices of arity at least one. Their number is bounded by a fixed multiple of the leaves after combining the linear maps. Their coefficients and the fixed per-leaf carrier costs are absorbed by a smaller input radius. The physical exponential length reserve in the field trees pays the stars. This proves both the connected family and the strong bound for the actual literal representative.

For the vector assertion perform the same actual fixed-point expansion with macroblocks from the outset. Let $\mathcal{E}_Q$ be a smooth macroblock partition, whose physical derivatives are bounded uniformly for $M \ge 1$, supported in the $M/10$ enlargement of its block. The product slots are supported strong fields on these enlargements; their bounded overlap reconstructs the global field. Let $\mathcal{I}_{Q'}$ restrict the fine and coarse forcings to a macroblock. The target norm is the maximum strong unit-cell norm on the support of the output slot. Work first with the infinite-cover inverse.

The unit-cell inverse estimate gives

$$\|\mathcal{E}_Q\mathcal{L}_{0,\infty}^{-1}\mathcal{I}_{Q'}\| \le Ce^{-s_0\,\mathrm{dist}(Q,Q')/2}, \qquad \sup_Q \sum_{Q'} e^{\kappa d_M(Q,Q')}\|\mathcal{E}_Q\mathcal{L}_{0,\infty}^{-1}\mathcal{I}_{Q'}\| \le C_\kappa. \tag{4.cccxlviii}$$

For the first estimate take the supremum over target cells after summing the exponential unit-cell kernel over source cells in Q'. There is no factor M^4. For the second, touching macroblocks give only a fixed number of terms; other terms have physical separation at least $cM(d_\infty(Q,Q')-C)_+$. Choose M larger than $C\kappa/s_0$. On a torus periodize these cover blocks, retaining the image $Q'+nP$ as a separate label before any carrier assignment. Give each such block a fixed path on the cover joining its two macroblocks. The sum over source blocks and period images is exactly the cover sum just bounded. Short endpoint distance in the quotient does not remove a long image path. Projection of this normally convergent tree construction solves the actual periodic fixed-point equation; contraction uniqueness identifies its sum with the finite-volume background.

The actual residual in eq. 4.cclxix, restricted to Q, reads only a fixed number of neighboring macroblocks when M exceeds its physical carrier radius. Its target is a forcing supremum norm. Its analytic bound is $C_L\|x\|^2$, independent of M: pointwise locality and the physical transpose bound are used before taking the supremum. Banach Cauchy counts these neighboring macroblocks, not their fine coordinates. The actual ordered-tree majorant therefore gives a macroblock field family of size $2C_\kappa r$ after reducing the radius below its nonlinear ceiling. The free constant in eq. 4.cccxlviii is uniform in L, since its direct rows depend on $N=L^k$, as explained after eq. 3.mcccv. Growth in C_L is paid only by the allowed radius. The actual node extension and finite-gauge map are local analytic maps on the same macroblock spaces. Their uniform path-row bounds give the stated literal-field vector family. Its amplitude constant is independent of M, L. □

Proposition 4.28 (Actual smooth intermediate fields)**.** There is a fixed $r_*>0$ such that eq. 4.cccxliv is admitted on $\|w\|_\infty<r_*$, at every pair of depths. For $\|w\|_\infty<r\le r_*$ there is a continuous connection $a_\xi(w)$, holomorphic in w, such that

$$B_{\xi,b}(w) = \xi\, a_\xi(w)(\xi m_b), \qquad \|a_\xi(w)\|_{C^{1,\alpha}} \le Cr. \tag{4.cccxlix}$$

For any fixed requested cube rate, with M and the radius chosen accordingly, each raw coordinate also has an actual local analytic family

$$B_{\xi,b}(w) = \sum_{X\ni q(\xi m_b)} B_{\xi,b,X}(w_X), \qquad \sum_X e^{\kappa_0 d_M(X)}\|B_{\xi,b,X}\|_r \le C\xi r. \tag{4.cccl}$$

The norm uses the final M-cube lattice; $q(x)$ is a cube containing x. There is also a Banach-valued version of eq. 4.cccl: all old bond coordinates in one old M-cube can be grouped into a single vector with its supremum norm. Its rooted family has the same bound $C\xi r$. ■

Proof. Apply Lem. 4.26 to the literal field of Lem. 4.27. The raw angle and all intermediate raw inputs are bounded by $C\xi r$ and $Cr\xi_t$. The node products remain in their actual charts. A fixed reduction of r_* proves admission.

For the spatial assertion write $A=\widehat{A}_k(w)$. Translation by ξe_ν preserves every grid in the partial hierarchy. The actual mean commutes with this translation. Put $\delta_\nu A=\tau_{\xi e_\nu}A-A$. The first two derivatives of the full plain mean give

$$D^\xi_\nu(B_\xi/\xi) = \xi^{-2}\int_0^1 D\mathscr{P}_{h,s}(A+t\delta_\nu A)[\delta_\nu A]\,dt. \tag{4.cccli}$$

The fine physical strong norm gives $\|\delta_\nu A\|_\infty \le C\xi r$, so the right side is bounded by Cr. At an old-grid displacement y of physical size $d\le 1$,

$$\|\tau_y\delta_\nu A-\delta_\nu A\|_\infty \le C\xi r d^\alpha.$$

The points on the two interpolation segments satisfy $\|\tau_y(A+t\delta_\nu A)-(A+t\delta_\nu A)\|_\infty \le Crd$: use their convex-combination expression. Equation eq. 4.cccxlvi therefore bounds the difference of eq. 4.cccli by

$$Crd^\alpha + C\xi r^2 d \le Crd^\alpha.$$

The zeroth supremum of B_ξ/ξ is Cr. The exact staggered interpolation Prop. 5.22, at mesh ξ, now gives eq. 4.cccxlix. It is a fixed linear interpolation and hence preserves holomorphic parameter dependence.

To prove the family assertion, keep the absolute degree m raw row before attaching external-field carriers. Its fine inputs lie within $C_L\xi$ of the root. Join those m points to the root by a physical tree of length at most $C_L m\xi$, and substitute their actual literal-field trees. The coefficient sum is bounded by $C^m\xi^m$; the field trees contribute $(Cr)^m$. Charging the join costs only $e^{C\kappa_0 m}$ after passage to M-cubes, and a physical length cost bounded by $e^{Cm\xi}$. These are per-leaf costs, absorbed by a smaller fixed radius. Sum $\sum_{m\ge1}(C\xi r)^m$. This proves eq. 4.cccl. There is no separate rounding cost at each of the arbitrarily many intermediate averaging stages.

For the grouped assertion, the image of an old M-cube has side $\xi M \le M$. Its raw output vector reads the fine field in a fixed enlargement of that image. Apply Banach Cauchy to the actual plain-mean map on the fixed number of neighboring macroblock strong spaces. The map is analytic for an input supremum c/ξ, and its whole output vector has supremum Cc there, by eq. 3.mcccv. Its multilinear coefficients are consequently bounded $C^m\xi^m$, with only a fixed macroblock-slot factor. Compose the whole-cube literal-field families of the preceding lemma. This proves the vector bound without counting the old bond coordinates in that cube. □

Lemma 4.29 (All-depth physical nesting)**.** On a fixed smaller ball, in common physical units,

$$U_s(V_{s,k}(W)) \sim U_k(W), \qquad S_s(V_{s,k}(W)) = S_k(W). \tag{4.ccclii}$$

The first equivalence is a fine gauge equal to one at the old coarse nodes. The old-unit fine mesh is L^{-s}. ■

Proof. Every variation tangent to an M^s-fibre is tangent to the M^k-fibre, since $M^k = M^{k-s}\circ M^s$. Thus $U_k(W)$ is critical on the former fibre. In old physical units its literal potential is $\xi\widehat{A}_k$, its first derivative is $\xi^2 D\widehat{A}_k$, and its local Hölder derivative has the corresponding additional ξ^α. Its strong norm is at most $C\xi r$. The old datum is admitted by Prop. 4.28. Orbit uniqueness in Prop. 3.183, including its competing-multiplier bound eq. 3.mccxci, identifies the two orbits for real data. Analytic continuation gives the equality of their plaquette traces and actions for complex data. Wilson action in four dimensions is unchanged by this change of physical units. This proves eq. 4.ccclii directly; no product of one-step uniqueness constants is used. □

4.14.2. *Complete pointed inputs and their quadratic coefficient.* An old pointed family is a normally convergent representation

$$f_z(B) = \sum_{X\ni q(z)} f_{z,X}(B_X), \qquad \sup_z \sum_X e^{\kappa d_M(X)}\|f_{z,X}\|_\rho \le \epsilon. \tag{4.cccliii}$$

Here X is a connected set of old M-cubes, $d_M(X) = |X|-1$, and $\|\cdot\|_\rho$ is the supremum on the old bond product ball $\|B\|_\infty < \rho$. Assign each positive bond to its starting-site cube. The complete f_z is normalized by $f_z(0) = 0$, invariant under all sufficiently small admissible site gauges, and covariant under translations of the anchor. The individual $f_{z,X}$ need not have these invariances.

On finite tori we use the canonical physical family and its infinite-lattice companion, with the coupling parameters held fixed during the comparison. Write $\Pi_P f_z^\infty(B) = f_z^\infty(B^{\mathrm{per}})$ for evaluation at the periodic lift of B. This is a function of the finite bond variables; it is not a quantum expectation on a larger torus. The compatibility property needed below is

$$f_z^P - \Pi_P f_z^\infty = \mathcal{W}_z^P, \qquad \|\mathcal{W}_z^P\|_{\rho,\kappa/2} \le C\epsilon e^{-c\kappa P/M}. \tag{4.ccccliv}$$

Here P is the shortest old physical period. The notation on the second line means an actual rooted analytic family with the stated norm. Its terms retain a finite-period-tail label. For the canonical families this property is proved below from their lifted operator and cluster carriers. Gauge invariance on one finite torus alone would not imply it.

Lemma 4.30 (Ward moments of the complete density)**.** The infinite companion has zero first jet. Its Hessian $K_z = D^2 f_z^\infty(0)$ has, for some $m > 0$, an absolute two-leg moment

$$\sum_{b,c} e^{m(|m_b - z| + |m_c - z|)} \|K_z(b,c)\| \le C\epsilon, \qquad K_z[\mathrm{d}\lambda, a] = K_z[a, \mathrm{d}\lambda] = 0. \tag{4.ccclv}$$

The Ward identity extends to polynomial λ, a. Define

$$a_\mu^F(x) = \frac{1}{2}\sum_\nu F_{\nu\mu}(x_\nu - z_\nu), \qquad q_f(F) = \frac{1}{2} K_z[a^F, a^F]. \tag{4.ccclvi}$$

If the complete pointing is covariant under the full hypercubic group, including reflections, then

$$q_f(F) = \frac{b_f}{2}\sum_{\mu<\nu}\langle F_{\mu\nu}, F_{\mu\nu}\rangle, \qquad |b_f| \le C\epsilon. \tag{4.ccclvii}$$

The colour pairing is bilinear on the complexified algebra. ■

Proof. The first derivative is a colour vector at each bond. Invariance under constant colour rotations forces each vector to be zero. Differentiate the local gauge identity once in the gauge parameter and once in a bond direction. The term containing a derivative of the gauge-coordinate transformation is multiplied by this vanished first jet. The remaining identity is the Ward identity for the Hessian.

A carrier contains at most $CM^4(1 + d_M(X))$ old bond and colour coordinates. Two Cauchy derivatives cost this coordinate-pair count and a fixed inverse power of ρ. Every coordinate in a rooted carrier is within $CM(1 + d_M(X))$ of its anchor. Choose m small relative to κ/M; the exponential and polynomial costs are paid by a reserved fraction of the rate in eq. 4.cccliii. This proves the moment bound. Cut off polynomial gauge parameters and arguments and pass to their limit using this absolute moment. No unbounded polynomial gauge transformation is applied to the nonlinear function.

Constant colour rotations make the quadratic colour pairing scalar. Independent axis reflections kill terms joining different curvature planes, since the two planes have different reflection characters. Axis permutations make the remaining six coefficients equal. The definition of a^F has no diagonal term $F_{\mu\mu}$; using a bond midpoint instead of its initial site therefore does not change it. The moment bound proves the estimate for its scalar coefficient. □

4.14.3. *An actual classical marginal representative.* Let $\theta_z(X) = \prod_{\lambda=1}^4 (1 - |X_\lambda - z_\lambda|)_+$, periodized on a torus. On the old lattice with fine spacing $h_s = L^{-s}$, put

$$e_{s,z}(B) = \sum_{p>0} \theta_z(m_p) a_p(U_s(e^{iB})). \tag{4.ccclviii}$$

The point m_p is the original fine plaquette midpoint in old physical units.

Lemma 4.31 (Exact representative and normalization)**.** The complete $e_{s,z}$ is gauge invariant and has an analytic rooted family with a bound uniform in s. It has zero value and first jet at the flat datum, and

$$\sum_z e_{s,z}(B) = S_s(e^{iB}), \qquad q_e(F) = \frac{1}{2}\sum_{\mu<\nu}\langle F_{\mu\nu}, F_{\mu\nu}\rangle. \tag{4.ccclix}$$

Moreover

$$\sum_z e_{s,z}(B_\xi(w)) = S_k(e^{iw}) \tag{4.ccclx}$$

on the actual common ball. Its finite periodic point function is exactly the evaluation of its classical infinite companion at periodic data. ■

Proof. The first identity follows from $\sum_z \theta_z = 1$. Each original fine plaquette trace is gauge invariant as a function of its actual critical orbit, by eq. 4.ccxcix. The action trees keep the factor h_s^4 at that original plaquette. Summing the plaquettes in the fixed support of θ_z therefore gives a bounded rooted family, by eq. 4.cclxxviii; there is no fine-count loss.

For every plaquette orientation the exact identity

$$h_s^4 \sum_{p \text{ in that orientation}} \theta_z(m_p) = 1 \tag{4.ccclxi}$$

holds. To see it in one coordinate, write the fine index as $Nn + r$, $0 \le r < N = h_s^{-1}$. For each fractional shift, including the half shift of a plaquette midpoint, the sum over integer translates of the one-dimensional tent is one. The N residue classes therefore sum to N. Take the product of the four identities.

The actual affine first response is the sampled affine fine potential modulo a fine gradient, by eq. 5.clxxiii. Every plaquette has zero first variation at the flat field, so no second background response contributes to its quadratic jet. The fine quadratic action is $h_s^4\langle F_{\mu\nu}, F_{\mu\nu}\rangle/2$. Equation eq. 4.ccclxi gives the second identity in eq. 4.ccclix.

Classical critical fields lift to periodic covers: the lifted field and multiplier solve the same local critical equations and constraints and stay in the strong uniqueness class. Orbit uniqueness identifies them with the constructed background. Each fixed plaquette trace is consequently unchanged by that lift. The compact tent, with its periodic sum, then gives the last assertion. This is a statement about a classical function, not about a Gaussian determinant or a quantum cutoff integral. Finally use eq. 4.ccclii to obtain eq. 4.ccclx. □

For a scalar input set

$$r_{s,z} = f_{s,z} - b_s e_{s,z}, \qquad b_s = b[f_s^\infty]. \tag{4.ccclxii}$$

It has complete first jet zero, curvature readout zero, and input norm at most $C\epsilon_s$. The subtracted coefficient multiplies S_k exactly after nesting. It is not replaced by a coarse Wilson action that only approximates S_k.

4.14.4. *A large analytic carrier bound from the actual map.*

Lemma 4.32 (Coarse block composition)**.** Suppose $f_z(0) = Df_z(0) = 0$ and eq. 4.ccliii holds. For a fixed range $\xi \le \xi_{\max} \le 1$, choose a target rate $\kappa_0 > 0$ and a field radius $r > 0$ satisfying

$$C\kappa_0\xi_{\max} + C_{\kappa_0}\xi_{\max} r/\rho < \kappa/4, \qquad C_{\kappa_0}\xi_{\max} r/\rho < 1/4. \tag{4.ccclxiii}$$

The actual composition $f_z(B_\xi(w))$ then has a rooted final-scale analytic family with

$$\|f_z \circ B_\xi\|_{r,\kappa_0} \le C\epsilon r^2 \xi^2. \tag{4.ccclxiv}$$

All constants are independent of the depths. Using whole-cube Banach groups, the conditions in eq. 4.ccclxiii contain no coordinate-count factor M^4. ■

Proof. Replace each local representative by

$$f_{z,X}(B_X) - f_{z,X}(0) - Df_{z,X}(0)[B_X].$$

Its complete sum is unchanged. The removed constant and linear sums vanish; their absolute convergence follows from Cauchy and a rate reserve.

Treat the variables in each old M-cube as one complex Banach vector with its supremum norm. There are $n = |X| = 1 + d_M(X)$ such groups. Multivariate Cauchy and polarization give a coefficient bound $\|f_{z,X}\|_\rho (e/\rho)^m$ at total degree m, for each distribution of degrees among the groups. To verify the polarization factor, insert independent scalars in the j slots of a homogeneous polynomial.

Cauchy on circles of radius $1/j$ bounds its multilinear norm by $j^j/j! \le e^j$ times its polynomial norm. Multiplying over the groups gives the stated factor, independently of their dimensions.

The grouped actual intermediate family in Prop. 4.28 has norm $d = C_{\kappa_0}\xi r$ for each group. The Taylor terms of degree at least two are therefore bounded by

$$C\|f_{z,X}\|_\rho\, n^2(\xi r/\rho)^2 \exp(C_{\kappa_0}\xi r n/\rho). \tag{4.ccclxv}$$

Indeed sum the degree distributions with the product generating function $(1-ed/\rho)^{-n}$, subtract its degrees zero and one, and use Taylor's formula for that scalar function.

The image of the connected old cube carrier can be joined in the final cube lattice with at most $C(1+\xi d_M(X))$ edges. Scale a spanning curve of length at most $CMd_M(X)$ and cover its $O(\xi M)$ neighborhood by final M-cubes; a curve of length ℓ needs at most $C(1+\ell/M)$ such cubes. This joins all grouped output roots at once, including all coordinate positions in each old cube image. Union this join with their actual intermediate families. Extra fixed costs per Taylor slot are absorbed in C_{κ_0}. The geometric rate charge is $\exp(C\kappa_0(1+\xi d_M(X)))$.

The two exponential costs in this expression and eq. 4.ccclxv fit in the input rate by eq. 4.ccclxiii. The remaining polynomial n^2 uses another fixed rate reserve. Summing the old family gives eq. 4.ccclxiv. This filing is an exact analytic substitution; its pieces read only the final bond variables in their indicated connected carriers. □

4.14.5. *Canonical physical inputs and finite-period tails.*

Lemma 4.33 (The actual canonical input class)**.** The complete physical normalizer, mismatch and interacting pointings obtained from Prop. 4.18 belong to the class eq. 4.cccliii on a fixed output coarse bond ball, after subtracting their vacuum values. Their rooted norm bounds can be taken respectively as

$$C, \qquad C|\tau-1|, \qquad C\{(g\mathfrak{b})^2 + e^{-c\mathfrak{b}^2}\}. \tag{4.ccclxvi}$$

For the interacting term this assertion concerns the homogeneous classical-pullback model with zero ordinary profile and the physical pointing of Cor. 4.20. These canonical families satisfy eq. 4.ccccliv. ■

Proof. The intrinsic functions are local analytic families by Prop. 4.18. Their physical arguments are the actual intermediate data $p_j(W)$, not independent fine currents. The p_j in the physical pointing is in its one-step axial gauge. On a fixed sufficiently small output ball both it and $p_j^{\mathrm{lit}}(W) = M^{j-1}U_j(W)$ are admitted, and the prescribed node-fixed gauge connects them. Apply gauge invariance to the complete pointed function first:

$$f_z^{\mathrm{phys}}(p_j(W)) = f_z^{\mathrm{phys}}(p_j^{\mathrm{lit}}(W)).$$

The identity extends holomorphically on this admitted overlap by the joint chart identity. The local representatives below are composed with p_j^{lit}; they are not individually replaced by gauge invariance. To see a full analytic carrier bound after this substitution, group each intrinsic localization cube as one Banach vector. In output units its side is M. The actual one-level-before-output map has whole-cube family norm $C\rho/L$, by Prop. 4.28. Apply the block Cauchy argument in Lem. 4.32, retaining the constant and linear degrees when necessary. The old intrinsic cube has side LM in its input units; after output rescaling the geometric join costs $C(1+d_M(X))$, with only fixed L constants. Request a larger intrinsic rate first, then choose a fixed smaller output radius so the block Cauchy charge fits that rate. The bound is linear in the intrinsic rooted norm. There is no count of its $(LM)^4$ individual coordinates.

The complete interacting pointing is gauge invariant by eq. 4.ccc and Cor. 4.20. For the normalizer use its exact definition eq. 4.cclxii. Point $\log J_U(0)$ at its pivot factors and $-\frac{1}{2}\operatorname{Tr}\log K$ at its diagonal free bonds, with the midpoint tents and the stated vacuum subtraction. Under a real coarse gauge the actual free coordinates transform by the block-orthogonal matrix O_g of eq. 4.ccc. Thus $\log K$ conjugates by O_g, and the colour trace of each diagonal block is invariant. The pivot

determinant transforms on both sides by adjoint matrices of determinant one. This proves invariance of the complete pointed normalizer before any carrier filing. For the mismatch use its exact pointing eq. 4.cclii. The diagonal colour trace of $K_G Q_{\tau,u}^{-1}$ has the same covariance. These arguments also give the vanished first jets by global colour rotations.

The matrix-log localization is eq. 4.ccli, with the actual nonlocal near/tail construction eq. 4.ccxc and eq. 4.ccxciv in place of a finite-range precision. Group powers before attaching their parameters and retain every precision carrier in the diagonal trace. The absolute rooted logarithm series gives the normalizer bound. The mismatch interpolation gives its factor $|\tau - 1|$. The interacting estimate is the physical even-coupling bound eq. 4.cccxv. Taking a vacuum difference changes these bounds by at most a fixed factor. The original midpoint pointing, the symmetric middle pivot pattern and the actual orbit map preserve translations and the full hypercubic group. The scalar readout is therefore applicable.

We give the finite-period argument explicitly. Retain the lifted propagator paths in the background trees, all precision carriers in the grouped matrix powers, and the full assigned carriers of the normalized local Gaussian functionals and Mayer clusters. In particular, the precision cutoff is by the full lifted connected carrier Γ, containing both matrix ends and every external background input, *before* periodic projection. Its charged length is $\ell(\Gamma)$. The stronger input estimate is already eq. 4.cclxxxv: the absolute Schur sum carries $e^{t_0 \ell(\Gamma)}$, by the HET connected-tree estimate and marked leaves. Symmetrize a real term with its transposed lifted carrier, and cut $\ell(\Gamma) \le R$. A long winding carrier never enters the short precision because its projected endpoints happen to be close.

The covering estimate used in HAF also holds for cubes on the cover:

$$S^{\#\Gamma_M^{\mathrm{cover}}} \le S^C \exp\{C(\log S)\ell(\Gamma)/M\}.$$

Thus its stronger lifted weight is paid by the displayed exponential input norm. The exact telescoping tails retain that weight. Combine each short power on the cover before projection; its finite-range Hilbert-row proof is unchanged, since the real cover gap follows by local limits of the uniform quadratic-form gap. The resulting short-step ball includes all its external background support. For the finite recipe lift the auxiliary cube parameters and the fixed held root guards periodically: parameters of period images are identified, while their full lifted carriers remain separately charged. The cover operator is then deck covariant; its row and column Schur sums descend without a sheet factor. A nonwrapping object sees the same single guard and wall recipe as its companion. The grouped root and the matrix-log series therefore have their absolute lifted carrier bounds as well. Subsequent absolute Gaussian and cluster estimates use submultiplicative carrier weights and an upper bound on the number of integration variables. The lifted weight is still submultiplicative, and identifying period images only reduces that number of variables. Retaining these labels throughout the absolute estimates gives the same rooted canonical-family bound with a reserved lifted rate.

For this comparison the support of a common object includes its entire fixed held root guard and the data and trace collars, also before projection. These are fixed-layer enlargements of the connected cube support. Their size is at most a fixed multiple of its size. Request that larger rate in the formation estimate first and reserve the needed fraction for this enlargement. A rooted object contained in a common embedded old neighborhood of radius $P/8$ is calculated by exactly the same local formulas on the torus and on its lift. For a Gaussian trace, a nonzero endpoint period image is a long object and is not put in this common part. For a local Gaussian marginal the comparison uses the same fixed root, guard and wall domain; it is not a comparison between different choices of held root guards. The normalized finite-dimensional integral, cutoff, source pointing and cluster coefficient of a common object are consequently identical.

Objects not paired in this way have connected carriers reaching distance cP from their root, or carrying a period winding. Their charged lifted cube size is at least cP/M. The stronger weight just described pays this size even when projection identifies some of its cubes. Reserve half of the

exponential input rate. The absolute remaining rooted sum is bounded by $C\epsilon e^{-c\kappa P/M}$. Projecting a lifted carrier to the torus only decreases the required cube-tree length. This constructs the difference family in eq. 4.cccliv, including its finite-period-tail label. Cauchy derivatives and any fixed rooted spatial moments use a further rate reserve and obey the same exponential comparison with a smaller c.

This proves a comparison of pointed analytic functions and their local expansions. The finite determinant and cutoff integral are not identified with those on a larger cover, which would introduce extra quantum fluctuation modes. □

4.14.6. *A slow-field estimate from a small local gauge.*

Lemma 4.34 (Complete slow-field expansion)**.** Let f_z^∞ obey the input norm and complete gauge identity above. For a continuous connection with $\|a\|_{C^{1,\alpha}} \le r$ put

$$B_\xi(b) = \xi a(\xi m_b).$$

On a fixed smaller radius, uniformly in $0 < \xi \le 1$,

$$\left| f_z^\infty(B_\xi) - \xi^4 q_f(F_a(\xi z)) \right| \le C\epsilon r^2 \xi^{4+\alpha}, \quad F_{\nu\mu} = \partial_\nu a_\mu - \partial_\mu a_\nu + i[a_\nu, a_\mu]. \tag{4.ccclxvii}$$

The same estimate holds uniformly on holomorphic external-field balls of such connections. ■

Proof. For sufficiently small ξ, take $R = R_0 + D\log(1/\xi)$, with D large compared with the inverse rooted spatial rates. In old coordinates $y = x - z$, let a smooth cutoff equal one on $|y| \le R$ and zero on $|y| \ge 2R$. Set

$$A_\mu = a_\mu(\xi z), \qquad g(z+y) = \exp\left(i\xi \chi_R(y) \sum_\mu A_\mu y_\mu \right).$$

Its exponent is bounded by $C\xi r R$, and its old first difference by $C\xi r$. For ξ below a fixed threshold, $\xi R \le 1$. The original and transformed bond logarithms both have supremum at most $C\xi r$, strictly inside the original analytic ball. For real connections the gauge is unitary. The equality $f_z^\infty(B_\xi^g) = f_z^\infty(B_\xi)$ extends jointly and holomorphically while both arguments remain in that ball. In particular it applies to a holomorphic connection $a(w)$. No arbitrary complex gauge saturation is used.

Within the region where the cutoff is one, second-order BCH, with the stated gauge convention, gives

$$B^g_{\xi,\mu}(z+y) = \xi^2 \Big\{ \sum_\nu \partial_\nu a_\mu(\xi z)(y_\nu + \tfrac{1}{2}\delta_{\nu\mu}) + \frac{i}{2} \sum_\nu y_\nu [A_\nu, A_\mu] \Big\} + E_\mu(y),$$
$$|E_\mu(y)| \le Cr\xi^{2+\alpha}(1+|y|)^3. \tag{4.ccclxviii}$$

To check the commutator, the three leading exponents are $i\xi Y, i\xi A_\mu, -i\xi(Y + A_\mu)$, where $Y = \sum A_\nu y_\nu$. Their BCH bracket is $\frac{1}{2}\xi^2 [Y, A_\mu]_{\mathrm{H}}$. The continuous first-order Taylor remainder costs $r\xi^{2+\alpha}(1+|y|)^{1+\alpha}$; the cubic BCH terms are bounded by $Cr^3\xi^3(1+|y|)^3$, which fits the displayed error since $\alpha < 1$.

The leading polynomial is $\xi^2(a^F + \mathrm{d}\chi)$, where

$$\chi(y) = \frac{1}{4} \sum_{\mu,\nu} (\partial_\nu a_\mu + \partial_\mu a_\nu)(\xi z) y_\mu y_\nu. \tag{4.ccclxix}$$

Its exact forward difference contributes $\frac{1}{2}\partial_\mu a_\mu$, so this identity includes the staggered midpoint term. The Ward identity removes $\mathrm{d}\chi$ in both Hessian arguments.

Expand each local representative through degree two at zero, and sum. The complete constant and first terms vanish. For a carrier contained in the inner patch the transformed angle is bounded by $C\xi^2 r(1 + M d_M(X))$. Block Cauchy bounds its cubic remainder by $\|f_{z,X}\|_\rho \xi^6 r^3$ times a fixed polynomial in $1 + d_M(X)$. The exponential Taylor charge can be bounded using the global supremum

$C\xi r$; it is paid by a fixed rate reserve. Summing such carriers gives $C\epsilon\xi^6 r^3$. A carrier exiting the patch has $d_M(X) \geq cR/M$. Its cubic remainder, estimated using the global angle bound, is $C\epsilon\xi^3 r^3 e^{-cR/M}$ after reserving rate and coordinate-count polynomials. Choose D so that this is also bounded by $C\epsilon\xi^6 r^3$.

For the quadratic term use eq. 4.ccclv. Inside the patch, replacing either argument by the error in eq. 4.ccclxviii costs $C\epsilon r^2\xi^{4+\alpha}$; the fixed spatial polynomials are summable against the two-leg exponential moment. Outside the patch, compare the globally bounded transformed field with the leading polynomial using the exponential tail of that moment. Increasing D pays this error as well. The remaining quadratic term is exactly $\xi^4 q_f(F_a(\xi z))$. Since $\xi^6 r^3 \leq r^2\xi^{4+\alpha}$, the estimate follows for small ξ.

For ξ above the fixed threshold the ordinary degree-two Cauchy bound and $|q_f(F)| \leq C\epsilon r^2$ prove the same statement with a larger fixed constant. All estimates hold in the complex norm, so they are uniform on the indicated holomorphic external-field ball. □

Apply this lemma to the actual interpolant in eq. 4.cccxlix. For the remainder eq. 4.ccclxii the curvature readout is zero. It has the complete bound

$$\|r^{\infty}_{s,z}(B_\xi(\,\cdot\,))\|_r \leq C\epsilon_s r^2\xi^{4+\alpha}. \tag{4.ccclxx}$$

On a finite torus its old shortest period satisfies $P_{\text{old}} \geq 2/\xi$. By eq. 4.cccliv and Lem. 4.32, the difference from this periodic companion has a large carrier norm bounded by

$$C\epsilon_s r^2\xi^2 e^{-cP_{\text{old}}}. \tag{4.ccclxxi}$$

For small ξ this is at most the right side of eq. 4.ccclxx. For $\xi \geq \xi_0 > 0$, the large bound $C\epsilon_s r^2\xi^2$ suffices, with a constant depending on ξ_0. The finite composed remainder therefore has the same small supremum estimate. Equivalently the logarithmic gauge patch can be used in the finite old torus whenever $8R < P_{\text{old}}$, which holds below a fixed ξ_0. No nonperiodic polynomial gauge is applied to that finite torus.

4.14.7. *Block Möbius interpolation without a volume loss.* The small complete supremum in eq. 4.ccclxx is stronger than the large norm eq. 4.ccclxiv, but is not itself a local-family estimate. We now construct one by an exact block decomposition.

Lemma 4.35 (Rooted block interpolation)**.** Let $F(0) = 0$ be holomorphic on a bond ball $\|w\|_\infty < r$. Suppose it has a connected family rooted at a cube Q_0, with norm at most E at rate $\kappa_0 > 0$, and $\|F\|_r \leq \delta$. Fix $0 < \vartheta < 1$. There are $t > 0, a > 0$, independent of the number of blocks, for which F has an actual rooted local family on $\|w\|_\infty < tr$, satisfying

$$\|F\|_{tr,a} \leq C\delta^{\vartheta} E^{1-\vartheta}. \tag{4.ccclxxii}$$

The construction is linear in F. It preserves holomorphic auxiliary parameters. ■

Proof. For a finite set S of final M-cube groups let w_T keep the groups in $T \subset S$ and set the others to zero. Define

$$F_S(w_S) = \sum_{T\subset S} (-1)^{|S\setminus T|} F(w_T). \tag{4.ccclxxiii}$$

On a finite torus inclusion-exclusion gives $F = \sum_S F_S$ exactly; $F_\varnothing = 0$. Each F_S reads only the indicated groups.

Put $u = t/(1-t)$. For a fixed w_S of norm at most tr, write each group as tv_Q. The holomorphic function $F(\sum_{Q\in S} z_Q v_Q)$ has supremum δ on $|z_Q| < 1$, since the groups are disjoint. The alternating sum in eq. 4.ccclxxiii keeps only the Taylor terms of positive degree in every group. Cauchy in these scalars therefore gives

$$b_S := \|F_S\|_{tr} \leq \delta u^{|S|}. \tag{4.ccclxxiv}$$

There is one scalar per block, not one per bond or colour coordinate.

For a local representative G_X of the given large family, its S-projection vanishes unless $S \subset X$, and obeys the same estimate with $\|G_X\|_r$ in place of δ. Let d_S be the length of a minimal Steiner cube tree joining S and Q_0. Then $d_S \le d_M(X)$ whenever $S \subset X$. Choose $0 < \kappa' < \kappa_0$ and t small enough that $\log(1+u) + \kappa' < \kappa_0$. Summing the projections of the large family gives

$$\sum_S e^{\kappa' d_S} b_S \le \sum_X \|G_X\|_r e^{\kappa' d_M(X)} (1+u)^{|X|} \le CE. \tag{4.ccclxxv}$$

Only triangle inequalities are used here; cancellations between representatives are used solely in the complete bound eq. 4.ccclxxiv.

Choose $a < (1-\vartheta)\kappa'$, and put $\lambda = ((1-\vartheta)\kappa' - a)/\vartheta > 0$. Hölder's inequality, applied to $b_S^{1-\vartheta} b_S^{\vartheta}$, gives

$$\sum_S e^{a d_S} b_S \le \delta^{\vartheta} (CE)^{1-\vartheta} \left\{ \sum_S u^{|S|} e^{-\lambda d_S} \right\}^{\vartheta}. \tag{4.ccclxxvi}$$

The last sum is finite for a fixed sufficiently small t, at every positive λ. Here is a bound that does not assume a large enough rate for an unweighted animal count.

For $n = |S|$, the minimum metric spanning tree on $S \cup \{Q_0\}$ has length at most $2d_S$: traverse a Steiner tree and shortcut the resulting walk. Consequently

$$e^{-\lambda d_S} \le \sum_{\mathcal{T} \text{ on } \{0,\dots,n\}} \prod_{\{i,j\} \in \mathcal{T}} e^{-\lambda |Q_i - Q_j|_1 / 2}.$$

Allow repeated positions and divide by $n!$ to overcount the sets. For a fixed labelled tree, sum its leaves successively. Each leaf costs at most $B_\lambda = \sum_{x \in \mathbb{Z}^4} e^{-\lambda |x|_1/2} < \infty$. The number of labelled trees is $(n+1)^{n-1}$. Thus

$$\sum_S u^{|S|} e^{-\lambda d_S} \le 1 + \sum_{n \ge 1} \frac{u^n}{n!} (n+1)^{n-1} B_\lambda^n < \infty \quad \text{if } euB_\lambda < 1. \tag{4.ccclxxvii}$$

On a periodic cube lattice the sum of the metric exponential is no larger than this infinite-lattice sum, by choosing nearest representatives of the period classes. The same constant is therefore valid.

File F_S on a fixed minimal Steiner tree joining S to Q_0. A fixed geometric tie rule suffices; it depends on no field or coupling parameter. Equations eq. 4.ccclxxvi and eq. 4.ccclxxvii prove eq. 4.ccclxxii. For the infinite lattice, the projections can be interchanged with the given large family by the absolute bound eq. 4.ccclxxv. Each local representative has the finite inclusion-exclusion identity, so their sum still reconstructs F. This proves both normal convergence and the exact identity there. Every operation is linear and the estimates are uniform on smaller auxiliary polydiscs, proving the last assertion. □

For the actual remainder take

$$\vartheta = \frac{2+\beta}{2+\alpha}. \tag{4.ccclxxviii}$$

Combining eq. 4.ccclxx and eq. 4.ccclxiv gives, per old anchor,

$$\|r^{\infty}_{s,z} \circ B_\xi\|_{tr,a} \le C(\epsilon_s r^2 \xi^{4+\alpha})^{\vartheta} (\epsilon_s r^2 \xi^2)^{1-\vartheta} = C \epsilon_s r^2 \xi^{4+\beta}. \tag{4.ccclxxix}$$

The equality of exponents uses $2 + (2+\alpha)\vartheta = 4 + \beta$. The reconstructed complete function remains gauge invariant. This conclusion does not assert invariance of its Möbius pieces.

4.14.8. *A compatible finite-volume filing.* We retain the finite-period information when making the improved filing. Merely replacing every finite-volume coefficient by a short minimal carrier could hide its winding dependence.

First perform the construction in Lem. 4.35 on the infinite companion. Evaluate its normally convergent local family at periodic final data and project its full carrier to the torus. Its analytic supremum does not grow: identifying some of its input variables still gives values inside the same

product ball. Its required cube length does not grow either. Keep its lifted carrier label before projection.

Classical lift compatibility identifies the actual finite B_ξ with the periodic restriction of its infinite counterpart. The difference of the two transported quantum densities is therefore the composed old finite-period difference. By eq. 4.ccclxxi it has large norm $C\epsilon_s r^2\xi^2 e^{-c_w P_{\mathrm{old}}}$. Put $\gamma_{\mathrm{per}} = Mc_w$; the prescribed period exponent is measured in M-cube units, as $e^{-\gamma_{\mathrm{per}}P_{\mathrm{old}}/M}$. Both complete remainders have the small supremum in eq. 4.ccclxx, so their difference has it as well. Apply block interpolation to this difference. It gives

$$C\epsilon_s r^2\xi^{4+\beta}e^{-(1-\vartheta)c_w P_{\mathrm{old}}} \tag{4.ccclxxx}$$

for its minimal-carrier family.

Retain its finite-period-tail label and enlarge each of these carriers by a fixed shortest period cycle through the root. This is a legitimate enlargement of a carrier: it alters no function and adds no field variables. If $P_{\mathrm{fin}} = \xi P_{\mathrm{old}}$ is the shortest final period, the extra length is at most $C(1 + P_{\mathrm{fin}}/M)$. Choose $a > 0$ also to satisfy

$$Ca\xi_{\max} < (1-\vartheta)\gamma_{\mathrm{per}}/2. \tag{4.ccclxxxi}$$

The added weight is paid by eq. 4.ccclxxx. The remaining rooted norm is bounded by

$$C\epsilon_s r^2\xi^{4+\beta}e^{-c'_w P_{\mathrm{old}}} = C\epsilon_s r^2\xi^{4+\beta}e^{-(c'_w/\xi)P_{\mathrm{fin}}}.$$

Thus all coefficients with genuine finite-period dependence remain explicitly in long carriers. The short part is the projected companion construction. The output again satisfies a compatibility estimate of the form eq. 4.cccliv, now with the improved size. This argument compares functions through their absolutely convergent local expansions; it does not add or remove quantum modes.

4.14.9. *Summing old anchors and the exact counterterm.*

Proposition 4.36 (Actual homogeneous physical irrelevance)**.** Let $f_{s,z}$ be complete gauge-invariant, translation-covariant physical pointed densities on the old coarse ball, with full hypercubic covariance, input bound ϵ_s, and the compatible companion property above. This includes the actual canonical inputs of Lem. 4.33. Set $b_s = b[f_s^\infty]$ and $r_{s,z} = f_{s,z} - b_s e_{s,z}$. For every fixed L there are fixed positive output radius r_{out}, rate a, and constant C such that

$$\sum_z f_{s,z}(B_\xi(w)) = b_s S_k(e^{iw}) + \sum_y \mathcal{R}_{s\to k,y}(w), \qquad \sup_y \|\mathcal{R}_{s\to k,y}\|_{r_{\mathrm{out}},a} \le C\epsilon_s r^2 L^{-\beta(k-s)}, \tag{4.ccclxxxii}$$

where $r_{\mathrm{out}} = tr$, with the fixed large-ball radius r chosen in eq. 4.ccclxiii. Each complete output density is gauge invariant and has zero first jet and zero companion curvature coefficient. It has an actual compatible local analytic representation; its individual representatives need not be gauge invariant. ∎

Proof. With the final unit tents define the complete output density by the exact formula

$$\mathcal{R}_{s\to k,y}(w) = \sum_{z\ \mathrm{old}} \theta_y(\xi z)\, r_{s,z}(B_\xi(w)). \tag{4.ccclxxxiii}$$

Only old anchors within fixed final distance of y occur. Transfer their roots to y by bounded cube joins. By eq. 4.ccclxxix and the compatible finite-period construction, the rooted norm is at most

$$C\epsilon_s r^2\xi^{4+\beta}\sum_z \theta_y(\xi z).$$

Because ξ^{-1} is an integer, the same residue-class tent computation as eq. 4.ccclxi gives

$$\xi^4\sum_z \theta_y(\xi z) = 1. \tag{4.ccclxxxiv}$$

This proves the bound in eq. 4.ccclxxxii. It also proves the uniform finite-period-tail bound after the old-anchor sum, with exponential rate in P_{fin}.

The tents sum to one in y. Sum eq. 4.ccclxxxiii over y, substitute the definition of $r_{s,z}$, and apply eq. 4.ccclx. This proves the exact identity in eq. 4.ccclxxxii.

Under a small final coarse gauge, actual orbit covariance of U_k changes $V_{s,k}$ by an old-lattice site gauge. The complete old functions are invariant, and the tents are geometric scalars. Thus each complete output density is invariant. Its first jet is zero, either by the chain rule or global colour rotations.

For the companion curvature coefficient test a final affine potential of constant curvature. The actual affine response eq. 5.clxxiii, followed by the literal partial mean, is the old affine potential with its length factor, modulo an old gradient. The node-frame correction is included as in eq. 5.clxxvi. The old constant term is another polynomial gradient. The remaining old curvature is $\xi^2 F$. The second chain rule contains no second background response because $Dr_{s,z}(0) = 0$. The two-leg Ward identity removes all gradient terms and gives

$$\frac{1}{2} D^2(r_{s,z} \circ B_\xi)(0)[a^F, a^F] = \xi^4 q_{r_s}(F) = 0.$$

All polynomial substitutions are justified by the exponential moments of the actual response and old Hessian. Multiplication by the fixed root tents and their finite anchor sum preserves zero. Translation and hypercubic covariance of the complete density are preserved since ξ^{-1} is an integer. The compatible filing was constructed above and is an exact representation of this same complete function. □

Corollary 4.37 (Uniform sum of proper old scales)**.** If $0 \le s < k$ and $\epsilon_s \le E_0$ on common parameter domains, their transported remainders satisfy

$$\sup_y \left\| \sum_{s<k} \mathcal{R}_{s\to k,y} \right\|_{r_{\mathrm{out}},a} \le C r^2 \sum_{s<k} \epsilon_s L^{-\beta(k-s)} \le \frac{C r^2 E_0}{L^\beta - 1}. \tag{4.ccclxxxv}$$

Their complete sum is invariant, has zero companion curvature coefficient, and has the same finite-period compatibility. The total classical counterterm is exactly $(\sum_{s<k} b_s) S_k$. ■□

Proof. Sum the positive rooted bounds. The age is at least one, so the geometric series is $\sum_{n\ge 1} L^{-\beta n} = (L^\beta - 1)^{-1}$. Normal convergence preserves the identities and holomorphy. The finite-period comparison has at least the final-period exponential at every old scale, so its sum has the same property. □

4.14.10. *Rate and analytic-radius bookkeeping.* For arbitrary fixed odd L, the proof gives a fixed positive output rate and one fixed smaller field ball. The loss is independent of the number of old scales. One can prescribe an output rate $a > 0$ in advance for proper old ages. Choose κ_0, κ' with $(1-\vartheta)\kappa' > a$, then choose t using eq. 4.ccclxxvii. Since $\xi_{\max} = 1/L$, the conditions eq. 4.ccclxiii and eq. 4.ccclxxxi are met for all proper old ages by taking L sufficiently large relative to these fixed rates and a fixed ratio r/ρ. The old-carrier geometric charge contains $\xi d_M(X)$, and the finite-period padding charge contains $P_{\mathrm{fin}} = \xi P_{\mathrm{old}}$. Both improve under this coarsening. Write $\gamma'_{\mathrm{per}} = M c'_w$. The remaining finite-period tail is $e^{-\gamma'_{\mathrm{per}} P_{\mathrm{fin}}/(M\xi)}$. To retain a prescribed compatibility exponent $\gamma_{\mathrm{per,target}}$ in M-cube units, impose $L\gamma'_{\mathrm{per}} \ge \gamma_{\mathrm{per,target}}$, in addition to the padding reserve. These conditions contain no M: the common M^{-1} length conversion cancels. They compensate the fixed $1-\vartheta$ interpolation loss for every proper age. Thus a chosen carrier rate and a chosen finite-period compatibility exponent can both be retained under sequential proper transport when the blocking integer is large enough. Choose M afterwards to realize the requested macroblock field rate.

The grouped family bound in Prop. 4.28 has an amplitude constant independent of M, L, while its allowed radius can depend on L. Thus eq. 3.mcccvi gives the necessary buffer in literal coordinates:

an outer data ball of radius R maps inside a working input ball of radius $tR/4$ if $C/L < t/4$. Fluctuation substitution additionally requires $g\mathfrak{b} < tR/4$, with the fixed chart constants included. These inequalities can be imposed in the order: rates and t, blocking integer, localization size, common small physical radius, then coupling floor. The nonlinear radius need not be uniform as L grows.

The theorem proves the physical homogeneous transport estimate from actual intermediate maps and explicit canonical inputs. A complete RG trajectory additionally requires formation and substitution on the buffered domains at every step. No transport theorem for arbitrary independent fine-current cores, proper history domains or changing nonlinear towers is asserted here.

4.15. **Formation at the literal centre.** The literal intermediate map decreases bond angles by a factor L^{-1}. We use that decrease to evaluate the old interaction on its original analytic ball while allowing a larger ball of output data. The relative contour gauge gives an exact change to the axial step on their real overlap. Holomorphy on the larger ball will follow from the literal integral itself.

4.15.1. *The input and parameter domains.* Fix the middle pivots and real product colour balls of Prop. 4.25. Choose a carrier rate $\kappa > 0$. An input h consists of pointed functions

$$h_z(B) = \sum_{X \ni q(z)} h_{z,X}(B_X), \qquad \|h\|_{r,\kappa} = \inf_{\{h_{z,X}\}} \sup_z \sum_X e^{\kappa d_M(X)} \|h_{z,X}\|_r. \tag{4.ccclxxxvi}$$

Here $B = i^{-1} \log V$ is in old coarse units, and X is a connected set of old M-cubes. The complete h_z is gauge invariant, normalized at $B = 0$, and covariant under old-lattice translations and the hypercubic group. Its companion coefficient eq. 4.ccclvii is zero. Take the Banach quotient of local analytic families by representations whose complete function is zero at every anchor. The infimum in eq. 4.ccclxxxvi is its quotient norm. Write $\mathfrak{H}_{r,\kappa}$ for the closed subspace with the stated identities, and put

$$H(V) = \sum_z h_z(i^{-1} \log V). \tag{4.ccclxxxvii}$$

The sum is finite on a torus. We also write $h_z(V) = h_z(i^{-1} \log V)$. The conditions on the complete functions are closed and linear: evaluation, the Ward moment extractor and covariance identities are continuous in this norm. Complex variations of h below are in this space. Reality is required only when a real transfer is asserted.

For families over compatible periods, include an infinite companion and take the supremum of these spatial norms. Fix $\gamma_{\mathrm{per}} > 0$ in cube units and also require

$$\|h\|_{r,\kappa,\gamma_{\mathrm{per}}} = \max\left\{ \sup_P \|h^P\|_{r,\kappa}, \|h^\infty\|_{r,\kappa}, \sup_P e^{\gamma_{\mathrm{per}} P/M} \|h^P - \Pi_P h^\infty\|_{r,\kappa/2} \right\} < \infty. \tag{4.ccclxxxviii}$$

The notation Π_P is periodic evaluation, as in eq. 4.cccliv. Write $\mathfrak{H}_{r,\kappa,\gamma_{\mathrm{per}}}$ for this space. The same norm notation will be used for output pointings before their scalar coefficient is subtracted.

Let $t \in (0, 1/8)$ be the fixed shrink in Lem. 4.35. We shall use the radii

$$r = tR. \tag{4.ccclxxxix}$$

Choose an intrinsic output rate κ_{int} larger than a fixed geometric multiple of $\kappa + \gamma_{\mathrm{per}}$. The whole-cube intermediate bound in Prop. 4.28 has an amplitude C_p, independent of L, M on an allowed smaller ball. Choose an odd L so large that

$$\frac{64 C_p}{Lt} < \min(1, \kappa_{\mathrm{int}}), \qquad \frac{C \kappa_{\mathrm{int}}}{L} < \frac{\kappa}{8}. \tag{4.cccxc}$$

The fixed constants include the rate and padding reserves in the transport theorem. Choose M afterwards for those rates and for the covariance construction. Then choose $R > 0$ inside the common background and graph radii. These choices are independent of depth and volume. The nonlinear radius may depend on L.

Fix a real reference coupling θ_0, and set

$$g_0=\theta_0^{-1/2},\qquad \mathfrak{b}_0=A_1(\log\theta_0)^p,\quad p>1/2,\qquad x=\theta_0\tau. \tag{4.cccxci}$$

Choose $\delta>0$ so that $|\tau-1|<8\delta$ lies in the admitted Gaussian disc, and retain $|\tau-1|<\delta$ for the Lipschitz conclusions. The reference gauge weight θ_0, all tame thresholds, and the real cutoff $\chi_{\mathfrak{b}_0}$ stay fixed as x varies. Numerical powers of g_0 and Gaussian determinants are separated below.

4.15.2. *The literal graph and old arguments.* At stage j, define

$$V_*(W)=\mathsf{p}_j(W):=M^jU_{j+1}(W),\qquad W=e^{iw},\quad \|w\|_\infty<R. \tag{4.cccxcii}$$

The output spacing is one; the old input spacing is $1/L$ in these units. Thus p_j is the map p_{j+1}^{lit} in eq. 3.mcccvi. It is not put in its one-step axial gauge. The actual graph about $V=V_*(W)$ is

$$Z_V(u)=e^{i\Phi_V(u)}V,\qquad M(Z_V(u))=W,\qquad \Phi_V(u)|_E=u,\qquad \Lambda_V(u)=i^{-1}\log Z_V(u). \tag{4.cccxciii}$$

All logarithms here are on the admitted branches.

Lemma 4.38 (Admission on the two radii)**.** For R as above,

$$\|\log V_*(W)\|_\infty\le C_pR/L<r/64.$$

There is $C_{\mathrm{dom}}=C_{\mathrm{dom}}(L)$ such that the actual graph and logarithm satisfy

$$\|\Lambda_V(u)-\Lambda_V(0)\|_\infty+\|\Phi_V(u)\|_\infty\le C_{\mathrm{dom}}\|u\|_\infty.$$

Consequently every argument of h in eq. 4.cccxciii stays in its old r-ball for all nested fluctuation boxes used by the formation theorem, provided

$$64C_{\mathrm{dom}}|\gamma|\mathfrak{b}_0<r \tag{4.cccxciv}$$

and the fixed graph ceiling holds. These domains are holomorphic in w,γ. At the real physical value $\gamma=g_0$, the retained regular fibre is precisely this graph on the free box. ■

Proof. The first assertion is the literal mean bound and eq. 4.cccxc. The graph estimate is the joint local pivot estimate in eq. 4.ccxxx, followed by the logarithm of $e^{i\Phi_V(u)}V$. Its constants do not involve j. Increase C_{dom} to include the fixed nested box factors and radial margins of that theorem. The two inequalities leave a fixed margin inside the old r-ball. In particular the same old function is evaluated before and after substitution.

At real W, the background curvature is below the fixed regular ceiling when R is small. The actual three-free-edge pivot anchor eq. 4.cclxviii puts every other point of that regular coarea fibre, with its free values in the box, inside the pivot uniqueness ball. It therefore has the graph value. Conversely the graph remains in the regular coarea set by the same curvature and free-angle bounds. The argument uses its fixed absolute regular ceiling, not an extra history plaquette threshold. The background, graph and logarithm are jointly holomorphic, and every argument of the old functions remains in their declared ball. This proves the stated complex domain directly. □

The contour tests can be removed on the physical box. Set $\varepsilon_0=A_0g_0(\log\theta_0)^p$ with the same retained test convention as the homogeneous step. The relative argument is $T_{y,x}(Z_V(g_0B))T_{y,x}(V)^{-1}$. Internal contours use no middle pivot. The normalized path/mean derivative bound therefore puts this argument within $C_Lg_0\mathfrak{b}_0$ of one, uniformly in the background. Choose $A_0>2C_LA_1$. The tests are then identically one on $\chi_{\mathfrak{b}_0}$, exactly as in the proof of eq. 4.cclxv. The analytic deformation in γ below is defined after this removal. The remaining real integration box does not vary.

4.15.3. *The change to axial gauge.* For a real V, define

$$s_V(x) = T_{y,x}(V) \quad (x \in B(y)), \qquad s_V(y) = 1, \qquad V^{\mathrm{ax}} = V^{s_V}.$$

This is a unitary gauge equal to one at the output nodes. Put

$$G_V(u) = \sum_{x \neq y(x)} \left[1 - \frac{1}{2}\,\mathrm{tr}\{T_{y(x),x}(Z_V(u))T_{y(x),x}(V)^{-1}\}\right]. \tag{4.cccxcv}$$

Lemma 4.39 (Exact axial comparison on the real overlap)**.** Whenever both old arguments are admitted, the literal-centre integral with gauge G_V equals the axial physical step. The free-coordinate change is $(O_V u)(b) = \mathrm{Ad}(s_V(b_-))u(b)$. It preserves the real product colour balls. ■

Proof. The endpoint gauge law gives the exact identities

$$T_{y,x}(V^{s_V}) = 1, \qquad T_{y,x}(Z^{s_V}) = T_{y,x}(Z)T_{y,x}(V)^{-1}. \tag{4.cccxcvi}$$

Thus the absolute contour weight and its tame test at Z^{s_V} are the relative ones at Z, including their numerical normalizer. The actual graph uniqueness and joint gauge identity give

$$\Phi_{V^{\mathrm{ax}}}(O_V u) = O_V \Phi_V(u), \qquad Z_{V^{\mathrm{ax}}}(O_V u) = Z_V(u)^{s_V}. \tag{4.cccxcvii}$$

For real V, O_V is block orthogonal and has determinant one. It preserves the free box, Haar/coarea density and regular plaquette bounds. It is independent of the integration variable u.

Gauge invariance gives $S_j(Z^{s_V}) = S_j(Z)$ and $h_z(Z^{s_V}) = h_z(Z)$ on their admitted overlap. Apply these identities to the complete functions h_z, before local filing. Equations eq. 4.cccxcvi and eq. 4.cccxcvii now identify the two coarea integrals by a real orthogonal change of free coordinates. No old function is evaluated outside its own ball in this comparison. □

For fixed L this overlap contains a neighborhood of $W = 1$. On the full R-ball the literal integral below is defined without evaluating h on the axial representative. Its holomorphy there will not require complex gauge saturation of the old domain.

4.15.4. *The integral and its Gaussian factors.* Let $d\lambda_W$ denote regular coarea disintegration of normalized Haar measure on $M(Z) = W$. Restrict it to the retained free box about $V_*(W)$, and use the contour tests just removed. Define

$$\mathcal{I}_j(W; x, h) = z(\theta_0, \varepsilon_0)^{-n_s} \int_{M(Z)=W}^{\mathrm{reg}} \chi_{\mathfrak{b}_0}(u/g_0)\, e^{-xS_j(Z)+H(Z)-\theta_0 G_V(u)}\, d\lambda_W(Z), \quad V = V_*(W). \tag{4.cccxcviii}$$

The notation for χ means the graph free coordinates of eq. 4.cccxciii. The omitted contour tests equal one on this real support. Here n_s is the number of old sites other than output nodes. This definition uses only the retained regular component. For complex data we use its literal graph pullback displayed below, with the same fixed real integration variables B.

Criticality and nesting give

$$S_j(V_*(W)) = S_{j+1}(W), \qquad D_u S_j(Z_V(u))|_{u=0} = 0. \tag{4.cccxcix}$$

Define the matrices

$$K_A(V) = D_u^2 S_j(Z_V(u))|_0, \quad K_G(V) = D^2 G_V(0), \quad K_\tau(V) = \tau K_A(V) + K_G(V), \quad K(V) = K_1(V). \tag{4.cd}$$

They include the complete inner background and outer constraint-curvature derivatives. The gap and full lifted carrier bounds are those of eq. 4.cclxxxiv and eq. 4.cclxxxv. We do not replace a precision carrier by the distance between its matrix endpoints.

Let $J_V(u)$ be the exact coarea density eq. 4.ccliv. Put

$$R_V^A(u) = S_j(Z_V(u)) - S_j(V) - \tfrac{1}{2}u^{\mathsf{T}} K_A(V) u,$$
$$R_V^G(u) = G_V(u) - \tfrac{1}{2}u^{\mathsf{T}} K_G(V) u,$$

$$P_{\gamma,\tau,h}(V,B) = -\tau\gamma^{-2}R^A_V(\gamma B) - \gamma^{-2}R^G_V(\gamma B) + \log\frac{J_V(\gamma B)}{J_V(0)} + H(Z_V(\gamma B)) - H(V). \tag{4.cdi}$$

The divided remainders have removable values at $\gamma = 0$. The graph, precision and cutoff are independent of γ. Define

$$Z_j(\gamma; V, \tau, h) = \int \chi_{\mathfrak{b}_0}(B) e^{P_{\gamma,\tau,h}(V,B)}\, d\mu_{K_\tau(V)^{-1}}(B). \tag{4.cdii}$$

For complex data the normalized Gaussian uses the determinant branch from positive real data. The local expansion below fixes the zero-free logarithm.

Lemma 4.40 (Exact normalization at the literal centre)**.** Let n_f, n_c count positive old and output bonds, $d = 3(n_f - n_c)$, and $r_{\mathrm{g}} = 3n_s$. At $V = V_*(W)$,

$$\det K_\tau(V) = \tau^{d-r_{\mathrm{g}}} \det K(V). \tag{4.cdiii}$$

For the physical value $\gamma = g_0$, the coarea integral factors exactly as

$$\begin{aligned} \mathcal{I}_j(W; x, h) &= C_{\mathrm{num}}(\theta_0) g_0^d (2\pi)^{d/2} J_V(0) (\det K_\tau(V))^{-1/2} \\ &\quad \times e^{-xS_{j+1}(W)+H(V)} Z_j(g_0; V, \tau, h), \\ C_{\mathrm{num}}(\theta_0) &= \sigma_0^{n_f-n_c} z(\theta_0, \varepsilon_0)^{-n_s}. \end{aligned} \tag{4.cdiv}$$

Here σ_0 is Haar density at zero. All determinant branches start at positive real data and $\tau = 1$. ■

Proof. The graph change of variables has exactly the density eq. 4.ccliv. Rescaling $u = g_0 B$ contributes g_0^d. The fine Haar and coarse delta densities give $\sigma_0^{n_f-n_c}$, as in eq. 4.cclxvi. The action is centered by eq. 4.cccxcix. Subtract its full quadratic part and that of the relative gauge. Gaussian integration with precision K_τ gives eq. 4.cdiv, including the extracted value $H(V)$.

The action Hessian annihilates the tangent to node-fixed gauge orbits, by constrained criticality and gauge invariance. For the relative gauge at a nonaxial V, the orbit derivative of its contour logarithm at an internal site is $-\mathrm{Ad}(T_{y,x}(V))\lambda(x)$. This is an invertible real orthogonal change of the gauge parameter. It gives the same form decomposition as eq. 4.ccxxii, with gauge dimension r_{g}. The complete precision is positive on real data by HAF. Applying Prop. 4.12 after this parameter change proves eq. 4.cdiii. Equivalently conjugate to the axial graph using eq. 4.cccxcvii. Both arguments retain the full constraint curvature in K_A. The identities continue to the admitted complex domain. □

Define

$$N_j(W) = \log\frac{J_{V_*(W)}(0)}{J_1(0)} - \frac{1}{2}\log\frac{\det K(V_*(W))}{\det K(1)}. \tag{4.cdv}$$

It is independent of x, h. Equation eq. 4.cdiii puts the entire remaining power of τ in a scalar factor. At the identity the raw pivot derivative is $L^{-3}I_3$, so $J_1(0) = L^{9n_c}$. Consequently the factor outside the field-dependent terms is

$$C^0_j(\theta_0, x) = C_{\mathrm{num}}(\theta_0) g_0^d (2\pi)^{d/2} J_1(0) (\det K(1))^{-1/2} \tau^{-(d-r_{\mathrm{g}})/2}. \tag{4.cdvi}$$

In particular no logarithm of this factor is included in the intrinsic remainder.

4.15.5. *Admission and filing of the old source.* For an intrinsic construction before composing with $V_*(W)$, use the centered extension

$$s_V(u) = S_j(Z_V(u)) - S_j(V) - DS_j(V)[D\Phi_V(0)u]. \tag{4.cdvii}$$

It is the coarse version of the completion in eq. 4.ccxxxi. It has zero first jet. Its Gaussian Hessian is the full composed Hessian, including the outer constraint curvature. At $V = V_*(W)$, its last term is zero and it equals the action difference in eq. 4.cdi. This extension supplies local functions on an old background ball; it does not alter the physical integral.

Lemma 4.41 (The ordinary source budget)**.** Suppose $\|h\|_{r,\kappa} \le H_*$. On the intrinsic background ball $\|i^{-1}\log V\|_\infty < r/8$, its source in eq. 4.cdi has an actual potential family with budget

$$\|\mathbf{V}^h_\gamma\|_{\kappa_{\rm int}} \le C_{L,M,r} H_* |\gamma| \mathfrak{b}_0. \tag{4.cdviii}$$

The input functions and their arguments are the ones in eq. 4.ccclxxxvi; no extension of their domain is used. ■

Proof. For each representative use exactly

$$V^h_{z,X}(V,B) = h_{z,X}(\Lambda_V(\gamma B)) - h_{z,X}(\Lambda_V(0)). \tag{4.cdix}$$

On the nested cutoff boxes the path $\zeta \mapsto h_{z,X}(\Lambda_V(\zeta\gamma B))$ is admitted for $|\zeta| < cr/(C_{\rm dom}|\gamma|\mathfrak{b}_0)$. Its supremum is bounded by $\|h_{z,X}\|_r$. One-variable Cauchy, with the constant value subtracted, gives

$$|V^h_{z,X}| \le C \frac{C_{\rm dom}|\gamma|\mathfrak{b}_0}{r} \|h_{z,X}\|_r.$$

This bound treats all the coordinates of X at once.

The local substitution reads only the actual double-block enlargement of X. After changing to output units, its carrier has at most $C(1 + d_M(X)/L)$ output M-cube edges. Cover the scaled old spanning curve and its fixed output-size collar, as in Lem. 4.32. Thus the requested rate cost fits the old one by eq. 4.cccxc.

We also convert the pointed norm to an incidence norm before applying HAF. If an input carrier contains a bond in cube Q, its size is at least the cube distance from $q(z)$ to Q. Reserve part of the old rate and sum the anchors:

$$\sup_Q \sum_{z, X \ni Q} e^{\kappa d_M(X)/2} \|h_{z,X}\|_r \le C_{\kappa,M} H_*.$$

Indeed each old cube contains $O(M^4)$ unit anchors and the remaining sum is a convergent metric exponential. This factor affects the source budget, not its analytic domain. Combine all origins with the same carrier before estimating its potential. The source has no additional Gaussian coordinates and introduces no number of potential types proportional to the volume. These estimates prove eq. 4.cdviii. □

Choose a fixed ceiling $4H_* + 1$ for the norm of h. The actual interaction budgets of HAF and the preceding lemma are small on a disc

$$|\gamma| < c_{H_*}/\mathfrak{b}_0. \tag{4.cdx}$$

The positive constant c_{H_*} is below the graph and old-source ceilings and the UM potential ceiling. It can depend on H_*, L, M, r. The Gaussian structure and its domains were chosen before H_*; only this coupling ceiling depends on that norm. Increasing the reference coupling floor makes g_0 lie in one half of this disc.

4.15.6. *Formation on the larger output ball.*

Lemma 4.42 (A local family on the two radii)**.** The normalized integral eq. 4.cdii, with the centered extension for intrinsic filing, is zero free. Its logarithm is a holomorphic family on eq. 4.cdx, the larger τ-disc, and the $4H_* + 1$ input ball. After composing with $V_*(W)$, it has a local family on $\|w\|_\infty < R$, with any fixed output rate chosen above. The constants are independent of j and volume. ■

Proof. Use the actual covariance construction eq. 4.ccxciv. It truncates full lifted precision carriers, including external background inputs, before projection. Held root guards contain the entire support of each graph, potential and required data collar. The matrix dimension of a local functional remains at most $C(LM)^4 \# Z$. The old source changes its potential but not this Gaussian structure.

The action, relative gauge and coarea budgets are those proved in HAF. Equation eq. 4.cdviii supplies the ordinary input budget on its actual domain. The UM, Mayer and connected cluster proof therefore gives the intrinsic analytic family on eq. 4.cdx. This is the existing proof applied with the specified source, rather than an assumption on its desired output. It fixes a logarithm by its convergent local series. No whole-volume lower bound for a cutoff probability is used.

The intrinsic carrier is on output localization cubes, of side LM in old input units. Group its external background coordinates as one Banach vector per such cube. Its image in output units has side M. Use the Banach-valued proof for all old bond midpoints in this final cube: the target is their supremum norm, the pure mean row bound holds for all of them, and only the same fixed neighboring macroblocks are read. Their number does not enter that proof. The literal whole-cube family has norm C_pR/L, by Prop. 4.28. Its ratio to the intrinsic background radius $r/8$ is at most $8C_p/(Lt)$. The block Cauchy argument of Lem. 4.32, retaining all degrees, therefore gives a charge $\exp(CC_p|X|/(Lt))$. The intrinsic rate reserve pays it by eq. 4.cccxc. This counts cube groups, not their $(LM)^4$ individual background coordinates. The bounded root joins and rate reserve give a bounded composition operator on the local family norm.

The map $V_*(W)$ is independent of γ, τ, h, so this composition preserves their holomorphy and any norm-valued derivative estimate. On physical data the centered extension equals the action difference by eq. 4.cccxcix. Thus the resulting family is the logarithm of the literal integral already defined, after its stated Gaussian factors have been removed. □

4.15.7. *Pointing the old source.* Write $\langle A\rangle_{\gamma,V,\tau,h}$ for the normalized expectation obtained from eq. 4.cdii by inserting A. For one old anchor set

$$\Delta h_{z,V,\gamma}(B) = h_z(Z_V(\gamma B)) - h_z(V). \tag{4.cdxi}$$

This definition precedes every local representation of h_z. Let $\mathscr{F}^0_{j,y}(W;\gamma,\tau)$ be the HPT pointing with $h = 0$, composed with the literal centre using complete gauge invariance on the real overlap. Extend it to the R-ball by the literal formula. Define

$$\begin{aligned}\mathscr{F}^{\mathrm{raw}}_{j,y}(W;\gamma,\tau,h) &= \mathscr{F}^0_{j,y}(W;\gamma,\tau)\\ &\quad + \sum_{z\ \mathrm{old}} \theta_y(z/L)\int_0^1 \langle \Delta h_{z,V,\gamma}\rangle_{\gamma,V,\tau,\ell h}\, d\ell, \qquad V = V_*(W).\end{aligned} \tag{4.cdxii}$$

The tents use output units. The sum over y is $\log Z_j(\gamma;V,\tau,h)$: differentiate that logarithm along ℓh and use the partition of unity of the tents.

Lemma 4.43 (A marked source family)**.** The pointings eq. 4.cdxii have local analytic representations on the R-ball. Their complete functions are gauge invariant and hypercubic covariant. They are even in γ. The part depending on h vanishes at $\gamma = 0$. ■

Proof. Introduce independent ordinary source parameters ζ_z, multiplying $\Delta h_{z,V,\gamma}$. The incidence estimate in Lem. 4.41 is uniform on a fixed product disc in these parameters: their number adds no Gaussian coordinates or potential types. Differentiate the convergent connected cluster expansion in ζ_z. Each resulting object contains one old-source insertion rooted at z, with its entire original carrier and the graph collar retained. The marked vertex has budget $C|\gamma|\mathfrak{b}_0$ times the old rooted norm. Sum its unmarked branches by the same convergent cluster bound. This constructs the local family of the expectation in eq. 4.cdxii without a whole-volume factor. The old origins are combined on their assigned carriers before forming the local Gaussian functionals. Root transfer by $\theta_y(z/L)$ costs only fixed L, M constants.

Under a small real site gauge the actual graph changes by the same linear adjoint map in its free variables as in eq. 4.ccc. Both $Z_V(\gamma B)$ and V remain in the old ball. Gauge invariance of the complete h_z therefore preserves eq. 4.cdxi. The Gaussian, cutoff and coarea change by the corresponding real orthogonal coordinates. The normalized expectation is unchanged. The same

is true for the $h = 0$ pointing, so each complete function in eq. 4.cdxii is invariant. At the output, orbit covariance of the actual background induces exactly such an old site gauge between the two centres. The argument uses complete functions before local representatives are composed. Joint holomorphy extends the identity on the admitted complex domain.

Lattice covariance follows from Prop. 4.25. The middle-pivot set and real colour balls in that proposition are the ones fixed here. The old insertions are covariant by the input assumption, and their tents transform with their anchors. Thus this assertion concerns the actual integral, not a subsequent average of pointings.

Finally every occurrence of the group field has argument γB. Hence the exact transformation $(\gamma, B) \mapsto (-\gamma, -B)$ preserves the exponent and all insertions, including their Taylor subtractions. The centered Gaussian and fixed cutoff are even. The HAF filing commutes with this transformation; each local Gaussian integration and connected extraction therefore gives an even function of γ, as in FEC. At zero coupling $\Delta h_{z,V,0} = 0$ exactly. The normalized empty Gaussian selection has zero derivative in an old source. These facts prove the last assertion at the level of the marked family. □

Lemma 4.44 (Even-coupling bound on the output family)**.** On a fixed smaller τ-disc, $\|h\|_{r,\kappa} \le 4H_* + 1$, and $|\gamma| \le c_{H_*}/(2\mathfrak{b}_0)$, the pointed logarithm satisfies

$$\|\mathscr{F}_j^{\mathrm{raw}}(\gamma, \tau, h)\|_{R,\kappa} \le C_{H_*}\{|\gamma|^2\mathfrak{b}_0^2 + e^{-c\mathfrak{b}_0^2}\}. \tag{4.cdxiii}$$

The constants are uniform in depth and volume. ■

Proof. The original HAF estimate and Lem. 4.41 give the norm bound $C_{H_*}|\gamma|\mathfrak{b}_0 + Ce^{-c\mathfrak{b}_0^2}$ on eq. 4.cdx, including the marked family of Lem. 4.43. The composition on the R-ball is a bounded operator on this norm by Lem. 4.42. At zero coupling the logarithm is the cutoff wall contribution $\log \mu_{K_\tau(V)^{-1}}(\chi_{\mathfrak{b}_0})$. Its pointed norm is bounded by $Ce^{-c\mathfrak{b}_0^2}$, and it is independent of h.

Subtract this zero-coupling value. The remaining activity-valued function is analytic and even, with a double zero at the origin. The norm-valued Cauchy argument of Prop. 4.21 on a fixed inner circle of eq. 4.cdx gives $C_{H_*}|\gamma|^2\mathfrak{b}_0^2$. All these bounds are for a rooted local family; no extensive error is differentiated. Adding the cutoff wall term proves eq. 4.cdxiii. □

4.15.8. *Companions and the quotient norm.* In eq. 4.ccclxxxviii, the difference representations retain their lifted carriers and finite-period-tail labels, as in the construction following eq. 4.ccclxxx. The infimum is over compatible representations with those labels. The formula compares complete functions; it does not discard the labels when an infimum is approached.

Lemma 4.45 (Preservation of the period norm)**.** Fix $\gamma_{\mathrm{per}} > 0$ in cube units. The rate choices and then L can be made so that the bound eq. 4.cdxiii also holds in the full norm $\|\cdot\|_{R,\kappa,\gamma_{\mathrm{per}}}$ for input norm at most $4H_* + 1$. The same exponent is retained at every step. ■

Proof. The old shortest period is LP when the output period is P. Decompose the old input as

$$h^{LP} = \Pi_{LP}h^{\infty} + w^{LP}.$$

Retain the entire old carriers and the finite-period-tail labels of w^{LP} in the potential eq. 4.cdix. The source incidence estimate is linear in its norm and gives its extra factor $e^{-\gamma_{\mathrm{per}}LP/M}$. Marking this source in the connected expansion retains that factor. The normalized empty selection has zero old-source derivative, and parity makes the resulting difference even in γ with value zero at the origin. Cauchy on eq. 4.cdx therefore supplies its $|\gamma|^2\mathfrak{b}_0^2$ factor as well.

For the remaining difference between the finite integral and its companion, compare the full lifted operator, Gaussian and cluster objects before projection, as in Lem. 4.33. The precision has the $e^{t_0\ell(\Gamma)}$ bound eq. 4.cclxxxv. The near cutoff is by its whole lifted carrier. Finite auxiliary parameters and held guards are lifted periodically with image parameters identified. Include all guards

and data collars in the common-object support. Nonwrapping objects therefore have identical coefficients. Every unmatched primitive Gaussian object or connected cluster pays a fixed cube-unit period exponential. Request an intrinsic rate large enough to make that exponent larger than the prescribed γ_{per}.

These estimates hold uniformly on the auxiliary coupling disc. At zero coupling the only wrapping terms are cutoff wall terms, with their $e^{-c\mathfrak{b}_0^2}$ factor. The nonconstant difference in γ is even and has a double zero. The same norm-valued Cauchy argument therefore supplies $|\gamma|^2\mathfrak{b}_0^2$ with the period factor retained.

In refiling the old source tail, its period LP leaves an exponential reserve for fixed carrier and guard padding at output period P. Choose L so that the remaining exponent is at least γ_{per}. All exponents are in M-cube units; M cancels from this choice. The same estimates apply to the vacuum value at $W = 1$. This proves the full-norm assertion. □

Define the vacuum-subtracted pointings at the physical coupling by

$$F_{j,y}(W; x, h) = \mathscr{F}^{\mathrm{raw}}_{j,y}(W; g_0, \tau, h) - \mathscr{F}^{\mathrm{raw}}_{j,y}(1; g_0, \tau, h), \qquad \mathbf{F}_j(x, h) = (F_{j,y})_y. \tag{4.cdxiv}$$

Their sum is the field-dependent remainder. The subtracted total is part of a scalar vacuum factor.

The definition eq. 4.cdxii depends only on the complete h_z. Two local representations of the same pointings give the same $\mathbf{F}_j$ in the quotient. All estimates above can be applied to representatives whose norms approach the input quotient norm. On any finite-dimensional affine subspace of inputs, choose local representatives for the base and directions. The cluster construction is holomorphic in their coefficients. Uniform local bounds, Cauchy estimates and polarization give a norm-convergent Taylor series on a smaller input ball. Thus $\mathbf{F}_j$ is a holomorphic map of the quotient Banach spaces, including their period component.

4.15.9. *The formation estimate and its derivatives.*

Proposition 4.46 (Formation with a fixed radius buffer)**.** Choose the rates, $t, L, M, R, r = tR$ as above. Fix $H_* < \infty$. There is a coupling floor such that for every reference θ_0 above that floor, the literal regular step is defined on $\|w\|_\infty < R$, $|x/\theta_0 - 1| < \delta$, and $\|h\|_{r,\kappa,\gamma_{\mathrm{per}}} \le H_*$. Its nonconstant Gaussian term is N_j from eq. 4.cdv, independent of x, h. The map $\mathbf{F}_j$ is holomorphic on fixed larger relative coupling and profile domains and satisfies

$$\begin{aligned} \|\mathbf{F}_j(x,h)\|_{R,\kappa,\gamma_{\mathrm{per}}} &\le C_{H_*}\epsilon(\theta_0), \\ \|D_h\mathbf{F}_j(x,h)[a]\|_{R,\kappa,\gamma_{\mathrm{per}}} &\le C_{H_*}\epsilon(\theta_0)\|a\|_{r,\kappa,\gamma_{\mathrm{per}}}, \\ \|\partial_x\mathbf{F}_j(x,h)\|_{R,\kappa,\gamma_{\mathrm{per}}} &\le C_{H_*}\epsilon(\theta_0)/\theta_0, \qquad \epsilon(\theta_0) = \theta_0^{-1}(\log\theta_0)^{2p}. \end{aligned} \tag{4.cdxv}$$

Its complete pointings are gauge invariant, translation covariant and hypercubic covariant, and are normalized at the flat field. For real data the map is real. The constants are independent of depth and compatible volume. ■

Proof. At $\gamma = g_0$, eq. 4.cdxiii and Lem. 4.45 give the first bound, including the vacuum subtraction. The cutoff tail is absorbed in $\epsilon(\theta_0)$ after increasing the floor, because $2p > 1$. No cutoff varies in this estimate.

The same bound holds on $\|h\| < 4H_* + 1$ and the larger fixed τ-disc. The quotient construction permits Cauchy in any input direction on a fixed norm margin. It gives the h derivative with its direction norm retained. Cauchy on the larger τ-disc gives $C_{H_*}\epsilon(\theta_0)$ for $\partial_\tau\mathbf{F}_j$. Since $\tau = x/\theta_0$, $\partial_x = \theta_0^{-1}\partial_\tau$. This proves all three estimates. Neither an indicator nor the input h is rescaled by x.

Gauge invariance and lattice covariance are Lem. 4.43; the cutoff symmetry is Prop. 4.25. Their definitions on complete pointings make the identities independent of the chosen local representatives. For real data the integral is positive and its coarea density has the identity sign. Its logarithm and source interpolation are real on the selected branch.

Finally eq. 4.cdiv and eq. 4.cdiii give N_j with no remaining field-dependent τ power. The scalar factors are outside the remainder. Every domain and norm provider is uniform in j and volume, as required. □

For two inputs on the retained margins, integrating the derivative bounds gives

$$\|\mathbf{F}_j(x,h) - \mathbf{F}_j(\widetilde{x},\widetilde{h})\| \le C_{H_*}\epsilon(\theta_0)\left\{|x-\widetilde{x}|/\theta_0 + \|h-\widetilde{h}\|_{r,\kappa,\gamma_{\mathrm{per}}}\right\}. \tag{4.cdxvi}$$

The norm on the left is the output norm in eq. 4.cdxv. It controls the local interaction rather than an extensive logarithm.

4.15.10. *Transport on the same field ball.* For $i<k$, let $\mathsf{p}_{i,k}(W)$ be the literal partial mean of the actual orbit at depth k, expressed on the old unit lattice. Put $\xi = L^{-(k-i)}$, and define the linear transport of complete pointings by

$$(T_{i,k}h)_y(W) = \sum_z \theta_y(\xi z)\, h_z(\mathsf{p}_{i,k}(W)). \tag{4.cdxvii}$$

The sum means the periodized sum on a torus. Its lifted carriers are retained in the norm.

Corollary 4.47 (A common field ball for transport)**.** Choose $0<\beta<\alpha<1$. After increasing the fixed L, the rate and radius choices above give

$$\|T_{i,k}h\|_{r,\kappa,\gamma_{\mathrm{per}}} \le C_T L^{-\beta(k-i)}\|h\|_{r,\kappa,\gamma_{\mathrm{per}}}, \qquad i<k. \tag{4.cdxviii}$$

The constants are uniform in the depths and compatible periods. The transports obey $T_{j,k}T_{i,j} = T_{i,k}$. ■□

Proof. Apply Prop. 4.36 with its large test ball equal to R, its input radius equal to $r = tR$, and its output radius equal to $tR = r$. The literal intermediate map has size $C_{\mathsf{p}}\xi R$ on the large test ball, by Prop. 3.187 and the actual intermediate-field construction in the transport proof. For every proper age, $\xi \le L^{-1}$. The inequalities eq. 4.cccxc therefore place the entire intermediate vector family inside the old r-ball. They also pay the big-composition Cauchy and carrier-rate costs. Thus no shrink is iterated with $k-i$. The Ward–Möbius estimate and old-anchor count give eq. 4.cdxviii. The infimum over local representations passes through this linear bound.

The period estimate uses $P_{\mathrm{old}} = P_{\mathrm{new}}/\xi$. The dimensionless retained exponent from eq. 4.ccclxxx is multiplied by ξ^{-1} in output cube units. The large-L choice retains γ_{per}, including the carrier padding reserve. It is uniform for every proper age.

For the semigroup identity, actual nesting identifies successive literal partial means up to a gauge on the old lattice. Apply complete gauge invariance before choosing local representatives. For integer ξ^{-1}, the nodal hat identity is

$$\sum_z \theta_y(\xi z)\theta_z(s) = \theta_y(\xi s). \tag{4.cdxix}$$

Indeed both sides are multilinear on each old unit cube, and they agree at its vertices; the knots of the left-hand coarse hat are aligned with old vertices. Periodization preserves the identity. Substitution in eq. 4.cdxvii now proves the semigroup law. It is an identity of complete functions, not of filed pieces. □

4.15.11. *The exact physical step.* Let $e_{j+1,y}$ be the action pointing from the actual fine-plaquette hats. It has sum S_{j+1}, companion coefficient one and a uniform norm on the fixed field ball. For a compatible family a, write $b[a]$ for the scalar quadratic coefficient of its infinite-volume companion, defined by its Ward kernel. This is a bounded linear functional in the norms used here: Cauchy controls the quadratic jet, and the reserved spatial rate controls its second moment.

Choose the complete Gaussian pointings $\mathbf{N}_j$ with sum N_j as in the homogeneous Gaussian construction. Define

$$b_j = b[\mathbf{N}_j], \qquad\qquad n_j = \mathbf{N}_j - b_j e_{j+1},$$

$$r_j(x,h) = b[\mathbf{F}_j(x,h)], \qquad f_j(x,h) = \mathbf{F}_j(x,h) - r_j(x,h)e_{j+1}. \tag{4.cdxx}$$

All pointings in these differences are normalized at the flat field. The infinite-volume scalar coefficient of n_j, f_j is zero. The norm of n_j is bounded uniformly in j, and b_j, n_j are independent of x, h. For r_j, f_j, the three bounds eq. 4.cdxv hold with a changed fixed constant, both on the larger output ball and after restriction to the working ball.

Corollary 4.48 (Closure of one regular physical step)**.** On the domains of Prop. 4.46, there is a field-independent, holomorphic nonzero factor $C_j(x,h)$ such that

$$\mathcal{I}_j(W;x,h) = C_j(x,h)\exp\left\{-x_+ S_{j+1}(W) + \sum_y (h_+)_y(W)\right\}, \qquad \begin{cases} x_+ = x - b_j - r_j(x,h), \\ h_+ = T_{j,j+1}h + n_j + f_j(x,h). \end{cases} \tag{4.cdxxi}$$

The new profile belongs to the same quotient space on radius r, with the same spatial and period exponents. Its norm satisfies

$$\|h_+\|_{r,\kappa,\gamma_{\mathrm{per}}} \le C_T L^{-\beta}\|h\|_{r,\kappa,\gamma_{\mathrm{per}}} + C_N + C_{H_*}\epsilon(\theta_0). \tag{4.cdxxii}$$

■□

Proof. By the partition of unity for the hats,

$$H(\mathsf{p}_j(W)) = \sum_y (T_{j,j+1}h)_y(W).$$

The exact factorization eq. 4.cdiv, eq. 4.cdv and eq. 4.cdxiv therefore give

$$\mathcal{I}_j(W;x,h) = C_j(x,h)\exp\{-xS_{j+1}(W) + H(\mathsf{p}_j(W)) + N_j(W) + \sum_y F_{j,y}(W;x,h)\}.$$

Here C_j is the scalar eq. 4.cdvi times $\exp\{\sum_y \mathscr{F}^{\mathrm{raw}}_{j,y}(1;g_0,\tau,h)\}$. The zero-free normalized integral makes this factor nonzero on the retained domains. For real data it is positive.

Insert eq. 4.cdxx and $\sum_y e_{j+1,y} = S_{j+1}$. This proves eq. 4.cdxxi with its stated signs. Gauge invariance and hypercubic covariance hold for every complete term. The exact action counterterm and the Ward readout give zero companion scalar coefficient for h_+. The period estimates and the common-radius transport give membership and eq. 4.cdxxii. □

The integral in this result is the regular step with action xS_j, the literal Haar and coarea densities, the relative contour gauge and the fixed free-bond colour-ball cutoff. Its old input is a complete coarse-field interaction h. The result supplies a fixed-radius producer for this model. It makes no identification with an arbitrary transported interaction on independent fine-current cores or a conditional history measure.

4.15.12. *A derivative of constant diagonal weights.* Let $a = (a_1, \dots, a_4)$ range over a fixed complex polydisc about 1, and set

$$S^a_j(V) = \mathscr{A}^a_{h_j}(U^a_j(V)), \qquad \mathsf{p}^a_j(W) = M^j U^a_{j+1}(W). \tag{4.cdxxiii}$$

The action, actual orbit and literal representative are those of Prop. 5.47. The mean, middle pivots, relative contour gauge and frozen free cutoff are unchanged. For fixed a, the required lattice symmetries are translations and independent coordinate reflections. Axis permutations act jointly on a and the fields.

Write $\mathfrak{H}^{\mathrm{ref}}_{r,\kappa,\gamma_{\mathrm{per}}}$ for the quotient space with gauge invariance, these reflection and translation identities, flat-field normalization, and zero coefficient in each of the six curvature planes. Its norm is eq. 4.ccclxxxviii. At $a = 1$, the hypercubic subspace with zero scalar coefficient is contained in this space. The six readouts are the $b_{\mu\nu}$ of § 5.15. Independent reflections exclude cross-plane quadratic curvature terms, so these readouts exhaust the quadratic curvature part. They are continuous by the same Cauchy and Ward moment bounds used above.

Put

$$K_\tau^a(V) = \tau D_u^2 S_j^a(Z_V(u))|_0 + D^2 G_V(0).$$

Define $\mathbf{F}_j^a$ by eq. 4.cdxiv with the weighted action and centre. Define N_j^a by eq. 4.cdv with K_1^a, p_j^a, and use its complete Gaussian pointings $\mathbf{N}_j^a$ as above.

Proposition 4.49 (The first weight jet of formation)**.** On a smaller fixed weight polydisc, the literal formation construction is jointly holomorphic in a, x, h, with input $\|h\|_{\mathfrak{H}^{\mathrm{ref}}} \le H_*$. Its formation $\mathbf{F}_j^a(x,h)$ satisfies the three bounds eq. 4.cdxv uniformly in a, and also

$$\|D_a \mathbf{F}_j^a(x,h)[e]\|_{R,\kappa,\gamma_{\mathrm{per}}} \le C_{H_*}\epsilon(\theta_0)|e|. \tag{4.cdxxiv}$$

The nonconstant Gaussian $\mathbf{N}_j^a$ is independent of x, h. Its norm and first weight derivative are uniformly bounded. Covariance under axis permutations is a joint identity in a, h; full hypercubic covariance at $a = 1$ is recovered for hypercubic h. ∎

Proof. We first verify the providers needed uniformly on a weight disc. The principal change in the actual joint equation is the constant local operator $K_a - K_1$ of eq. 5.ccxci. The exponentially weighted $\mathcal{W}_p$ joint inverse in Lem. 5.46 therefore gives an a-dependent inverse by a convergent Neumann series on a fixed weight disc. Each factor has a fixed physical carrier; retain the connected chain of those carriers in the series. Its exponentially weighted cell sum is uniform on a larger weight disc.

Smooth unit-cell localization is bounded on $\mathcal{W}_p$ by the product rule through two differences. The remaining actual nonlinear vertices have arity at least two and uniform Banach Cauchy bounds, by eq. 5.ccxciii and the unchanged constraint recursion. The ordered-tree proof of Prop. 4.17 thus applies with this inverse. Its scalar majorant and its connected-tree length charge are uniform in a. This is an all-arity carrier bound, not just a separate bound for each fixed jet. Multiplying each original fine-plaquette density by $a_\mu a_\nu$ preserves its h_j^4 bound and the cancellation of the fine plaquette count. Consequently the full lifted precision family, including every background leg and winding label, has the uniform bound required in eq. 4.cclxxxv.

The actual free form has the lower and upper bounds eq. 5.ccxcvii. The unchanged contour gauge gives the complementary gauge gap. Equivalently use the relative-form perturbation argument in Lem. 5.49 for the physical Gaussian. The full composed constraint curvature is retained. On a smaller complex product domain the normalized inverse is a Neumann continuation of the real gap. The HAF near/tail construction therefore works uniformly, always cutting by the whole lifted carrier before projection.

The free inverse and its local L^p upgrade have constants for the odd mesh parameter N, independent of its factorization $N = L^j$. Their linear amplitude is therefore uniform in L. The nonlinear radius may shrink with L. Use this amplitude in eq. 4.cccxc when choosing L, and decrease the common R afterward. The HFM plain-row bound then gives $\|\mathsf{p}_j^a(W)\| \le CR/L$ uniformly on the larger weight disc. This verifies the literal old-source admission, rather than assuming it for the deformed orbit.

All algebraic identities for the relative gauge, the joint graph, Haar and coarea densities are independent of the action. Weighted criticality and nesting give eq. 4.cccxcix with S_j^a, p_j^a. The gauge-null Hessian and relative gauge rank give the same scalar power $\tau^{d-r_{\mathrm{g}}}$. Thus the Gaussian defined with K_1^a, after vacuum subtraction, remains independent of x, h.

The old-source budget uses analytic norms and gauge invariance, not axis permutations or scalar isotropy. It holds on $\mathfrak{H}^{\mathrm{ref}}$. The intrinsic exponent remains invariant under $(\gamma, B) \mapsto (-\gamma, -B)$. All activity, source-rooting and period estimates above are uniform on the larger weight disc, giving eq. 4.cdxv. Cauchy in the fixed weight margin gives eq. 4.cdxxiv. It also bounds the first weight jet of $\mathbf{N}_j^a$.

Finally the middle-pivot and colour-ball identity of Prop. 4.25 commutes with reflections and with simultaneous permutation of a. The actual weighted orbit has that covariance by uniqueness. Source interpolation before filing gives the stated covariance of the complete pointings. No invariance of an individual filed term is used. □

For a fixed old input h in $\mathfrak{H}^{\mathrm{ref}}$, define $T_j^a h$ by eq. 4.cdxvii with $\xi = L^{-1}$ and p_j^a. The big-composition estimate already gives a uniform norm on the larger weight disc: the whole old-coordinate family is $CR/L < r/64$; the coarsened old carrier rate pays the output rate; and the one-step old-anchor count is the fixed L^4. The constant may depend on this fixed L. Keeping the old period labels uses $P_{\mathrm{old}} = LP$ exactly as above. Hence Cauchy in a gives

$$\left\| D_a T_j^a h[e]\Big|_{a=1} \right\|_{r,\kappa,\gamma_{\mathrm{per}}} \le C_L|e|\,\|h\|_{r,\kappa,\gamma_{\mathrm{per}}}. \tag{4.cdxxv}$$

Every plane readout of $T_j^a h$ is zero on this weight domain: the actual affine response eq. 5.ccxcvi is independent of a modulo an actual gradient. The complete first jet vanishes, and Ward annihilates the gradient in the quadratic jet. Differentiating this exact identity proves that the profile in eq. 4.cdxxv also has six zero readouts. It is a bounded profile; no power of g_0 is claimed for it.

At the isotropic point, take $\sum_\mu e_\mu = 0$. Let $e^{\mathrm{str}}_{j+1,e}$ be the complete fine-action pointing

$$(e^{\mathrm{str}}_{j+1,e})_y(W) = \sum_{p\|\mu\nu} (e_\mu + e_\nu)\theta_y(x_p)\, a_p(U_{j+1}(W)). \tag{4.cdxxvi}$$

Its six coefficients are $e_\mu + e_\nu$, and its sum is $D_a S^a_{j+1}(W)[e]\Big|_{a=1}$. Indeed the derivative of the orbit makes no contribution to the total first variation at fixed mean, by actual constrained criticality. The coefficient claim follows from the exact fine-hat quadrature and the affine response.

Use the transfer index j and put $b^a_{j,\mu\nu} = b_{\mu\nu}[\mathbf{N}^a_j]$. This is the increment from depth j to $j+1$, indexed $j+1$ in the cumulative sum in the Gaussian comparison. Joint permutation covariance gives numbers u_j, v_j such that $\partial_{a_\lambda} b^a_{j,\mu\nu}|_1 = u_j$ for $\lambda \in \{\mu,\nu\}$ and equals v_j otherwise. Put $m_j = u_j - v_j$. Then

$$D_a \mathbf{N}^a_j[e]\Big|_{a=1} = m_j e^{\mathrm{str}}_{j+1,e} + q_{j,e}, \qquad \|q_{j,e}\|_{r,\kappa,\gamma_{\mathrm{per}}} \le C|e|, \qquad b_{\mu\nu}[q_{j,e}] = 0. \tag{4.cdxxvii}$$

The normalization of this Gaussian is the canonical contour and coarea normalization of Prop. 5.50. That proposition identifies

$$m_j = \frac{11}{3\pi^2}\log L + O_\sigma(L^{-\sigma j}) \qquad (0<\sigma<1).$$

The uniform norm in eq. 4.cdxxvii follows from weight Cauchy and the uniform action-pointing norm. The six-plane readouts of its difference vanish by the definition of m_j. Formation and its first weight jet can likewise be projected onto the six readouts and their zero-readout complement, retaining the $C_{H_*}\epsilon(\theta_0)$ bounds.

These statements differentiate a constant diagonal deformation on its actual common domain. They do not assert closure of a finite anisotropic trajectory or admit a spatially varying weight.

4.16. **The first weight derivative with a frozen centre.** The weighted formation step moves its critical centre. A stress insertion in a fixed regular kernel does not. We compare their first derivatives on the actual fibre. A node-fixed gauge aligns the relative contour factors exactly. The remaining difference is a surface source on the fixed free colour balls. Its Gaussian tail is small in the rooted local norm, including normalization and the finite-period companions.

This is a first-derivative result. A fixed-centre weighted kernel need not have the uniform small formation disc of the moving-centre construction: its off-centre linear force can have size $O((a-1)/g_0)$. No such disc is asserted here.

4.16.1. *The two actual integrals.* Use the homogeneous regular model and parameter choices of Prop. 4.46. In particular

$$g_0 = \theta_0^{-1/2}, \qquad b_0 = \mathfrak{b}_0 = A_1(\log\theta_0)^p, \quad p > \tfrac{1}{2}, \qquad x = \theta_0\tau.$$

The reference θ_0, colour-ball radius, middle pivots and all tame thresholds are fixed. The old input satisfies $\|h\| \le H_*$ in the compatible quotient norm of eq. 4.ccclxxxviii. For the analytic estimates retain the larger bounded h ball and τ disc used in the formation proof. All old interactions below are complete gauge invariant functions on their original field ball.

Fix real output data W first, and put

$$V_a = \mathsf{p}_j^a(W), \qquad V_0 = V_1, \qquad Z_0(B) = Z_{V_0}(g_0 B).$$

The index zero on V_0 means the frozen isotropic centre. It is not the depth index. Let $\mathcal{I}^{\mathrm{mov}}(a)$ be the actual weighted LCF integral with centre V_a, action S_j^a, relative contour factor G_{V_a}, and the product colour balls in its own free coordinates. Define the frozen-centre integral on the same Haar-disintegrated fibre by

$$\mathcal{I}^{\mathrm{fr}}(a) = z(\theta_0,\varepsilon_0)^{-n_s}\int_{M(Z)=W}^{\mathrm{reg}} \chi_{b_0}(B_0(Z))e^{-xS_j^a(Z)+H(Z)-\theta_0 G_{V_0}(Z)}\,d\lambda_W(Z), \qquad Z = Z_0(B_0(Z)). \tag{4.cdxxviii}$$

Here the old lattice spacing is one and the raw free angle is g_0B_0. The measure and graph in eq. 4.cdxxviii are frozen. The regular/tame tests have their strict admission margin and equal one on the retained support. For a real weight near one both charts lie in this same regular component. The size of that real weight interval may depend on g_0b_0. Only its derivative at one will be used.

At $a = 1$, write their common value as $\mathcal{I}_0$ and the corresponding normalized expectation as $\langle\cdot\rangle_0$. The envelope identity for the actual critical action gives

$$D_a \log\mathcal{I}^{\mathrm{fr}}(1)[e] = -x\langle E_{j,e}\rangle_0, \qquad E_{j,e}(Z) = D_aS_j^a(Z)[e]\Big|_1 = \sum_z E_{j,e,z}(Z). \tag{4.cdxxix}$$

The pointings on the right are the original fine-plaquette stress pointings, evaluated on the isotropic actual orbit. The derivative of that orbit pairs to zero by constrained criticality at fixed literal mean.

4.16.2. *Exact contour alignment and the surface velocity.* At an old site x in the output block rooted at y, write $T_a(x) = T_{y,x}(V_a)$, $T_0(x) = T_{y,x}(V_0)$. Define

$$s_a(x) = T_0(x)^{-1}T_a(x), \qquad \widetilde{V}_a = V_a^{s_a}, \qquad C_a(b) = i^{-1}\log(\widetilde{V}_a(b)V_0(b)^{-1}). \tag{4.cdxxx}$$

Then $s_a(y) = 1$, $C_1 = 0$, and $T_{y,x}(\widetilde{V}_a) = T_0(x)$. Put $c_{e,b} = D_aC_a(b)|_1[e]$. The logarithm in this definition is only needed near its zero at $a = 1$.

Lemma 4.50 (The exact frozen-coordinate cutoff)**.** For real admitted arguments, the change $Z \mapsto Z^{s_a}$ identifies every factor in $\mathcal{I}^{\mathrm{mov}}(a)$ with its frozen-centre counterpart except its free colour-ball indicator. In frozen coordinates that indicator is

$$\prod_{b\in\mathcal{F}} \mathbf{1}_{\{|F_{a,b}(B)|\le b_0\}}, \qquad F_{a,b}(B) = \frac{1}{g_0 i}\log(e^{ig_0B_b}e^{-iC_a(b)}). \tag{4.cdxxxi}$$

Here $\mathcal{F}$ is the actual set of free middle-pivot coordinates. At $|B_b| = b_0$, with $n_b = B_b/b_0$,

$$n_b \cdot D_aF_{a,b}(B)|_1[e] = -g_0^{-1}n_b \cdot c_{e,b}. \tag{4.cdxxxii}$$

■

Proof. The endpoint law for a node-fixed old gauge is $T_{y,x}(Z^s) = T_{y,x}(Z)s(x)^{-1}$. Consequently

$$T_{y,x}(Z^{s_a})T_0(x)^{-1} = T_{y,x}(Z)T_a(x)^{-1}.$$

This proves $G_{V_0}(Z^{s_a}) = G_{V_a}(Z)$, including the same numerical contour normalization and the removed tame tests. Both the action S_j^a and the complete old interaction are gauge invariant on

the real admitted overlap. Haar measure and its coarea disintegration on $M(Z) = W$ are unchanged, because the gauge is one at the output nodes. Thus no graph-Jacobian or coarea term is left over. Equivalently, the two graph densities transform as the pullbacks of this same intrinsic measure.

The joint graph identity sends the old free angle u_b to $\mathrm{Ad}(s_a(b_-))u_b$ relative to $\widetilde{V}_a$. This is a real orthogonal colour change with determinant one, so it preserves each product ball. A field in the frozen graph has free link $e^{ig_0B_b}V_0(b)$. Its relative free angle about $\widetilde{V}_a$ is exactly the logarithm in eq. 4.cdxxxi. Pivot coordinates follow by the uniqueness of the actual graph.

For the last assertion differentiate $i^{-1}\log(e^{iX}e^{-itY})$ at $t = 0$. Its derivative is $-Y$ plus terms containing commutators with X. Pairing with X kills every such term by invariance of the colour inner product. The convergent logarithm series therefore gives $\langle X, D_t i^{-1}\log(e^{iX}e^{-itY})|_0\rangle = -\langle X, Y\rangle$. Take $X = g_0B_b$, $Y = c_{e,b}$, and divide the paired identity by $g_0^2 b_0$. This proves the exact normal velocity, with no polynomial approximation to the group chart. □

The centre jet has a compatible local analytic family with

$$\|\mathbf{c}_e\|_{R,\kappa_+,\gamma_{\mathrm{per},+}} \le C|e|, \qquad c_{e,b}(1) = 0. \tag{4.cdxxxiii}$$

Indeed the weighted literal intermediate fields have their all-degree connected bounds on a larger weight disc. Cauchy gives the centre derivative. The finite L-step contours in eq. 4.cdxxx attach fixed local stars and point products. Their constants can depend on the fixed L, M, R, but not on the inner depth. The identity at $W = 1$ follows because every weighted trivial background is the identity. This construction uses only the background matrices. It never evaluates h on a complex gauge transform outside its old ball.

Define a radial surface functional at one free bond by integrating its three colour coordinates over $S^2_{b_0}$, with ordinary area measure, and all other coordinates over their retained balls. In the Gaussian pullback of LCF put

$$\mathbf{m}_b(W; x, h) = \frac{\displaystyle\int_{|B_b|=b_0} n_b \prod_{d\neq b} \chi_{b_0}(B_d) e^{P_{g_0,\tau,h}(V_0,B)} d\mu_{K_\tau(V_0)^{-1}}(B)}{Z_j(g_0; V_0, \tau, h)}. \tag{4.cdxxxiv}$$

The numerator notation means the surface functional just defined, not a product of an ambiguous boundary value of χ_{b_0} with a delta distribution. The full coarea and Haar densities are included in P. The scalar boundary source is

$$\beta_{e,b} = g_0^{-1} c_{e,b} \cdot \mathbf{m}_b. \tag{4.cdxxxv}$$

Proposition 4.51 (Exact total first-jet comparison)**.** For real admitted data,

$$D_a \log \mathcal{I}^{\mathrm{mov}}(1)[e] - D_a \log \mathcal{I}^{\mathrm{fr}}(1)[e] = \sum_{b\in\mathcal{F}} \beta_{e,b}. \tag{4.cdxxxvi}$$

The right side has the local analytic continuation and bounds proved below. This continuation does not differentiate a sharp indicator at a complex weight. ■

Proof. Use Lem. 4.50 to write both integrals in the frozen fibre measure. Their action derivative is identical, and their old interaction, relative gauge and measure are the same. The product of colour balls has first shape derivative

$$\sum_{b\in\mathcal{F}} g_0^{-1}(n_b \cdot c_{e,b})\, \delta(|B_b| - b_0) \prod_{d\neq b} \chi_{b_0}(B_d).$$

Intersections of two sphere boundaries have codimension at least two and contribute no first shape derivative. The formula follows by the one-variable thin-shell change of variables in each three-dimensional colour group. The finite graph and strict chart margin justify differentiation under these compact integrals. Divide by their common value $\mathcal{I}_0$. The exact LCF Gaussian factorization cancels its scalar prefactors, giving eq. 4.cdxxxiv and eq. 4.cdxxxvi. □

4.16.3. *A normalized rooted sphere estimate.*

Lemma 4.52 (One surface mark in the actual local expansion)**.** There are fixed $c, C, K > 0$ such that the complete sources eq. 4.cdxxxv have compatible holomorphic local families, rooted at their marked free bonds, with

$$\|\boldsymbol{\beta}_e\|_{R,\kappa,\gamma_{\mathrm{per}}} \le C_{H_*}|e|g_0^{-1}(1+b_0)^K e^{-cb_0^2}. \tag{4.cdxxxvii}$$

The norm includes the original centre-jet carriers, old-source carriers, coarea terms, normalization and the period companions. It is independent of total volume and inner depth. It holds on the smaller complex τ, h, W domains retained from LCF. ■

Proof. We verify the additional local functional estimate and then its normalization. Use the actual filed Gaussian matrices of eq. 4.ccxciv. Use its finer comparison error ε_D and Gaussian tilt δ_1, both at most $c_*(LM)^{-4}$. Its scalar dimension is $d \le C(LM)^4 \# Z$. Relative to the positive real comparison covariance D_0, the determinant and inverse estimates give

$$|d\mu_D(B)| \le e^{C\varepsilon_D d} e^{C\varepsilon_D |B|^2}\, d\mu_{D_0}(B).$$

Reweighting this positive Gaussian by $e^{(\delta_1 + C\varepsilon_D)|B|^2}$ changes its normalization by at most $e^{C(\delta_1+\varepsilon_D)d} \le e^{C'\# Z}$ and leaves its covariance between fixed positive constants. The constants are uniform on the enlarged covariance-parameter discs and local complex background domains. Replacing the three-dimensional integral at b by its sphere now uses the positive Gaussian's three-coordinate marginal and gives

$$\int_{|B_b|=b_0} |n_b| e^{\delta_1|B|^2} |d\mu_D(B)| \le e^{C\# Z}(1+b_0)^2 e^{-c_2 b_0^2}. \tag{4.cdxxxviii}$$

The factor is the area of a three-colour sphere. Remaining Gaussian moments and any fixed local parameter derivatives give only further polynomial factors, or a fixed exponential per wall cube. They do not introduce Gaussian coordinates from the inner fine hierarchy.

The integration set of this marked local functional is fixed. Gaussian densities, graph vertices and source functions are holomorphic in their actual parameters and have the same tilted domination. Thus the marked functional is holomorphic, and the usual covariance-parameter Cauchy estimates apply. Its full guard includes the marked coordinate, every potential support, the centre-jet coefficient carrier and all background read collars. A wall factorization is made only after these complete guards are included. If separated components remain, the marked functional is the marked root component times the ordinary functionals of the others.

The actual action/coarea interaction and bounded old source have the small budgets of Lems. 4.41 and 4.42 at the physical g_0. Their existing connected expansion uses the tilted Gaussian bound, parameter holomorphy and this wall factorization. The estimate eq. 4.cdxxxviii verifies these same requirements with one marked functional. It supplies an additional root factor $\eta_\partial = Cg_0^{-1}(1 + b_0)^K e^{-c_2 b_0^2}$. The centre coefficient is expanded first using eq. 4.cdxxxiii; its entire carrier is attached to that root. The reserved intrinsic rate pays its fixed guard enlargement. The sum over old free bonds in an output cube is at most $C(LM)^4$, a fixed local factor.

For completeness normalization is obtained by a single formal source, not a global lower bound for an integral. Give the boundary functional a parameter ζ with $\zeta^2 = 0$. The finite partition expression is $Z + \zeta Z_\partial$. The coefficient of ζ in its connected logarithm is exactly Z_∂/Z. In the actual polymer expansion every such connected term has one marked object and otherwise ordinary objects. At the marked coordinate the surface functional replaces its physical cutoff: an ordinary cutoff factor at that same coordinate is excluded. Larger nested auxiliary cutoffs equal one on the marked sphere by the retained admission margin. Thus no product of a radial delta with an unspecified boundary value of its own indicator is formed. This exclusion does not enlarge any absolute activity bound. The ordinary small activity majorant is ε, within the retained cluster ceiling. Its rooted tree sum

is bounded by

$$C\eta_\partial \sum_{n\ge 0}(C\varepsilon)^n \le C'\eta_\partial.$$

All original source origins are combined on their full carriers before this sum, exactly as in LCF. This proves the local bound for the normalized expectation, without estimating an extensive $1/|Z|$. Since the unmarked logarithm is the selected LCF branch, the formal degree-one identity equals the actual ratio in eq. 4.cdxxxiv. There is no product of two delta distributions at one colour coordinate.

The intrinsic output is composed with the actual literal centre on the large R-ball by the same whole-cube Banach composition of Lem. 4.42. It is a bounded operator on the rooted family norm; its rate cost and the old anchor incidence count are already paid by the blocking buffer. The surface root creates no extra background coordinates. The old input quotient is respected because the complete integral and marked expectation depend only on the complete h_z; take the infimum over their compatible representations.

Finally retain lifted carriers and finite-period labels before projection. In a companion difference, telescope the primitive matrices, centre factor, vertices and old-source families. One factor carries the existing period tail or a retained winding carrier. The marked Gaussian derivative still obeys eq. 4.cdxxxviii: $D\log d\mu_D$ is a trace term and a quadratic form in B, whose moments add only a fixed polynomial in b_0 and wall size. A slight decrease of c_2 pays the former; the spatial rate reserve pays the latter. Thus the period interpolation and padding of Lem. 4.45 retain γ_{per}. Construct all Gaussian and centre families on one common large cover, with the full periodic held guards, before descent. No comparison of quantum partition functions on different volumes is made. These estimates prove the full compatible norm in eq. 4.cdxxxvii. □

Before multiplication by $c_{e,b}$ and g_0^{-1}, the same marked construction gives a compatible local vector family for $\mathbf{m}_b$, with the corresponding sphere-tail bound and fixed W jets. Its exponential moments justify the affine product-rule probes used below; scalar gauge invariance is required only after pairing with the centre jet.

The construction also proves bounds for any fixed number of τ and bounded old-input derivatives, by Cauchy on their retained larger domains. Differentiation in x adds θ_0^{-1} per derivative. No derivative of the frozen reference cutoff radius is taken. Because $2p>1$, for every fixed N the right side of eq. 4.cdxxxvii is at most $C_{H_*,N}\theta_0^{-N}|e|$ after increasing the reference floor.

4.16.4. *Complete pointings and physical normalization.* Choose output hats θ_y in output units and define the complete pointing

$$(\mathcal{B}_{j,e})_y(W)=\sum_{b\in\mathcal{F}}\theta_y(m_b/L)\,\beta_{e,b}(W). \tag{4.cdxxxix}$$

Here m_b is the old bond midpoint. The finite local anchor count changes only constants. The hats sum to one, so this pointing has total $\sum_b\beta_{e,b}$.

Lemma 4.53 (Symmetry and the flat value)**.** The complete functions in eq. 4.cdxxxix are gauge invariant and jointly covariant under lattice symmetries acting on the weight direction e, old input h and fields. They vanish at $W=1$. These assertions precede local filing. ■

Proof. Let an output gauge induce old gauges k_a on V_a and k_0 on V_0. Their output-node values are the same. The contour endpoint law gives $s'_a=k_0s_ak_a^{-1}$. Hence $\widetilde{V}'_a=\widetilde{V}_a^{k_0}$: alignment to the frozen contour frame removes the weight-dependent gauge. Thus $C_a(b)$ and its first weight jet transform by the same frozen $\mathrm{Ad}(k_0(b_-))$ as the free colour variable. The sphere and its normal transform by this real orthogonal map. The complete old interaction, action and coarea factors are invariant on their admitted overlap. Each complete scalar surface source is therefore invariant. Holomorphy extends this identity on the stated complex domain.

Translations and reflections use the fixed middle-pivot identity of Prop. 4.25. For a reversed stored bond the centre jet and free colour variable have the same sign and adjoint twist. Joint axis permutation acts on e, h and the weighted orbit simultaneously. Their sphere pairing and the hats therefore have the stated covariance. At $W = 1$, $c_{e,b} = 0$, so the complete source vanishes exactly. □

Proposition 4.54 (A frozen-kernel stress jet with a rooted tail)**.** The moving weighted logarithmic first jet minus $\mathcal{B}_{j,e}$ is a compatible pointed representation of the actual frozen-kernel first jet eq. 4.cdxxix, after the same flat-field normalization. Moreover

$$\|\mathcal{B}_{j,e}\|_{R,\kappa,\gamma_{\mathrm{per}}} \le C_{H_*}|e|\theta_0^{1/2}(1+b_0)^K e^{-cb_0^2}. \tag{4.cdxl}$$

The same type of bound holds for any fixed x, h jet on smaller retained domains. Constants are uniform in depth and compatible volume. ■

Proof. The total identity is Prop. 4.51; the local family and normalization are Lem. 4.52. The symmetry lemma supplies the complete function identities required by the profile space. The flat value of the error is zero, so vacuum subtraction does not alter it. Select the frozen output pointings by subtracting this rooted family from the known moving weight-jet pointings. Their total is exactly the fixed-kernel first jet. This selection does not assert equality to every independently chosen per-anchor filing of a stress insertion. □

4.16.5. *The affine readout and the regular stress equation.* For the present homogeneous literal convention the boundary source has a further cancellation. It is not needed for its superpolynomial norm bound.

Corollary 4.55 (Zero boundary curvature readouts)**.** All six quadratic curvature readouts of $\mathcal{B}_{j,e}$ vanish. ■□

Proof. At $W = 1$, the frozen normalized law is invariant under global colour conjugation, also for complex h in the complete gauge invariant input class. Its vector surface moment in eq. 4.cdxxxiv consequently vanishes. We already know $c_{e,b}(1) = 0$.

The exact affine response of eq. 5.ccxcvi is independent of the constant weight modulo a gradient. Both literal means are the same prescribed affine datum, so that gradient can be chosen zero at the final output nodes: its node values are constant and the flat constant can be subtracted. Taking the actual partial mean gives an old-site gauge equal to one at the outer nodes. Contour alignment in eq. 4.cdxxx is unique on such an orbit. It therefore removes this gradient and gives

$$D_W c_{e,b}(1)[B^F] = 0$$

for every affine curvature probe B^F. These polynomial probes are interpreted in the exponentially summable infinite companion kernels, as in the affine response proof.

Differentiate the exact product $\beta_{e,b} = g_0^{-1} c_{e,b} \cdot \mathbf{m}_b$ twice in two affine directions. Its constant factors vanish at the flat field, and each remaining mixed product contains one of the displayed zero derivatives. Thus its entire quadratic affine form is zero. The absolute local family bound permits the hat and companion sums. Complete gauge invariance and the Ward readout then give all six stated zero coefficients. □

In a response $-tE_{j,e} + v$ of the fixed isotropic kernel, the weight direction is $a = 1 + (t/x)e$. Hence the actual output jet is the moving-weight one minus $(t/x)\mathcal{B}_{j,e}$. Using the selected pointings above, the stress recurrence of eq. 5.ccclxv has the same scalar leading coefficient; its profile forcing is changed from $A_j[e]$ to $A_j[e] - \mathcal{B}_{j,e}$. The change is in the six-zero-readout space and is superpolynomially smaller than the permitted formation error. Even without the affine cancellation, its readouts are bounded by eq. 4.cdxl and give only a superpolynomial scalar correction after division by x. The coupling-weighted Volterra estimates therefore retain their bounds.

This comparison proves only the first constant-weight jet of the stated homogeneous regular kernel with bounded old input. It neither assigns holomorphy to a sharp indicator nor establishes small formation on a fixed-centre weight disc. The frame, regular fibre, cutoff and normalization in the frozen response remain the isotropic ones.

4.17. **Large-field histories and induction.**

4.17.1. *Large-field regions, their weights, and induction.* Convergence of the regular expansion in § 4.5 requires that the plaquette variables of the backgrounds lie within $\varepsilon_k \eta_k^2$ of $\mathbf{1}$, with $\varepsilon_k = g_k p_0(g_k)$, and that the fluctuation fields stay below $\delta_k = (A_1/A_0)\varepsilon_k$. The two thresholds carry the same power of the logarithm and differ by a small fixed ratio. Nothing guarantees these conditions. For this reason each step inserts decompositions of unity $1 = \sum \prod \chi \prod \chi^c$ built from local tests. At a place where a test fails, no expansion is made and the fields there are stored. The weights present at that place then supply a factor $e^{-c\, x_k \varepsilon_k^2} = e^{-c\, p_0(g_k)^2}$. For a failed plaquette test this weight is the Wilson weight. When an approximate fluctuation test fails, the weights present are the Wilson weight together with the kept gauge-fixing exponents. When a fluctuation test, a collar test or a rim test fails, the weight is only the Gaussian form of the stored fluctuation field. (The failure of one of the sharper tests of the large-field operation $\mathbf{R}$ of §4.17.1.3 yields only $e^{-p_0(g_k)}$: 2a, 2c.) In this way the density becomes a sum over histories h, collected according to their labels $\mathcal{S} = (\Omega_j, \Lambda_j, S_j)_{j \le k}$, which consist of the regions of all levels. Beside the regions, a label carries the marks left by the operations $\mathbf{R}$, one for each island and for each drop-out that stands §4.17.1.1; the labels are thus labels with marks. The exponential form given below holds for sums of histories and not for an individual history (2a, 2d).

Proposition 4.56 (inductive description; ultraviolet stability)**.** Assume the primitive hypotheses $\mathcal{H}_{\mathrm{step}}$ of the joint step, on the actual histories and domains used below. Suppose that the constants are chosen in the prescribed order, beginning with the exponents and a large L and ending with a small γ §4.17.1.45. Suppose also that the torus is admissible up to level k, and up to K for the stability bounds; that is, $\ell L^{K-j} \ge 2L^{11} M \check{R}_j$ for $j \le k$, respectively for $j \le K$. This is a lower bound on ℓ, which is chosen after M and g. When $\ell \in \mathfrak{L}(g)$ and the datum is a first-passage datum, the condition follows from the upper flow bound up to K § 5.2.2. Assume further that $g_j \le \gamma$ and $\lambda_\sharp(j-i) - c_5 \le x_i - x_j \le B_\sharp(j-i)$ for $i \le j \le k$ (up to K for the stability bounds). When g is small, § 5.2.1 provides these conditions for any first-passage datum; they are conditions on how the couplings flow: β has no upper bound, and $K = K(\beta, g)$ is determined together with it. Then $\rho_k = (\mathbf{RT})^k \rho_0$ is defined, and

$$\rho_k(V_k) = \sum_{\mathcal{S}} \mathbf{T}'_k(\mathcal{S}) \big[\chi_{k,\mathcal{S}} \exp A_{k,\mathcal{S}}(U_k(\mathbf{V}))\big],$$

$$A_{k,\mathcal{S}} = -A(x_k(\cdot), U) + \mathbf{E}_k + \mathbf{R}_k + \mathbf{B}_k - \mathcal{E}_{k,\mathcal{S}},$$

$$\|E^{(j)}\|_{j,\kappa} \le E_0,$$

$$\|R^{(j)}\|_{j,\kappa} \le g_j^{\kappa_0},$$

$$|B^{(j)}(X,\cdot)| \le \mathsf{B}\, e^{-\kappa d_j^\natural(\mathcal{S};X)},$$

$$\mathsf{M}(i,X) \le e^{-(2-c')p_0(g_i)},$$

where $-\mathcal{E}_{k,\mathcal{S}}$ is the constant term of the action of the label and B is a constant fixed before γ (2d, 2e); $d_j^\natural$ is the hull length of § 4.17, and $\mathsf{M}(i,X)$ is the mass of a component X that, at some level $i \le k$, has passed all those tests of the operation $\mathbf{R}$ that come before the last one. Such a

component is either healed at that level or an island, which remains in the label. The mass is defined as follows. Let e^{Φ_ω} be the integrand of the operation $\mathbf{T}'_i(X)$ belonging to the component. This integrand contains the Wilson factor of the core (2b, 2c), and its exponent has the form $\Phi_\omega(\xi;\mathbf{p}) = \Phi^\circ_\omega(\xi) + \sum_f \Phi_{\omega,f}(\xi;\mathbf{p})$, which is Borel in ξ, analytic in $\mathbf{p}$ and real at real pairs; each factor $\Phi_{\omega,f}$ depends on ξ and on $\mathbf{p}$ only on a support $R_f \subset X^\sim$ § 4.17. Let ω run over the local histories of X, each with a frame in the hypercubic group W_4. Let ξ denote the stored variables and μ_ω their measure. Let $\mathbf{p} = (\mathbf{U},\mathbf{J})$ denote the complex pairs of the space $U^c_i(X^\sim,\alpha_{0,i},\alpha_{1,i})$, which contains the pairs at which a term evaluates the factor. Let $\mathsf{v}(\omega)$ be the space-time volume of the patch, which counts $\log x_j$ for each stored site of level j §4.17.1.40. Then

$$\mathsf{M}(i,X) := \frac{1}{|W_4|}\sum_\omega e^{c\,\mathsf{v}(\omega)} \int \sup_{\mathbf{p}} \left|e^{\Phi_\omega(\xi;\mathbf{p})}\right| \mu_\omega(d\xi).$$

The operation of a drop-out contains no Wilson factor of its own. For a drop-out the same bound holds in a modified form, with two changes. First, the Wilson weight over X of the carrying term is included with the operation; the carrying term is a term of some level $k \geq i$ in which X stands. Second, the supremum is taken over the evaluations at ξ. These are the real configurations that are compatible with ξ, regular layer by layer, and at which every test listed by ω, with the exception of the test whose failure made X a drop-out, takes its recorded value (the full list of these conditions is given in §4.17.1.40). This form follows from the induction and is not one of its clauses. The mass bound holds for every $c \geq 0$ in the weight $e^{c\mathsf{v}}$ and for every small $c' > 0$ in its exponent, provided the ceiling on the couplings is chosen after both c and c'; the reserve constant c_{r} of §4.17.1.45 is one such c. Apart from the core factors of the islands in Z §4.17.1.3, the operation $\mathbf{T}_k(Z)$ contains no Wilson weight. The factor coming from a failed plaquette test sits in $e^{-A(x_k(\cdot),U_k)}$, which is the function the operation acts on. In the sum over the labels, every component C of Z_k keeps a factor $e^{-c\,p_0(g_k)-\kappa_1|C|_k}$. The constant $\kappa_1 > 0$ outweighs the number C^n of connected sets of n cells that contain a given cell §4.17.1.40. Each term is a non-negative measure. Neither $E^{(j)}$ nor $R^{(j)}$ carries a label index. On non-wrapping domains with matching step data they are the values, at the lifts of the domains in those units, of a single family on $\mathbb{Z}^4$. (The constant $\mathcal{E}_{k,\mathcal{S}}$, by contrast, depends on the label and on the torus.) Finally, let $\chi_k = \chi_k(T_\ell)$ denote the product, taken over every cube of the torus, of the tests $\chi_k(\square)$. Then, uniformly, there is a constant E_- such that

$$\chi_k\, e^{-x_k A(U_k(V_k))-E_-|\mathbb{T}^{(k)}|} \leq \bar\rho_k,$$
$$\int \bar\rho_k\, dV_k \leq e^{C(1+\log x_k)|\mathbb{T}^{(k)}|},$$
$$\int \rho_k\, dV_k = Z_{K,\ell,\beta}. \qquad \blacksquare$$

The theorem is the case $\theta = x(\beta)$ of an induction carried out along an arbitrary frame θ (the frame setting of § 5.2). That induction runs on all admissible tori simultaneously. The tube is a clause of the class $\mathfrak{C}_k(\theta)$ of §4.17.1.45, and the step by itself does not yield this clause again (Prop. 4.65). For complex field arguments, each term depends on a triple $(U, A', \mathbf{J})$, in which U is G-valued and $A', \mathbf{J}$ are complex. For a term of level j, the pair of a triple is $\mathbf{p} = (\mathbf{U},\mathbf{J})$ with $\mathbf{U} = e^{i\eta_j A'} U$, and the triple is called a splitting of its pair. The domains of analyticity are defined by conditions on triples. One of the statements propagated by the induction is that a term takes the same value at any two splittings of one pair. The splitting is therefore a coordinate and not an argument, and a term is a function of the pair. (In the regular setting of § 2.2 the values coincide on a complex gauge orbit, with a margin left in the radii. Here what is asserted concerns two splittings of a single pair, and it holds on the domain itself.)

The core of the theorem is due to Bałaban: Comm. Math. Phys. 119 (1988) 243, Theorem 1 and Corollary 3, supplemented by 122 (1989) 175 and 122 (1989) 355, Theorem 1. For the idea of $\mathbf{R}$, he cites Gallavotti and co-workers as the closest earlier work. He states, for one torus, that neither the regular terms nor the part of the remainders produced by the fluctuation integral depend on the region Λ_{k+1} of the step (119, pp. 278–279). He also names a second choice of the thresholds and sets it aside; in that choice only the logarithm is evaluated on a bound of the flow known a priori (p. 246). The upper bound he gives is pointwise, $\varrho_k(V_k) \le e^{E_+ |T_\eta|}$, stated for his density and his volume ((2.50)), and Prop. 4.56 gives the integrated form in its place. Besides what is quoted here from his papers, this step contains the following:

- a proof of that independence and a range for it, covering the remainders in their entirety, simultaneously on all admissible tori and cutoffs, by means of one family on $\mathbb{Z}^4$ (for the counterterm, the paper 119, p. 281, uses "$\mathbf{E}^{(j)}(U_j, z)$ defined on the whole lattice $L^{-j}Z^d$");
- the positivity of each term, as a clause of the statement (in 122 (1989) 175, p. 176, Bałaban announces that the densities $\rho(Z'', V)$ are positive);
- measure and formula as two separate layers;
- the class taken as a set of presentations along a frame;
- the flow inequalities, hypotheses of Prop. 4.56, obtained as conclusions of the induction, carried out jointly with the flow § 5.2.1;
- covariance of the R-terms under translations only, term by term, and covariance of their totals by way of measures;
- the mass, with the complex supremum inside the integral and with a reserve weight;
- the hull length;
- the three possible fates of a component, two of which are recorded as marks of the label (in 122 (1989) 175, pp. 181–183, Bałaban removes from the region on which $\mathbf{R}$ acts any component in which a test of some stage fails, and in 122 (1989) 355, (1.102), he retains the operation $\mathbf{T}_k(Y)$ where the last test fails), and the two sequences of regions attached to a label;
- an order of the constants that contains no circle;
- exactness for each partition of the histories.

The route also makes use of the following:

- the collar and the rim of §4.17.1.1, which ensure that in the interior the mean of the conditional Gaussian measure stays under the thresholds set by the tests;
- the factor depending on two levels in the sum over the scales of the R-terms §4.17.1.45;
- the terms $V(Y)$, which are not of small amplitude, with the consequent removal of the empty family before the exponentiation § 4.17;
- in §4.17.1.40, a single count over the genealogy of a component, which replaces the double induction of 122 (1989) 355, pp. 384–387.

In that induction, the case in which two regions join rests on a sentence on p. 387. That sentence states that after n_1 further hull operations, where n_1 is a fairly small number, for instance $n_1 < 10$, the domain obtained from the region whose wait is the longer of the two contains the domain obtained from the other region. The count never compares two such regions. A joining of regions costs it no separate payment, because the count charges the joining to a created cell §4.17.1.40. The later steps rely on the theorem and on its sourced form §5.20.1.1, which contains the insertion formula.

4.17.1.1. The tests, the nested regions, and the content of a history. **The tests of step** $t = k + 1$ are applied to a term of ρ_k whose live region is $Y = \mathcal{Z}_k$. First, outside a margin of Y, the new field V_t undergoes the plaquette test $\chi_t(\square)$, and the cubes where this test fails make up P_t. The factor $\mathfrak{G}_k$ is inserted away from $P_t \cup Y$. By the Faddeev–Popov argument, its integral over the gauge group of the blocks equals 1. Next comes the approximate fluctuation test $\chi'_k(\square) =$

$\mathbf{1}\{|V_k(\mathcal{M}^k U_{t,\square}(V_t))^{-1} - \mathbf{1}| < 2\delta_k\}$. This test is evaluated at the bonds of $\square^{\sim 2}$ other than the pivot bonds § 4.5, and the third test below is evaluated at the same bonds. Here one takes from the orbit $U_{t,\square}(V_t)$ an element whose k-th average lies in the block axial gauge, and every such element gives the same tested number. The cubes where this test fails make up Q_t. These sets determine Ω_t, the region on which $U_t(\mathbf{V})$ and $\mathcal{A}_k$ exist. The backgrounds and the propagators on sequences of regions are taken from § 3.11, § 3.12.1, together with their regularity and their decay in the local scale. A label's sequence starts at $\Omega_0 = \Omega_1^{\sim}$, the first region enlarged by one layer of level-1 cells, and not at T_ℓ; this is required by Prop. 5.70 and Lem. 5.72 in §§ 5.20 and 5.22. After that the test $\chi^{(k)}(\square)$ is made, and its failures make up R_t. Hulls $(', \hat{\cdot})$ and layers are taken in level-t cells. At $t = 1$, P_0' is the level-one hull of failures of the bare density test. Its indicator on a level-zero density cube $\square$ requires $\sup_{p \subset \square^{\sim}} |\partial U(p) - \mathbf{1}| < \varepsilon_0$. Use the indicator and its complement in the positive partition by P_0. The first plaquette tests avoid $P_0'^{\sim 1}$ and the first gauge draw avoids $P_1'^{\sim 1} \cup P_0'^{\sim 2}$. The boxing map bx replaces each component contained in a cube of $O(1)$ cells by its bounding box, and repeats this until nothing changes. With these conventions,

$$\Omega_t^c = Q_t'^{\sim 2} \cup P_t'^{\sim 4} \cup H_t, \qquad H_t = \begin{cases} \widehat{Y}^{\sim 8}, & t \geq 2, \\ P_0'^{\sim 5}, & t = 1, \end{cases}$$

$$Z^{[0]} = \mathsf{bx}\big((\Omega_t^c)^{\sim 2} \cup R_t'^{\sim}\big),$$

$$Z^{[n+1]} = \mathsf{bx}\big(Z^{[n]} \cup (\text{cells of the failures of round } n)^{\sim}\big),$$

where the rounds are those of the recursion described below. The set $Z_t = \Lambda_t^c$ is the final $Z^{[n]}$, and $S_t = (\Omega_t \setminus \Omega_t^{\sim -1}) \cup R_t$. The numbers of layers are those of Bałaban. If the boxing map is omitted, $Z^{[0]}$ coincides with his Λ_t^c in the form that the display (3.20) gives it, that is, before he replaces the small components by rectangular parallelepipeds (Comm. Math. Phys. 119 (1988) 243, (3.16), (3.20), p. 269). The order of these numbers matters: an older set receives more layers, and each move is made one layer inside the region of the move before it. The creation set $\mathcal{W}_t^{\wedge}$ is the union of the hulls of every failure of the step: P_t', Q_t', R_t', the cells of the collar bonds that fail, and the rim cells that fail. At $t = 1$ it also includes P_0'. If nothing is created, the step reduces to the free evolution

$$\Phi_t(Y) = \mathsf{bx}(\widehat{Y}^{\sim 10});$$

in general

$$Z_t \subset \widehat{Y}^{\sim 10} \cup (\mathcal{W}_t^{\wedge})^{\sim O(1)}$$

up to boxing

That is, one coarsens, adds a margin and boxes; this is the $S(Z)$ of §4.17.1.40. The size $\check{R}_k$ is the smallest power of L that is not less than $(\log \min_{i \leq k} x_i)^r$, with $r \geq 2$. Because it is a power of L, all partitions are nested. Because it is formed from the running minimum, it is non-increasing (Bałaban forms it with g_k itself), and therefore $t \mapsto t - \mathsf{N}_t$ is strictly increasing. Moreover $\check{R}_k \leq L\check{R}_{k+1}$, and two consecutive drops never occur, because x changes by $O(1)$ per step and γ is small. A test cube $\square$ has side of order $M_2\check{R}_t$. Here M_2 is a power of L with $L^2 M_2 \leq M$ and $c\,\delta_0 M_2 \geq 1$. The last condition is a floor on M_2, and δ_0 is fixed together with L, which comes earlier. Hence a test cube lies well inside a cell of its own level.

What factorises, and why. The tests χ_t and χ_k' are built from localised backgrounds. They depend on V_t, V_k only within $O(1)$ test cubes. The third test, and also the collar and rim tests, depend on $\mathcal{A}_k = \frac{1}{i}\log(V_k(V_k^{\mathrm{bg}})^{-1})$, which is formed with the true averaged background on Ω_t.

These tests are therefore local in the new variable $\mathcal{A}_k$, but not in (V_k, V_t). Once $\mathcal{A}_k$ has become the variable, the surviving χ'_k (on S_t) compare $e^{i\mathcal{A}_k}V_k^{\mathrm{bg}}$ with $\mathcal{M}^k U_{t,\square}$. They therefore depend on V_t over the whole of Λ_t. Four facts together ensure that everything attached to Z_t factorises over its components:

- The backgrounds are localised.
- The substitution on the strip §4.17.1.3 is made. After it, every indicator kept in $\Omega_t \cap \Lambda_t^c$ depends on V_t in Λ_t^c alone, apart from the factors that equal 1 on the supports.
- The conditional quadratic form is cut §4.17.1.3.
- The pivot values are dealt with as follows. An old test $\chi_k(\square)$ of a cube $\square \subset \Omega_t^c$ adjacent to Ω_t also depends on V_k at pivot bonds § 4.5 inside Ω_t. There V_k is not a stored variable, and through $e^{i\mathcal{A}_k}V_k^{\mathrm{bg}}$ a test of one component depends on the fields stored in another. At such a bond, V_k is given the value that solves, for the pivot bond, the averaging constraint $\mathcal{M}(V_k)(c) = V_t(c)$ of the single coarse bond c. Bałaban (122 (1989) 175, (1.3)) retains only those old tests whose cubes lie outside $\Omega_t^{\sim}$; the tests that he leaves out equal 1 on the supports by Lem. 4.57 (a), whose margin is this layer.

Inside **R**, the tests are built from backgrounds localised in the component, never from the background of the torus. The induction carries the following property: each indicator stored in $\mathbf{T}_k(Z)$ depends only on those field variables that are localised in Z.

Totality. By definition, a test is the indicator function of the set where all objects occurring in it are defined and where its inequalities hold. These objects are the localised minimal orbit, which must exist and be a single orbit, the contour variables, and the logarithms. Consequently $\chi^c = 1$ wherever some object is undefined. A factor of $\mathfrak{G}_k$ equals 1 where $V(y,x)$ is undefined, by a separate convention for that factor. Hence $\int \mathfrak{G}_k(V^u)\,du = 1$ for every V, and each insertion $1 = \sum\prod\chi\prod\chi^c$ is an identity that needs no assumption. The tests are not empty conditions. The averaging constraint transports smallness: $|\partial V_k - \mathbf{1}| < 2\varepsilon_k$ implies $|\partial V_t - \mathbf{1}| < CL^2\varepsilon_k$. Therefore $U_{t,\square}(V_t)$ exists on the carried supports, and the new test further restricts a field that is regular already (Comm. Math. Phys. 119 (1988) 243, p. 246 at the first step, p. 264 at a general step). The cost is that χ^c contains configurations that are not large in any quantitative sense. These configurations must also produce the small factor §4.17.1.40.

For the convention just stated, normalization can be checked one site at a time. Let $D_{y,x}$ be the set where the prescribed mean $V(y,x)$ exists. Uniqueness of the mean and its biunitary covariance show that $D_{y,x}$ is gauge invariant and that, when the block centers are fixed, $V^u(y,x) = V(y,x)u(x)^{-1}$ on $D_{y,x}$. On this set the integral of the normalized site factor over $u(x)$ is 1 by Haar invariance. Off $D_{y,x}$ the site factor is identically 1, so its integral is again 1. Each noncentral site belongs to one block, and the Haar variables $u(x)$ are independent. Integrating the product therefore gives $\int \mathfrak{G}_k(V^u)\,du = 1$ for every V. This uses the sitewise extension: a defined site retains its prescribed weight even if a different site's mean is undefined.

Collar and rim: this device is an addition to the step of Comm. Math. Phys. 119 (1988) 243, Sect. 3. The stored part of the fluctuation field moves the mean of the conditional Gaussian measure of §4.17.1.3. The thresholds δ_k are stated in the unscaled normalisation, and in that normalisation $\mathcal{A}_k|_{\Lambda_t}$ has the mean

$$\mathbf{m} = -\,C^{(k)}(\Lambda_t)\,\Delta^{(k)}\,\mathcal{A}_k|_{\Omega_t\setminus\Lambda_t}$$

This map is linear, so in terms of the scaled fields A, A' of §4.17.1.3 it is the same map, with each threshold divided by g_k; only $|\mathbf{m}|$ enters. This shift must remain well below the least threshold among the inner tests; that threshold is $\theta_c\delta_k$ on bonds that cross $\partial\Lambda_t$, and δ_k further in. A recursion therefore keeps enlarging the region until, along its boundary, $\mathcal{A}_k$ satisfies two sharper tests:

- $|\mathcal{A}_k| < \delta_k/(4\Theta_1)$ on the collar, the set of stored bonds whose distance from Λ_t, measured in level-k units, is at most ϖ_T. With a qualifying word added, the same name serves for three further objects. In §4.17.1.3, the collar of a stage means the shell over which that stage integrates. In §4.17.1.40, the waiting collar is the set that keeps $X \cap \Omega_{m_\flat}$ apart from the floor. In § 4.17, §4.17.1.45, the collar of a component X means the enlarged component $X^{\sim}$, that is, X together with one layer of M-cubes of its level.
- $|\mathcal{A}_k| < \theta_c \delta_k$ on the rim, the set of cells of level t of Z_t that touch Λ_t.

At greater distance, all that is known is $|\mathcal{A}_k| < C\delta_k$. Every round examines bonds and cubes that no earlier round examined. Hence the recursion terminates, and the admissible outcomes it produces constitute a decomposition of unity. The kernel of $\mathbf{m}$ is bounded, with exponential decay. The contributions of the collar, the rim and the remaining part give

$$|\mathbf{m}| \le C(\Theta_1^{-1} + \theta_c e^{-c\varpi_T} + e^{-cM\check{R}_t})\delta_k < \tfrac{1}{2}\theta_c\delta_k$$
$$\text{if } \theta_c\Theta_1 \ge C,\ \varpi_T \ge C,\ \gamma \text{ small.}$$

The rim fraction $\theta_c \in (0,1)$, the collar width ϖ_T and the collar factor Θ_1 serve this purpose.

Lemma 4.57 (the new tests imply the old; the form reproduces itself)**.** (a) On $\Omega_t^{\sim}$, that is, on Ω_t enlarged by a margin of one layer of cells, the indicators in $\mathfrak{G}_k$ and the tests $\chi_k(\square)$ that the term carries all equal 1. This holds on the support of the new tests together with the tests and averaging constraints that the term still carries alongside them. (b) The test $\chi^{(k)}$ is made only on cubes $\square \subset \Omega_t^{\sim -1}$. For such a cube, if $\square \not\subset R_t$, then $\chi^{(k)}(\square)$ implies $\chi'_k(\square)$. Consequently, within Ω_t, the test χ'_k remains only on S_t. (c) After the step, the tests that stand outside the integral operations are exactly $\chi_{t,\mathcal{S}} := \chi_t(\Omega_t) = \prod_{\square\subset\Omega_t} \chi_t(\square)$. They are formed with the action sequence defined below, and with χ_t^c on an island less a margin. ■

For (a): up to a gauge transformation,

$$U_{k,\square} = \exp\left[i\eta_k \mathbf{H}_{k,\square}(\tfrac{1}{i}\log[V_k(\mathcal{M}^k U_{t,\square'})^{-1}])\right] U_{t,\square'}$$

. Here $\mathbf{H}_{k,\square}$ is the localised response $\mathbf{H}_k$ of § 3.11, so the argument has the form displayed only off a boundary layer of the cube; inside that layer the argument is built from the lift of V_k and is bounded by $C\varepsilon_k$. It follows that

$$|\partial U_{k,\square} - \mathbf{1}| \le (1+c)\varepsilon_t\eta_t^2 + C(\delta_k + e^{-c\,\delta_0 M_2 \check{R}_k}\varepsilon_k)\eta_k^2 \le (CL^{-2} + CA_1/A_0 + Ce^{-\check{R}_k})\varepsilon_k\eta_k^2 < \varepsilon_k\eta_k^2.$$

Three mechanisms appear repeatedly:

- Curvature scales by the factor $\eta_t^2/\eta_k^2 = L^{-2}$.
- The ratio $\delta_k/\varepsilon_k = A_1/A_0$ is small.
- The artificial boundary conditions of localised minimisers act only through $e^{-c\delta_0\,\mathrm{dist}}$ (1b, 1c). On cubes whose side is proportional to $\check{R}_k \approx (\log x_k)^r$, this quantity is smaller than every power of g_k, because $r > 1$. In the present estimate it needs to beat only constants (Bałaban, Comm. Math. Phys. 119 (1988) 243, (3.7)); on the strip §4.17.1.3 it must beat a negative power of g_k (ibid., p. 269, below (3.22), where on S_{k+1} the bound $O(1)\varepsilon_k \exp(-R_k)$ is obtained, "hence by any positive power of g_k").

For (b):

$$|V_k^{\mathrm{bg}}(\mathcal{M}^k U_{t,\square})^{-1} - \mathbf{1}| \le C\tfrac{A_0}{A_1}e^{-c\check{R}_k}\delta_k < \delta_k$$

((3.17)–(3.19) of the same paper). The factor 2 between the two thresholds gives exactly the room needed for this. For (c): a test cube of step t serves also as a test cube of the density of level t,

carrying the same background and the same threshold. The old tests inside Ω_t^c pass into the integral operation. The same ladder of implications holds inside **R** §4.17.1.3. On the support of the tests of a stage, the following tests equal 1: those of the preceding stage, and those of the single stored step whose fields the stage integrates (the plaquette tests of its two levels, the gauge indicators, the approximate fluctuation tests). Further, consider any point at which a term is evaluated: the triple $(U, 0, J(U))$, where U is the background of the label, at fields where no characteristic function of the term vanishes. At such a point, $\chi_q(\square)(V_q) = 1$ holds on every cube $\square$ of level q that lies in the layer $\Omega_{q+1}^{\sim} \setminus \Omega_{q+1}$ and not in a drop-out. Also at such a point, the current of the bare field, formed from the plaquettes inside Ω_0 only, stays within the bound that the domains of analyticity impose on their current (the size $|\mathbf{J}|$ is smaller than the first radius of the domain, measured in the units of the local scale). This bound holds also at the bonds of Ω_0 that have a plaquette leaving Ω_0.

Proposition 4.58 (geometry)**.** The regions are nested, $T_\ell \supset \Omega_1 \supset \Lambda_1 \supset \cdots \supset \Lambda_k$, with gaps of at least $cM\check{R}_j$ in level-j units. Every large-field region and every creation set is a union of cells of its own level. Both statements hold for the regions that the steps produce (119, p. 256). Each operation **R** has stage sequences and prepared sequences (namely the regions that the label has after m of its stages, and after all N_k of its stages; see §4.17.1.3), on which the backgrounds of §4.17.1.3, § 4.17 are formed, and drop-outs keep nests. In these sequences and nests the boxes are only unions of M-cubes, and the only lower bound on the gaps is one M-cube of the later level:

$$\mathrm{dist}_\infty(Z_j, \Omega_{j+1}) \geq LM,$$
$$\Omega_{j+1} \subset \Lambda_j^{\sim -1},$$
$$Z_j^{\sim} \cap \Omega_{j+2} = \emptyset$$
(level-j units; layers of M-cubes of level j),

the first inequality is an equality at the active indices $k_0(t) + 2 \leq j < t$ of the upper part of a nest prepared at level t, where $\Lambda_j = \Omega_j$. Here $k_0(t)$ is the change-of-scale index in eq. 4.cdxliv. At $j = k_0(t) + 1$ the gap is instead $w_j - w_{j+1}$ in bare units, which still gives the displayed lower bound but can be larger; the reason is that a step places eight layers around the old region, and the preparation removes most of them again. Consequently the estimates of § 3.11, § 3.12.1 must hold with a separation of only one M-cube. A smallness $e^{-c\check{R}_j}$ from a separation is available only at regions produced by steps. In each decomposition exactly one outcome equals 1, and hence $\rho_k \, dV_k = \sum_h \tau_h$ holds exactly. A history records every outcome: P_t, Q_t, R_t, the collars and rims, and the outcomes inside **R**. It determines the label, the creations and the ages. There are two kinds of creation:

- Creations by step t are the cells $\mathfrak{c}$ of $\mathcal{W}_t^{\wedge}$, which are $M\check{R}_t$-cubes of level t. They are counted one cell at a time, and each carries one factor $e^{-c\, p_0(g_t)^2}$.
- Creations by an operation are its marked components (next paragraph); the tests of an operation are decompositions of unity component by component. Each marked component counts as one creation and carries one factor $e^{-p_0(g_t)}$, which must pay for $\mathsf{N}_t + 1$ levels of one small box.

All later statements of locality rest on this. ∎

Three fates, marked components, two sequences of regions (Bałaban declines "a systematic description of all possible cases": 122 (1989) 175, p. 183). We set $t_\flat := t - \mathsf{N}_t$. In each component X of its class §4.17.1.3, the operation **R** of level t prepares a nest $Z_l''(X)$, $t_\flat < l \leq t$. The nest consists of increasing boxes in $\Omega_l^c \cap X$. Each box is what remains of the large-field region of scale l after the stage that integrates the stored fields of level $l - 1$. A component has one of three fates:

- *Healed* (every test passed): $\Omega_l, \Lambda_l, S_l \mapsto \Omega_l \cup X, \Lambda_l \cup X, S_l \setminus X$ for $l \le t$, and X leaves the label.
- *Island*, also called second class (only the last test fails, namely χ_t of the new field on X less a margin): the same replacement is made for $l < t$ and for Ω_t, S_t, but Λ_t is left unchanged. Thus $X \subset Z_t$ remains, as a component without inner regions. On it, $\mathbf{T}'_t(X)$ is kept together with its variables, its measure and its factors § 4.17.
- *Drop-out* (some test fails after $n \le \mathsf{N}_t$ stages): X remains in Z_t and retains, as its integral operation §4.17.1.3, the operations carried out up to that point. Moreover

$$\Omega_l \cap X = X \setminus Z''_l(X)$$
$$(t_\flat < l \le t_\flat + n),$$
$$\Lambda_l \cap X = X \setminus Z''_l(X),$$
$$S_l \cap X = \emptyset$$
$$(\text{the same } l,\ l < t),$$
$$\text{all other entries unchanged, so } \Lambda_t \cap X = \emptyset.$$

  (For $n = \mathsf{N}_t$, then, the entry $S_t \cap X$ keeps its previous value; on the support of the tests of the last stage, the tests retained on it equal 1, by the ladder of implications inside $\mathbf{R}$ that is stated in the argument for Lem. 4.57.)

Islands and drop-outs are the *marked components*. A mark persists until a later healed component or island swallows it. The word also denotes two other objects: the mark $\Theta^{(k)}$ below, which is a weight on histories, and a marked term of a cluster expansion §4.17.1.45. A drop-out's mark keeps the regions $\Omega_l^\circ = \Omega_l \cap X$, and likewise $\Lambda_l^\circ, S_l^\circ$, which X possessed before the operation. For $0 \le \boldsymbol{\nu}(X) \le n(X)$ we set

$$\Omega_l^{\boldsymbol{\nu}} \cap X = X \setminus Z''_l(X)\ (t_\flat < l \le t_\flat + \boldsymbol{\nu}(X)),$$
$$\Omega_l^{\boldsymbol{\nu}} \cap X = \Omega_l^\circ\ (t_\flat + \boldsymbol{\nu}(X) < l \le t_\flat + n(X)).$$

The choice $\boldsymbol{\nu} = n$ gives the *determining sequence*, which describes the field in its present state. It governs the determining sets, $U_k(\mathbf{V})$ and the propagators; the analyticity spaces involve all the $\Omega^{\boldsymbol{\nu}}$. The choice $\boldsymbol{\nu} = 0$ gives the *action sequence*, the regions for which the terms were constructed. It governs the index sets of $\mathbf{E}_k, \mathbf{R}_k, \mathbf{B}_k$, the profiles φ_j and hence $x_k(\cdot)$, the carried tests, and the constants $\mathcal{E}_{k,\mathcal{S}}$. No single sequence can play both roles. A stored region in a determining position requires variables that have already been integrated. A stage region in the sums re-sorts terms that were made for other regions. Three facts make the device workable. *Marks wait*: a mark of level s lying inside a class component of level t satisfies $s < t_\flat$. Hence standing marks that share a part are nested, their windows $(s_\flat, s]$ are disjoint, and at any one place and level at most one drop-out mark is active. Next, each $\Omega^{\boldsymbol{\nu}}$ is the geometric label obtained by stopping the operations after $\boldsymbol{\nu}$ stages. Its steps, classes and nests coincide with those of the history at hand, and so Prop. 4.58 applies to it: *the later geometry does not depend on how far an interrupted operation had progressed.* Finally, a term created at a moment μ (following the step, or the operation, of a level $j \le t$) retains permanently the space in which it was made:

$$\Omega_l^{\boldsymbol{\nu}_\mu}(\mathcal{S}_t) = \Omega_l(\mathcal{S}^\mu) \cup Z_{[j,t]}$$
$$(l \le j),$$

where $\mathcal{S}_t$ denotes the level-t label as it stands once the operation $\mathbf{R}$ has been performed, $\boldsymbol{\nu}_\mu = n$ on each mark older than μ and is 0 on each later mark, $\mathcal{S}^\mu$ is the label at that moment, and $Z_{[j,t]}$ is the union of all components that were healed or became islands at levels $j, \dots, t$.

4.17.1.2. Changing stage indices. Keep the recorded step data and the three fates fixed, and change the stage indices on the drop-outs within their allowed ranges. To form the new top regions of level s, the recursion uses the recorded step data and the top stored region from level $s-1$. Changing the stage index leaves that region fixed. At each level the class and the nests for the next operation are also fixed. Indeed, a difference at an earlier index l in a candidate component can only be carried by a standing drop-out of level s with $l < s < t$. If l is in the eligibility window of level t, then s is in that window as well. The drop-out lies in the candidate component by nesting, so that component is ineligible in both labels. All eligible components therefore have the same traces through their windows. Their nests are determined by these traces and the grids.

The dependence on the indices can be checked one cell at a time. Fix a level l in a later label and take q in a common cell refinement of the regions being compared. Look for a standing drop-out X of level s with $q \subset X$ and $s_\flat < l \le s$. There is at most one such drop-out because standing marks that meet have disjoint windows. If there is none, membership of q in the level-l regions is unchanged. Otherwise let m be the replacement stage index of X. For the Ω entry, the membership is given by

$$q \subset \Omega_l^{\mathrm{new}} \quad \Longleftrightarrow \quad \begin{cases} q \not\subset Z_l''(X), & l \le s_\flat + m, \\ q \subset \Omega_l(\mathcal{S}'_s), & l > s_\flat + m. \end{cases} \tag{4.cdxli}$$

For $l < s$ the same rule holds for Λ_l with $\Lambda_l(\mathcal{S}'_s)$ in the second line. At $l = s$ the drop-out keeps q outside Λ_s.

These assertions follow together by induction over the operations. At a step, the earlier entries and standing marks are copied. At an operation, a healed component or an island overwrites the older entries on its region, and any mark it swallows ceases to stand. Outside the class no entries change. On a drop-out the new entries through stage m are the complements of the corresponding prepared boxes, and the earlier rule supplies all entries outside its window. The eligibility check above shows at each induction step that the recorded components and their fates still define the same choices of regions. This proves eq. 4.cdxli, including the case of zero stages. It also explains why the action and determining sequences can use different indices on the same records. In using this identity for an integral, one must still use the measures, variables and test factors carried by that integral.

The resulting labels obey the stage version of the nesting rules. A fully prepared box need not be a component of the stored region, and at the current operation one uses the prepared margins in place of the ten-layer margin of an ordinary step.

Locality in the history. If the large-field regions of two histories never touch, the two histories combine into a single history $h^1 \cup h^2$. There are two reasons for this. (i) *A margin beats a reach*: two regions made of level-t cells that do not touch are separated by at least one cell. One cell exceeds the largest range of a bond test, of a pivot bond and of a collar (in the case of the collar, this is the floor $M \ge \varpi_T$ of §4.17.1.45). Taking hulls and adding layers commute with forming unions, and boxing depends on a single component only. A step therefore acts on each component separately. (ii) The class of $\mathbf{R}$ depends on the past: it depends on every object whose creation falls in the window $(t_\flat, t]$, or which carries a mark at a level in $[t_\flat, t)$. Moreover, the recursion is not monotone: a later region may cover a healed place once more. *Window lemma*: no creation within the window of t has been healed. Indeed, healing at a level $i < t$ something created at step s requires $s \le i - \mathsf{N}_i$, and for something marked at level s it requires $s < i - \mathsf{N}_i$. On the other hand $i - \mathsf{N}_i < t - \mathsf{N}_t \le s$, since $\mathsf{N}_t = \check{R}_t$ is non-increasing. Within the window, therefore, the creations and the marks of each history still lie in that history's own region. It follows that each history is the superposition of its clusters, and that clusters may be interchanged between histories.

Each cluster has a root. The root is of one of two kinds: a component that remains live at the last level, or a healed component, considered at the level where its healing took place. The cluster is made up of the components of earlier levels that flow into the root, together with everything the history records in them. Each component, at whatever level, lies in the cluster of precisely one root, namely the last of its successors; thus nothing recorded about the healed components is lost.

A hard-core gas; the standing part. Erasing clusters of healed components from a history yields a history with the same label. The *standing part* $h^\flat$ of h is what remains after the clusters of all its healed components are removed. For a string s of outcomes of the next step one has $(h,s)^\flat = (h^\flat, s)^\flat$. Let $\bar h$ be a history of level k in which no component is healed at any level. In the rest of this paragraph each history is taken without the clusters healed below level k. It stands for the class of histories that yield it once these clusters are erased. Consider the histories that reduce to $\bar h$ once one erases the clusters belonging to those components that were healed at level k. They are in bijection with the pairs $(\mathfrak{X}, (\varsigma_X)_{X\in\mathfrak{X}})$. Here $\mathfrak{X}$ is a finite collection of possible healed components which touch neither one another nor $Z_k(\bar h)$. Further, $\varsigma_X \in \mathcal{H}^1(X)$ ranges over the histories of X alone in which X is healed and nothing is healed before it, and the choices for different components are independent. All these histories share one label. An individual τ_h is a measure produced by the moves, and it has no exponent of the form in Prop. 4.56. The part of $R^{(k)}$ produced by $\mathbf{R}$ arises only through the sum over $(\mathfrak{X},\varsigma)$, a sum which $\mathbf{R}$ itself performs (under the exact-operation hypothesis and the locality hypothesis). This sum is a polymer sum. The reasons are the gas property and two facts of locality in the history: $\mathbf{T}'_k(X)$ is the same in all the summands containing X, and a healed patch leaves no trace outside itself § 4.17.

Traces and charts. Let W be a region, and let W_i^+, the *window* of level i, denote the enlargement of this region by a single layer of level-i cells. The trace of a label is

$$\mathrm{tr}_W \mathcal{S} := \big(\Omega_i^c \cap W_i^+,\ Z_i \cap W_i^+,\ S_i \cap W_i^+\big)_{i\le k},$$

with two additions. The first addition is the marks of the label. They enter collectively rather than individually. For every level, every kind of mark and, for drop-outs, every number of stages carried out, the trace records the union of all components carrying such a mark, together with the unions of their stored regions and of their nests. Hence the trace does not show which pieces in W_i^+ belong to the same component. The second addition consists of three separate sets of stored bonds of level $i-1$ contained in W_i^+: those in the collar, those at a rim cube, and those in the cut-off zone of the strip. The cut-off zone consists of those bonds of the strip that lie near the set where the fluctuation field is large and carry no kept small-field condition of that field; there the substitution of §4.17.1.3 uses the cut-off ϑ_{co}. Where a bond carries a kept condition, the variables are left unchanged, while on the remaining bonds of the strip the substitution proceeds with no cut-off. The terms depend on these three sets, and the regions in W_i^+ do not fix them: to decide if a cube is a rim cube one has to look at its neighbours, and Ω_i^c enters up to two layers away. The trace $\mathrm{tr}_W h$ of a history is formed in the same way from everything that h records, including the labels of its earlier moments. It is finer: knowing the trace of a label does not fix the traces of the histories that carry it. A *chart* $\iota : W \to W'$ is a translation whose vector belongs to the lattice of level-t cells. It acts either within one torus or, through a common lift of a non-wrapping region, from one torus and cutoff to another. It leaves invariant the lattices $\mathbb{T}^{(i)}$, $i \le t$, and also the partitions of all levels up to t into cubes and cells. Neither a shift by a single site nor a mere isometry of the windows does so. Suppose that $\iota\,\mathrm{tr}_W h = \mathrm{tr}_{W'} h'$, that the increments and the earlier terms in W correspond, and that the bare weight corresponds on the window W_t^+ (this window contains $W^{\sim O(1)}$, since the cells of level t are $M\check R_t$-cubes). Then the two histories produce corresponding terms with domains in W, including their natural domains of definition. Here a term is regarded as a partial map on the fields on W, and one of two corresponding terms is defined exactly where the other is. The integration of V_k over the box is the move (3) of §4.17.1.3 and forms part of the

main step of **R**. Consider the part of the regular terms on a domain of level m that this integration takes. It depends only on the trace through the levels $i \geq m$, whatever the values of k, of $i-m$, of the size of the domain and of the volume. The standing operations, that is the $\mathbf{T}'_i(X)$ of the islands carried by a term, are transported likewise, measures included and one factor at a time §4.17.1.45. For the analyticity spaces more is needed. The spaces of two corresponding terms are mapped onto one another if two further conditions hold. First, the bonds of the bare lattice carrying their fields must form corresponding sets. This is needed because whether a bond leaving the domain ends in $\Omega_1^{\sim}$ is decided outside the window; for a domain in Ω_1 there is no condition. Second, at each level, two unit cubes of the bare lattice lying in the domain must belong to a common drop-out mark of that level if and only if their images do. This is needed because a domain that is not convex may cut a mark into two pieces; where no mark meets the domain there is no condition. On the infinite lattice no sum over labels is formed. The only terms formed there are those of the never-large label, the label at which no region stands; domain by domain, these terms contain the sums over healed components that **R** performs (under the exact-operation hypothesis and the locality hypothesis). A term whose window W_t^{+} lies in Λ_t coincides with the corresponding term of that label (the terms belong to the standing part $h^{\flat}$, and everything that this part records lies in Z_t: 2e). For a non-wrapping domain and corresponding step data under the chart, the lifted term is the same function, and in this way $E^{(j)}$ and b_j are computed § 5.2.2. It is this that links the geometry to § 5.2.2 and §5.20.1.2.

The net form of the exponent. Each function $\mathfrak{t}$ of the exponent has a fixed place, given by its level, its domain and the way it is made. The label enters only through the sorting into $\mathbf{E}_k, \mathbf{R}_k, \mathbf{B}_k$, the profile and one number:

$$A_{k,\mathcal{S}}(U) = -\beta A(U) + \sum_{\mathfrak{t}} \mathfrak{t}(U) + \mathrm{const}(\mathcal{S}),$$

because

$$x_k(\cdot) + \sum_{j \leq k} b_j \varphi_j(\cdot) = \beta$$

and $c \mapsto A(c,U)$ is linear. Consequently a change of label changes no local term.

The law of the histories. The set $\mathfrak{H}_k$ of histories of level k is finite. A run has the datum $\mathfrak{d} = (\beta, m, g)$ and takes place on T_{ℓ_m}, $\ell_m = 2L^m$. The mass of a history $h \in \mathfrak{H}_k$ is $\mathfrak{t}(h) := \tau_h(\mathcal{V}_k) \geq 0$. Since the steps are exact §4.17.1.45, $\sum_{h \in \mathfrak{H}_k} \mathfrak{t}(h) = Z_{K,\ell,\beta}$ at each level. The law of the histories of the last level, and in the same way the law of the histories of any level, is

$$\tilde{\nu}_{K,\ell,\beta}(\mathsf{E}) := Z_{K,\ell,\beta}^{-1} \sum_{h \in \mathsf{E}} \mathfrak{t}(h),$$

where events of histories are written in sans-serif letters, $\mathsf{E}_k \subset \mathfrak{H}_k$. The creation set of step j is $\mathcal{W}_j^{\wedge}(h)$, as before. Without the superscript, $\mathcal{W}_K(g)$ denotes the first-passage window. The live region $\mathcal{Z}_k(h)$ is $Z_k(h)$ with the components healed at step k removed; it is the input region of step $k+1$. The event that the cell $\mathfrak{c}$ is live at level k, that is $\mathfrak{c} \subset \mathcal{Z}_k$, is written $\mathfrak{lv}_k(\mathfrak{c})$. For a cell z of level n, the survival event $\mathcal{E}_z^{(n)}(k)$ is the event that $z \subset \mathcal{Z}_i$ for $n \leq i \leq k$. For the flow and history statements below, we continue the run past K. For these statements we fix an anchor coupling $\gamma_\star \in (0, \gamma_J]$, which is determined by the constants up to c_a and by γ_J, and put $X_\star = \gamma_\star^{-2}$. The anchor level is $K_\star = K(\beta, \gamma_\star)$; it goes to infinity as β does. In these statements the reference coupling obeys the ceiling $g \leq \gamma_\star$, and the bounds on the flow hold up to $K_\star$. Also, at a given β, the run passes the window of g no later than the window of $\gamma_\star$, $K(\beta, g) \leq K_\star$; this follows from $g \leq \gamma_\star$ and the monotonicity of the first passage.

Lineages and marks. Let X be a component of $Z_k(h)$, at any level, that is either live at level k or healed at step k; a component live at $k = K$ is a terminal component. Its lineage regions are $\mathsf{Z}_k(X) := X$ and, going down the levels, $\mathsf{Z}_j(X) :=$ the union of all components that are live at level j and contained in $\mathsf{Z}_{j+1}(X)$. Its lineage consists of these components (j, C) together with the creations (j, W) inside the $\mathsf{Z}_j(X)$. The weight of a level-j cell is $\mathsf{r}_j := M^4 \check{R}_j^5$. We write $|C|_j$ for the number of level-j cells in C. For comparison, $\#_j(Y)$ counts the sites of $\mathbb{T}^{(j)}$ in Y, and a cell contains $(M\check{R}_j)^4$ of them. Finally, for a component W of the set that step j creates in the lineage, $d'_j(W)$ is its tree length measured in these cells; the marks set by the operations **R** do not enter Dep. Then

$$\mathrm{Vol}_k(X; h) := \sum_{(j,C) \text{ in the lineage}} 2\,\mathsf{r}_j\,|C|_j,$$

$$\mathrm{Dep}_k(X; h) := \sum_{(j,W) \text{ created in the lineage}} c\,p_0(g_j)^2 (d'_j(W) + 1).$$

The mark at level k has two dials, $\mathsf{w} \in [0, 1)$ and $c_a \geq 0$, the second also called the age constant. The mark and the end mark $\Theta := \Theta^{(K)}$ are

$$\Theta^{(k)}(h) := \sum_{X \text{ live at level } k} \left[\mathsf{w}\,\mathrm{Dep}_k(X; h) + c_a\,\mathrm{Vol}_k(X; h)\right] \geq 0.$$

The mark keeps back the fraction w of the small factor of each creation in such a lineage. It also charges $2c_a$ for every cell, multiplied by the weight of the cell, and for every level. The constant c in Dep is a single number. It is chosen after the fractions of the fluctuation threshold, namely those at which a step evaluates its tests: $1/(4\Theta_1)$ on the collar and θ_c on the rim. It is subject to $c \leq c' \min\{\Theta_1^{-2}, \theta_c^2\}$, where c' is chosen after (A_1, A_0) and contains the ratio $(A_1/A_0)^2$ of δ_k^2/g_k^2 to $p_0(g_k)^2$. No ceiling on g can take the place of this choice, since such a test has a deposit and a gain that are both of degree $2\mathfrak{p}_0$ in $\log x_j$.

Three ages are attached to a component C that is live at level k. (1) The age in the label is determined by the oldest region of the label within C: $\mathrm{age}^{\mathrm{lab}}(C) = k - \min\{t : C \cap Z_t \neq \emptyset\}$, where Z_t denotes the large-field region of the label $\mathcal{S}(h)$ at scale t. (2) The age of the lineage is $\mathrm{age}_k(C; h) = k - j_0$, with j_0 the earliest level that has a non-empty lineage region $\mathsf{Z}_j(C)$. The events $\mathfrak{lv}_k^{=a}(\mathfrak{c})$ and $\mathfrak{lv}_k^{\geq a}(\mathfrak{c})$ say that at level k the cell lies in a live component whose lineage has age a, respectively at least a. (3) The seed age is k minus the seed level. The seed level is the least t such that C contains, as a point set, some region created at step t. The corresponding events are written $\mathfrak{sd}_k^{=a}(\mathfrak{c})$. The first age is at most the second, and the second is at most the third. The second and the third can differ. Suppose that a region was healed at some earlier step and that a later live region again covers its place. Such a region counts for the seed level but is not part of the lineage. If the seed level is defined using the regions that no step before k has healed, the two ages coincide. Payment is made for the age of the lineage alone §4.17.1.45. Age has to be paid for with creations. In a lineage with n creations, those made by operations included, a creation made at step t satisfies $k - t \leq Cn(\mathsf{N}_t + \log n)$. Here a creation is a created cell or a mark. By the waiting bound and the count of §4.17.1.40, this bound holds for every lineage; hence an old lineage contains many creations. These objects enter §4.17.1.45 and §§ 5.20 and 5.22. Through the age series of §§ 5.20 and 5.22 they underlie both the two-point law §6.1.1.1–§6.1.1.11 and the four-point law Thm. A(c)(5), namely clauses (c)(3), (c)(4), (c)(5).

History data, effective densities, and large-field operations. **[1.6] The sequences of a label.** Let $\boldsymbol{\nu}' \leq \boldsymbol{\nu}$. Then $\Omega_l^{\boldsymbol{\nu}}$ is a region for π_l. The chain $\Omega_0 \supset \Omega_1^{\boldsymbol{\nu}} \supset \cdots \supset \Omega_s^{\boldsymbol{\nu}}$ holds, and any two consecutive boundaries in it lie at least one M-cube of the coarser level apart, which is the separation that

minimisers and propagators require. Further, $\Omega_l^{\nu'} \subset \Omega_l^{\nu}$ and $\Omega_l^n = \Omega_l$, so that *the entries make up the determining sequence*. The action regions are unions of coarse cubes,

$$T_\ell \supset \Omega_1^{\mathsf{a}} \supset \Lambda_1^{\mathsf{a}+} \supset \Lambda_1^{\mathsf{a}} \supset \Omega_2^{\mathsf{a}} \supset \cdots \supset \Lambda_s^{\mathsf{a}},$$
$$\Omega_{l+1}^{\mathsf{a}} \subset (\Lambda_l^{\mathsf{a}})^{\sim -1},$$
$$Z_s^{\mathsf{a}} = Z_s,$$

and the correspondence (entries, stored regions) $\leftrightarrow$ (action regions, nest) gives two presentations of one and the same datum.

4.17.1.3. Stored variables and integration in a large-field patch. **Measure and formula: two layers.** At the level of measures, a step acts as a finite sequence of moves on states $\sigma = (h, \xi)$, where h records the outcomes obtained up to that point and ξ the variables stored up to that point. Each move is given by positive kernels $\Pi^{(o)}$, finitely many and one for each outcome o, such that $\sum_o \Pi^{(o)}(\sigma, \cdot)$ has total mass one. A move is one of four kinds. It may be a test, that is, an indicator whose outcome is added to h. It may be a map. It may be a draw, that is, the image of a probability law, as for gauge fixings, hypercubic frames $r \in W_4$ and reference laws. Or it may delete a stored variable, which amounts to an integration. Everything expressed by a formula, such as Gaussian weights, Jacobians, expansions, resummations or the replacement of a test by 1, only recasts an integrand in another form. A gauge fixing is a draw as a move. For it to be the factor that the formula writes, the measure must be gauge invariant. Let ν_0 be any complex bare measure, let $\mu_0 \geq 0$, and let $\mathfrak{w}$ be any bounded Borel function of the bare field. Denote by K_h the kernel of the history h, obtained by composing the kernels $\Pi^{(o)}$ of its moves along its outcomes. Then

$$\tau_h[\nu_0] = \int \nu_0(dU)\, \mathsf{K}_h(U, \cdot),$$
$$\sum_h \mathsf{K}_h(U, \mathcal{V}_k) = 1 \ \forall U,$$
$$\sum_h |\tau_h|(\mathcal{V}_k) \leq |\nu_0|(\mathcal{V}_0),$$
$$\big|\tau_h[\mathfrak{w}\mu_0]\big| \leq \sup|\mathfrak{w}|\, \tau_h[\mu_0].$$

By totality (2a; a reference law whose normalisation does not lie in $(0, \infty)$ is not drawn, and in that case the component drops out; this case does not arise on the supports, see §4.17.1.45, "Reality and positivity"), every kernel is defined at every field, and no smallness condition is needed. They depend on the lattices and the constants. Of the frame θ (2e: the real sequence from which the choices are formed; in the present case $\theta = x$, and it is only through this frame that the kernels then vary with β; it is unrelated to the hypercubic frames r), they use only the gauge-fixing law, the coupling of the reference law, the cube sizes and the thresholds. Apart from their dependence through the frame, the kernels do not depend on any measure, on β, on a source, on any term of an effective action, or on whether some series converges. Exactness and positivity therefore come at no cost, because a move does nothing but split mass. The sourced densities come from $\nu_0 = \rho_0^w\, dU$ with the same kernels §5.20.1.1, and runs whose choices are frozen are runs of that same procedure § 5.2.3. The estimates of §4.17.1.40–§4.17.1.45 add only one further statement: the formulas are formed on the supports and there coincide with the measures. *Passengers*: divide the stored variables into those, $\mathfrak{v}$, that a move uses and the remaining ones, $\mathfrak{q}$. In step $t = k + 1$ the operation $\mathbf{T}$ uses the fields of level k and, from the lower levels, only the data of its backgrounds; the operation $\mathbf{R}$ uses variables only in the components of its class and next to them. Any variable not used by a move of the step is carried along unchanged,

$$\Pi^{(o)}((h,(\mathfrak{v},\mathfrak{q})),\cdot)=\Pi^{\flat(o)}((h,\mathfrak{v}),\cdot)\otimes\delta_{\mathfrak{q}}$$

, in which $\Pi^{\flat(o)}((h,\mathfrak{v}),\cdot)$ is a measure on the states $((h,o),\mathfrak{v}')$. This is the locality of a step, in measure-theoretic form.

T on a label (Bałaban, Comm. Math. Phys. 119 (1988) 243, Sect. 3) comprises the following, carried out on the regions fixed by the tests of §4.17.1.1. First the multi-scale background $U_{j+1}(\mathbf{V})$ is formed, on the determining set $\mathbf{B}[\Omega_\bullet]$ § 3.11; the third test of §4.17.1.1 is formed with this background. Next, a change of variables is made on the strip. Then a conditional Gaussian integral is taken over Λ_{j+1}. Finally, the logarithm of this integral is split into E, R and B. The operation sits between § 4.5, in which no regions occur, and the operation **R**.

The strip. The tests kept on $S_{j+1}\subset\Omega_{j+1}\setminus\Lambda_{j+1}$ depend on V_{j+1} non-locally, by way of V_j^{bg}. For $j\geq 1$ use the joined background on $Z_{j+1}\sqcap\Lambda_j$ with $Z_{j+1}=\Lambda_{j+1}^c$, and denote its average by V_j^{loc}. At the first step use the one-part localization. Then

$$V_j^{\mathrm{bg}}(V_j^{\mathrm{loc}})^{-1}=e^{i\mathbf{H}^{(j)}},$$

$$|\mathbf{H}^{(j)}|\leq C\varepsilon_j e^{-\check{R}_j};$$

$$V_j(b)=W' e^{-i\vartheta_{\mathrm{co}}(W')\mathbf{H}^{(j)}(b)}e^{i\mathbf{H}^{(j)}(b)}\,V_j^{\mathrm{loc}}(b),$$

The last line is a bondwise change of variables with $W'=e^{i\mathcal{A}'(b)}$. In it, ϑ_{co} is a smooth cut-off in $|\log W'|$. It equals zero for angles at most $4\delta_j/3$ and one for angles at least $5\delta_j/3$. This cut-off is applied on the cut-off zone of the strip (§4.17.1.1); at the remaining bonds where the substitution is made, $\vartheta_{\mathrm{co}}\equiv 1$. Consequently, on the cut-off zone, a test whose threshold does not exceed δ_j is the same function of the new variable as of the old one, while a test at $2\delta_j$ is now made against the localised background. Because $|\mathbf{H}^{(j)}|\ll\delta_j$, a contraction argument shows that the map on a bond is a diffeomorphism of G. Its Jacobian equals 1 wherever ϑ_{co} is locally constant, and it contributes to the action as a boundary term. Once the substitution has been made, the factors of the kept tests at those bonds next to Λ_{j+1} where no substitution takes place are omitted. On the supports these factors equal 1, and where $\vartheta_{\mathrm{co}}<1$, the $2\delta_j$ check relative to either strip background passes by the angle bound below. Moreover, at a pivot bond of Ω_{j+1} the value of V_j is taken from the constraint $\mathcal{M}(V_j)=V_{j+1}$. The strip tests after substitution have the support described below. Factorization of the integral operations also uses the locality of the integration domain and the full kernel.

Write $W=V_j(b)V_j^{\mathrm{bg}}(b)^{-1}$ and $H=\mathbf{H}^{(j)}(b)$. In the strip change of variables the backgrounds are held fixed while the bond variables are changed. The displayed substitution gives

$$W=W'\exp(-\mathrm{i}\vartheta_{\mathrm{co}}(W')H).$$

For $W\in\mathrm{SU}(2)$ let $\varphi(W)\in[0,\pi]$ be the angle of its eigenvalues $e^{\pm\mathrm{i}\varphi(W)}$. In particular, $\varphi(-\mathbf{1})=\pi$. Off $-\mathbf{1}$ the angle is the norm of $(1/\mathrm{i})\log W$ with the intrinsic logarithm. On the cut-off zone the cut-off vanishes for $\varphi(W')\leq 4\delta_j/3$ and equals one for $\varphi(W')\geq 5\delta_j/3$. Here $\delta_j\leq 1$, and we use the strip bound with $|H|\leq\delta_j/8$. The triangle inequality for the angle gives $\varphi(W)\geq\varphi(W')-|H|$. If $\varphi(W')<4\delta_j/3$, the substitution leaves $W=W'$. Otherwise

$$\varphi(W)\geq(4/3-1/8)\delta_j=29\delta_j/24.$$

Consequently, for $0<a\leq 29/24$, $\varphi(W)<a\delta_j$ and $\varphi(W')<a\delta_j$ are equivalent. If the test passes, $W=W'\neq-\mathbf{1}$. The strict inequality gives the same conclusion at the upper allowed threshold. This proves the assertion for the products and differences of sharp bond tests whose bonds are all either in the cut-off zone or unchanged. At unchanged bonds the test is literally the old one. On

the cutoff zone where $\vartheta_{\mathrm{co}} < 1$, the upper triangle inequality gives $\varphi(W) < (5/3 + 1/8)\delta_j < 2\delta_j$. Also $V_j(V_j^{\mathrm{loc}})^{-1} = W' e^{i(1-\vartheta_{\mathrm{co}})H}$, so its angle has the same upper bound. For an approximate test based on the test cube's own background, use the comparison with the localized strip background below.

4.17.1.4. The strip Jacobian. For fixed H write $\vartheta = \vartheta_{\mathrm{co}}$ and $\Psi(W') = W' \exp(-i\vartheta(W')H)$. The map is smooth on the whole group because the cutoff is constant near both ends of the angle chart. For given W its inverse solves $W' = W \exp(i\vartheta(W')H)$. With the bi-invariant metric this is a contraction when $\|d\vartheta\|_\infty |H| < 1$. The cutoff derivative costs C/δ_j, so the real shift bound is used with $C|H|/\delta_j \le 1/2$.

Measurability of the partial inverse holds on the full unique-solution set. The graph $\Psi_H(W') = W$ is closed in the variables (H, W, W'), and the last variable ranges over the compact group. Its projection is closed. The parameters with two different solutions are the union, over $n \ge 1$, of the projections with two solutions at distance at least $1/n$. Each of these projections is closed by compactness of the two group variables. The unique-solution set is therefore Borel. Intersecting the graph with W' in a closed subset of the group shows that the recovered value is Borel there. A fixed failure output on its complement is measurable.

When a change of measure requires a diffeomorphism, also require injectivity, surjectivity and nonvanishing Jacobian everywhere. Injectivity is the complement of the same countable family of collision projections, now over H. The image is compact, so surjectivity is equivalent to containing a countable dense set of target values. Nonvanishing of the Jacobian everywhere is open by compactness. This gives a Borel diffeomorphism domain. The inverse is jointly continuous on it, since any converging sequence of parameters and target values has inverse subsequential limits solving the same unique equation.

In left-trivialized tangent coordinates the differential is

$$X \longmapsto \mathrm{Ad}(\exp(i\vartheta H))X - iH\, d\vartheta_{W'}(W'X).$$

Factor out the adjoint, which has determinant one and fixes iH. The remaining rank-one determinant gives the Haar Jacobian for dW in the variable W' is

$$\mathcal{J}_b(W') = 1 - d\vartheta_{W'}(W'iH) > 0.$$

Its logarithm vanishes off the cutoff shell. At fixed real W' it is holomorphic in H on the smaller complex ball where $C|H|/\delta_j < 1$. Here the real differential in the last display is extended complex linearly.

For the local expansion take a decomposition $H = \sum_Y H_Y$ in which the carriers all contain the bond read and meet a boundary cube. Write $\ell(Y)$ for the size of a shortest connecting tree in the cell grid, including the fixed read. If $\sum_Y e^{\mu\ell(Y)}|H_Y|$ is available and its product with C/δ_j is less than $1/2$, expand $\log(1-u) = -\sum_{n\ge1} u^n/n$ with $u = d\vartheta_{W'}(W'iH)$. Put a product on the union of its carriers. Because they share the read, the size of a tree for their union is no more than the sum of their tree sizes. The absolute sum at weight $e^{\mu\ell}$ is then at most $2(C/\delta_j)\sum_Y e^{\mu\ell(Y)}|H_Y|$. The result still has a boundary cube on every carrier. It uses the holomorphic shift expansion on the admitted pair domain, while the cutoff variable itself stays real.

Where $\vartheta_{\mathrm{co}} = 1$, the substitution gives $V_j(b) = W' V_j^{\mathrm{loc}}(b)$. In an approximate fluctuation test at such a bond, insert this expression for $V_j(b)$. The localized datum of a test cube $\square$ uses only the level-$(j+1)$ bonds with both ends in $\square^{\sim 4}$. Agreement on those bonds fixes both whether the local background is defined and its value in the test. To see that these bonds lie in the retained region, put $t = j+1$ and use level-j units. The test cube has side $L^2 M_2 \check{R}_t$, its layers have width $LM_2\check{R}_t$, and a level-t cell has side $LM\check{R}_t$. A bond being substituted has an end z in the strip $(\Omega_t \setminus \Omega_t^{\sim -1}) \cup R_t$. If the bond occurs in the test on $\square$, its other end, or z itself, lies in $\square^{\sim 2}$. Each point of $\square^{\sim 4}$ is thus at distance at most $(L^2 + 6L)M_2\check{R}_t + 1 < LM\check{R}_t$ from z, using $L \ge 4$ and $L^2 M_2 \le M$. If z lies in the outer layer of Ω_t, its one-cell enlargement lies in $(\Omega_t^c)^{\sim 2}$. If it lies in R_t,

that enlargement lies in the one-cell enlargement of its hull. Both regions belong to the completed stored region Z_t, so $\square^{\sim 4} \subset Z_t$. The strip construction here requires V_j^{loc} to depend on V_t only through the bonds meeting $\Omega_t \cap Z_t$. These restrictions determine the transformed test including its zero value when the local background is undefined. The statement concerns this change of variables. Independence under a later integration requires the corresponding property of that integration's domain and kernel.

4.17.1.5. The local strip background. For a step $t = j + 1 \geq 2$ use the joined region $W = Z_t \sqcap \Lambda_j$, with Z_t a part at level t and Λ_j a part at level j. Here we use the step geometry in which their four-layer collars of M_1-cubes lie in the corresponding ambient layers, with the separation of the collars required for the join. The one-cell enlargement of the proposed strip is in Z_t, and the top torus has at least 6ρ sites in each direction. Use either admitted first member of the joined sequence. If the level-j curvature in W is at most ε' and $V_t = \mathcal{M}(V_j)$ on the level-t bonds of W, the joined test bound is $\max\{2L^2, \mathsf{k}_L\}\varepsilon'$ for sufficiently small ε'. At level j the tested holonomy is the one of V_j. At level t both types of bond in a test give the same values of $\mathcal{M}(V_j)$, using the exact constraint for the given bonds and the same average for the mixed ones. Its plaquette deviation is at most $L^2\varepsilon' + C_L(\varepsilon')^2$. The face lift transfers this test bound to the joined datum. Thus the joined datum has a real regular critical orbit under the background smallness and torus conditions.

Normalize this orbit by setting its averaged contour transports from the strip block centers equal to one at the level-j sites that are free to be gauged. A site that is a node of the joined determining set already has its gauge fixed. The centers themselves are nodes. The residual gauge relating two normalized representatives therefore equals one at the free sites whose contour transports were normalized as well. The level-j averages on the strip bonds, whose blocks lie in the joined first member and whose endpoints are such sites or nodes, are consequently independent of the representative. This gives V_j^{loc} from the retained real datum. For a union of components of W the same argument restricts to that union. The determining bonds and contour blocks used here belong to individual components.

4.17.1.6. The shift in the block axial frames. For a strip bond b, include in its read set the double block of the level-j average and the contour blocks used to fix the gauges of its two endpoints. Let D_b be the least distance to W^c on the bare averaging carriers of this set, in the ambient weighted distance, also including the order-q blocks of the fixed sites at their own levels $q \in \{j, t\}$. Consider a read on which the full datum is in the real comparison class of eq. 3.cdii, with test radius ε_1. Use a read set inside the common interior of the full and joined sequences. The two sequences use the same block centres and fix the same endpoints there. For each of these fixed sites, use the node comparison of the real collar estimate. In particular these sites must be outside the wide collars.

Write the restriction of the full field as E^w, where $E = e^{i\eta f} U_W^\circ$ in the notation of the collar comparison. The level-j fields $\mathcal{M}^j E$ and $\mathcal{M}^j U_W^\circ$ differ on the read set by at most

$$e_b = C\varepsilon_1 e^{-\delta_0 D_b/2}.$$

Indeed the bare field has plaquette bound $C\varepsilon_1 L^{-2j}$ on these blocks, since both layers are of level at least j. The relative perturbation, in the units of level j, is bounded by $C\varepsilon_1 e^{-\delta_0 D_b/2}$ by eq. 3.cdii. Apply the local average estimate of Prop. 3.6 to the full double blocks, using the bound for both the straightened angle and its endpoint factors. The same estimate at the fixed sites gives $|w(z) - 1| \leq Ce_b$ there, by $w(z) = v_q[f](z)^{-1}$. The order-q spacing is at most L times that of the level-j blocks. The bound for f is measured at the corresponding tops, at weighted distance $O(1)$ from these blocks. The contour means of the two fields in the comparison frame differ by at most $C_L e_b$, since their transports are products of bounded length and the derivative of the local mean is bounded on its small-diameter chart.

For a free site x with centre y write $T_E(y, x)$ for the contour mean of $\mathcal{M}^j E$. The normalization of the full field uses $w(y)T_E(y, x)w(x)^{-1}$ at x, by gauge covariance. Its composition with w is therefore $w(y)T_E(y, x)$. The joined field uses $T_{U_W^\circ}(y, x)$. The two factors differ by at most $C_L e_b$

since y is fixed and $w(y)$ is already close to one. At a fixed endpoint the only comparison factor is $w(x)$. Taking the product at the two endpoints of b proves

$$|V_j^{\mathrm{bg}}(b)V_j^{\mathrm{loc}}(b)^{-1}-1|\le C_L e_b.$$

The intrinsic logarithm has the same bound up to a constant. There is no need to estimate the unconstrained values of w.

On the strip read sets with a full layer of level-t cells between their bond and Z_t^c, the read carriers use only $O(L^t)$ of this margin. For the part of W^c coming from Λ_j^c, use the nested margin of Ω_t inside Λ_j, with the same allowance for the read carriers. The largest layer in the ambient sequence is t, so a physical margin $cM\check{R}_tL^t$ gives $D_b\ge cM\check{R}_t$ in the weighted distance. This yields the small real shift for such reads, with the prefactor given by the real datum radius. Taking the fixed M large enough gives the cutoff bound at small coupling. For each use we must check the full carriers and the common fixed-site clause. The real endpoint estimate does not supply the holomorphic expansion of the shift on an independent current domain used to transfer the boundary terms.

The datum in the response equation must be distinguished from the physical change of the averages. In the real collar comparison write $\widehat{U}=(U|_W)^g$ for the aligned restriction and $\widehat{V}=M_{\mathbf{B}^W}(\widehat{U})$. The alignment gives

$$\widehat{V}=e^{iB_1}V^W,\qquad B_1(c)=\frac{1}{i}\log\Big[\mathcal{M}^q(U^{v_a})(c)V_q^W(c)^{-1}\Big]$$

on the positively oriented collar bonds, and $B_1=0$ on the remaining determining bonds. Here c has level q and belongs to the collar of the part a. The physical increment that changes $\widehat{V}$ into V^W is therefore $b=-B_1$. For the response built at $\widehat{U}$, its row input is $B'=b_\natural$, with the conversion formed using $\widehat{V}$. At an interior row this is b; at an outward row it includes the endpoint factor of that conversion. In particular, the support of B' may include the outward rows whose endpoint blocks meet the support of b.

This conversion is holomorphic wherever its stated pair and logarithm bounds hold, and satisfies

$$|b_\natural|_y\le C_{\natural,\mathrm{s}}\max_{y'\in N_L(y)}|b|_{y'}.$$

It identifies the row input once an admitted physical defect b is given. To apply the complex response theorem uniformly, the aligned pair must lie in its joined local class and the converted input must satisfy

$$\|b_\natural\|_\infty<\varepsilon_{\mathrm{D,s}}e^{-32\varkappa}.$$

The real collar alignment supplies a real defect of size $C\varepsilon_1$.

4.17.1.7. The input on a fixed real collar chart. Fix the real configuration U used in the collar comparison. Let g_0 be its real alignment, equal to the supplied v_a on each wide collar Q_a and to one elsewhere. Keep g_0 fixed when the complex perturbation varies. On a part of level $j_a=j$, use level-j units and write

$$\mathbf{U}=e^{i\eta_jA'}U,\qquad \|A'\|_\infty\le\alpha_1,\qquad \eta_j=L^{-j}.$$

The full averaging carriers considered below lie in the collar region where the real plaquette bound is $|\partial U-1|\le C\varepsilon_1\eta_j^2$. Take $C\varepsilon_1$ and α_1 below the fixed averaging ceilings. Since g_0 is real, the same bounds hold after its action, with A' replaced by $\mathrm{Ad}(g_0)A'$.

The complex averaging formula, applied with real reference U^{g_0}, gives, for $0\le q\le j$,

$$\mathcal{M}^q(\mathbf{U}^{g_0})(c)=v_q(c_-)e^{ia_q(c)}\mathcal{M}^q(U^{g_0})(c)v_q(c_+)^{-1},$$

where the functions are holomorphic in A' and

$$|a_q|\le 2L^{q-j}\alpha_1,\qquad |v_q^{\pm1}-1|\le\frac{8}{Lr_*}L^{q-j}\alpha_1.$$

For $q = 0$ the site factors equal one. The central average is unitary. Subtracting it in the preceding formula and using the three displayed bounds therefore gives

$$\left|\mathcal{M}^q(\mathbf{U}^{g_0})(c) - \mathcal{M}^q(U^{g_0})(c)\right| \le C_L L^{q-j}\alpha_1.$$

This estimate includes the endpoint factors. Its constant is independent of j and q.

Form the joined datum $V^W[\mathbf{U}]$ by the same rule as at the real center: use the unchanged common rows and the face lifts of the top averages on the collar rows. At a collar row, the lift is either one or the value of a single top averaged bond. The estimate at $q = j$ consequently gives

$$|V^W[\mathbf{U}](c) - V^W[U](c)| \le C_L\alpha_1.$$

Set $\widehat{V}[\mathbf{U}] = M_{\mathbf{B}^W}((\mathbf{U}|_W)^{g_0})$. On the collar rows define

$$b[\mathbf{U}](c) = \frac{1}{i}\log\Big[V^W[\mathbf{U}](c)\widehat{V}[\mathbf{U}](c)^{-1}\Big].$$

At the center, $\widehat{V}[U] = e^{iB_1}V^W[U]$, so this logarithm is $-B_1$. For sufficiently small $C\varepsilon_1 + \alpha_1$, its argument stays in a fixed series-logarithm ball around one, and

$$\|b[\mathbf{U}]\|_\infty \le C_L(\varepsilon_1 + \alpha_1), \qquad b[U] = -B_1.$$

Indeed both matrix factors differ by $O(\alpha_1)$ from their unitary center values, and the center product is e^{-iB_1}. Inversion and the series logarithm are uniformly bounded and holomorphic on this smaller ball.

On a common row the alignment is one at both endpoints, by the collar geometry. Gauge covariance under the fixed real g_0 thus gives $\widehat{V}[\mathbf{U}] = V^W[\mathbf{U}]$ there. Set $b = 0$ on those rows. This proves exact support on the collar rows and the identity

$$e^{ib[\mathbf{U}]}\widehat{V}[\mathbf{U}] = V^W[\mathbf{U}].$$

For a closed set of response rows, the converted datum $B' = b_\natural$, formed at $\widehat{V}[\mathbf{U}]$, is holomorphic and has norm at most $C_{\natural,\mathrm{s}}C_L(\varepsilon_1 + \alpha_1)$. Its carriers include the endpoint blocks read by this conversion. The response radius is met when this bound is smaller than $\varepsilon_{\mathrm{D},\mathrm{s}}e^{-32\varkappa}$.

The current remains an independent variable. First form the restricted pair by keeping $\mathbf{J}$ at the bonds whose incident plaquettes all remain inside the joined first member, and by using the current of the restricted action only on its free boundary. Then apply the fixed real gauge g_0 to both members of this pair. The defect above does not depend on $\mathbf{J}$. Thus its holomorphy imposes no equation $\mathbf{J} = J(\mathbf{U})$ in the interior. The response still requires this restricted and gauged pair to belong to its joined local class.

4.17.1.8. A target defined by the complex configuration. The tower transports give a choice of target that depends only on the complex configuration. The response can remain based at the original restricted pair.

On a wide collar Q_a of level j, write $\mathbf{W}_q = \mathcal{M}^q\mathbf{U}$. For a bare site x let x_q be its ancestor at level q, so that $x \in B^q(x_q)$, and put $y = x_j$. Define

$$g[\mathbf{U}](x) = \mathsf{T}_{\mathbf{U}}(y, x) := \mathbf{W}_{j-1}(y, x_{j-1})\mathbf{W}_{j-2}(x_{j-1}, x_{j-2})\cdots\mathbf{W}_0(x_1, x).$$

Set $g[\mathbf{U}] = 1$ off the collars and at their top sites; for $j = 0$ the product is empty. This is the supplied tower transport, using the averaged contour variables of the same averaging scheme. Its factors depend only on the configuration in $B^j(y)$. On their averaging domain they are holomorphic functions of $\mathbf{U}$ itself. At a real configuration U this is exactly the descending collar alignment g_0.

The tower estimate is uniform in its depth. In the local representation $\mathbf{U} = e^{i\eta_j A'}U$ used above, with $\|A'\|_\infty \le \alpha_1$, the supplied product formula writes

$$E(x) := g[\mathbf{U}](x)g_0(x)^{-1} = \prod_{q=0}^{j-1} e^{Z_q(x)}, \qquad \sum_q |Z_q(x)| \le z := 2\kappa_6 C''_{\mathrm{mav}}L^{-1}\alpha_1 \le \tfrac{1}{8}.$$

The order of the factors is the one in the tower product. Thus $|E^{\pm1}-1| \le e^z - 1 \le C_L\alpha_1$. The real matrices g_0 are unitary, so these bounds also give uniform bounds on $g[\mathbf{U}]$ and its inverse. Every full averaging carrier used here is included in the collar carrier, as in the preceding chart estimate.

Let

$$V_* = M_{\mathbf{B}^W}(\mathbf{U}|_W), \qquad T = V^W[\mathbf{U}], \qquad R[\mathbf{U}] = T^{g[\mathbf{U}]^{-1}}.$$

The last expression is just the action on the endpoints of the determining rows. Define the physical input at the original restricted pair by

$$b_{\mathrm{can}}(c) = \frac{1}{i}\log\bigl(R[\mathbf{U}](c)V_*(c)^{-1}\bigr).$$

This expression is holomorphic and has the same uniform size as the previous chart input. To check this, set $\widehat{V}_0 = V_*^{g_0}$. At a row c, its logarithm's argument equals

$$g_0(c_-)^{-1}\bigl[E(c_-)^{-1}T(c)E(c_+)\widehat{V}_0(c)^{-1}\bigr]g_0(c_-).$$

The preceding chart calculation bounds $T\widehat{V}_0^{-1} - 1$ by $C_L(\varepsilon_1+\alpha_1)$. The bounds on $E^{\pm1}$, together with the bounded matrix factors in that chart, give the same bound for the bracket minus one. On the fixed logarithm ball this proves

$$\|b_{\mathrm{can}}\|_\infty \le C_L(\varepsilon_1+\alpha_1), \qquad e^{ib_{\mathrm{can}}}V_* = R[\mathbf{U}].$$

At both endpoints of a common row the tower gauge is one, by the same collar geometry used for the real alignment. There $T = V_*$ and $b_{\mathrm{can}} = 0$. Its possible nonzero rows are therefore collar rows. Form $B'_{\mathrm{can}} = (b_{\mathrm{can}})_\natural$ at the original restricted pair. On a closed determining row set, the conversion is holomorphic and gives

$$\|B'_{\mathrm{can}}\|_\infty \le C_{\natural,\mathrm{s}}C_L(\varepsilon_1+\alpha_1).$$

At a collar row c of level $q < j$, let $y_\pm$ be the level-j ancestors of $c_\pm$. Its physical input is determined by the bare configuration in $B^j(y_-)\cup B^j(y_+)$: these are the two tower blocks, the lower averaging blocks lie inside them, and the face lift reads either one or their common top bond. Both blocks lie in Q_a. The converted input also reads the neighboring physical rows and the endpoint blocks specified by the conversion. For a localized term these complete carriers must lie in its admitted enlarged domain. The response is defined when the displayed norm fits its radius and the original restricted pair is admitted to the joined class. The response is evaluated directly at that pair.

This target also gives the required gauge transformation law. For a real gauge u, define $\bar{u}(x) = u(y)$ in a top block $B^j(y)$ of a collar and $\bar{u} = u$ elsewhere. Covariance of the averaged contour variables cancels the intermediate factors in the tower product and gives

$$g[\mathbf{U}^u] = \bar{u}\,g[\mathbf{U}]u^{-1}.$$

The face lift is one inside a top block and takes the value of one top bond across its face. Hence its target transforms by $T[\mathbf{U}^u] = T[\mathbf{U}]^{\bar{u}}$. The same identity holds on common rows, whose endpoints in a collar are top sites. Consequently

$$R[\mathbf{U}^u] = R[\mathbf{U}]^u, \qquad b_{\mathrm{can}}[\mathbf{U}^u] = \mathrm{Ad}(u)b_{\mathrm{can}}[\mathbf{U}].$$

Covariance of the conversion and of the response applies at the unchanged restricted pair, with every interior current entry still independent. The resulting response is thus a holomorphic function of the pair and is covariant for all admitted complex cube parameters. Its definition is identical in overlapping real factorizations, since every factor in the input is a function of $\mathbf{U}$ itself.

At a real center, $g[U] = g_0$ and $\widehat{V}_0 = e^{iB_1}V^W[U]$. It follows that

$$b_{\mathrm{can}}[U] = \mathrm{Ad}(g_0^{-1})(-B_1).$$

The converted inputs obey the same identity, with the conversion on each side taken at its own base pair. Real-gauge covariance of the response therefore identifies this response with the earlier aligned response, conjugated by g_0^{-1}. On a full read star outside the collars, $g_0 = 1$, so their

covariantly formed dressed reads agree in the same fixed frame. For other read frames the explicit frame factors are retained.

4.17.1.9. The rows and their complete carriers. Use the rows prescribed by the decoupled response theorem: the positively oriented interior and outward bonds of the joined determining set $(\mathbf{B}^{W})^{\flat}$. These rows form a closed set. Indeed, if a row of level q has outer endpoint z, every positive level-$(q-1)$ bond joining sites of $B(z)$ is an interior row of the joined set. These are exactly the lower rows required by the conversion $b \mapsto b_{\natural}$.

Let $\mathfrak{k}$ be an active wall-component of the parameter partition $\mathsf{P} = \pi[\mathsf{w}]$, and put $Y = \bigcup \mathfrak{k}$. Work in level-t units. Every collar top level satisfies $j \le t$, so its block has side $\xi_j = L^{j-t} \le 1 \le \mathsf{w}$. Both side lengths are powers of L on the same centered grids. The nesting of standard partitions has the following consequence: if a bare lattice site x lies in Y, then the entire level-j block containing x lies in Y. To see this, the site belongs to one parameter cube, since lattice sites do not lie on its boundary walls. That cube is a union of complete level-j blocks. Its unique such block containing x is therefore contained in it.

Write $\mathbb{Y}^{\circ}_{\mathfrak{k}}$ for the sites carried by the component's walk terms. The response uses its source only at rows at $N_L(\mathbb{Y}^{\circ}_{\mathfrak{k}})$. The conversion at such a row uses physical inputs only at rows at $N_L^2(\mathbb{Y}^{\circ}_{\mathfrak{k}})$. The endpoints of these rows belong to $N_L^3(\mathbb{Y}^{\circ}_{\mathfrak{k}})$: for an interior row the neighboring endpoint has an adjacent block; for an outward row this is the outer-end assertion $B(z) \subset N_L(y_c)$. The margin lemma places the blocks of all sites in $N_L^4(\mathbb{Y}^{\circ}_{\mathfrak{k}})$ in the interior of Y.

Consequently every endpoint just listed lies in Y, and the partition argument places its complete collar top block in Y. Thus every tower transport and every top average used by a required physical input is read inside Y. The lower averaging carriers and the endpoint-block carriers of the conversion are inside Y by the same argument. The complete canonical input carriers thus lie in the active component even when a top block is larger than the joined row's own scale.

The original collar geometry is retained in this argument. At a noncommon row, its two endpoints lie in the wide collar of one part, in the original layer j, and the complete ancestor blocks lie in that collar. The original and joined region traces therefore specify the common-row classification, this original level and the tower blocks used in the source. When these traces agree on Y, the canonical inputs read by the component agree there as well. The margin comparison for the response then applies. This uses the original traces in addition to the joined traces; the latter alone need not identify the collar top level.

4.17.1.10. The source radius. Let K_B denote the constant in the canonical input bound, including the conversion and the fixed changes of local units, so that

$$\|B'_{\mathrm{can}}\|_{\infty} \le K_B(\alpha_0 + \alpha_1).$$

Suppose that the joined pair has the fixed configuration radii required by the response theorem and current radius at most $K_J\alpha_0$. In the strip domain $\alpha_0 + \alpha_1 \le ce^{-C\varkappa}$, choose $C \ge 32$ and

$$0 < c < \min\left\{c_0, \frac{\varepsilon_{\mathrm{D,s}}}{2\max\{K_B, K_J, 1\}}\right\},$$

where c_0 is smaller than the averaging and physical logarithm ceilings used in the canonical construction. Then both the converted source and the current radius are smaller than $\frac{1}{2}\varepsilon_{\mathrm{D,s}}e^{-32\varkappa}$. The constants are chosen after the geometric scales and before the final small-coupling threshold, as in the strip domain. Both radii enter the boundary size. Taking the infimum over the admissible radii gives

$$\|B'_{\mathrm{can}}\|_{\infty} \le K_B\mathfrak{n}_W(P).$$

The input has no cube-parameter dependence. Its radius and carrier bounds consequently hold throughout the parameter polydisc of the response theorem.

4.17.1.11. The retained current and the free boundary. The joined sequence is finer than the original sequence. At a site where its layer is q and the original layer is j, one has $q \le j$ and $\xi_q \le \xi_j$. Consequently the original pointwise bounds on curvature, the complex potential and its covariant difference, and the independent current imply the corresponding joined pointwise bounds at every retained stencil. This assertion concerns the pointwise clauses; local gauges are a separate clause of the pair class.

At a free-boundary bond replace the current by the first variation of the restricted plaquette action, as prescribed above. For any set of retained plaquettes the supplied first-variation formula is

$$J^\flat(\mathbf{U}) = D_{\mathbf{U}}^{\mathsf{T}} F_{\mathbf{U}}, \qquad F_{\mathbf{U}}(p) = \frac{\partial \mathbf{U}(p) - \partial \mathbf{U}(p)^{-1}}{2i\xi^2}.$$

Each bond receives at most six plaquette contributions. The scaled curvature bound implies $|F_{\mathbf{U}}(p)| \le C\alpha_0 \xi^{-2}$, and the one-bond transports in $D_{\mathbf{U}}^{\mathsf{T}}$ are uniformly bounded by the complex-potential ceiling. It follows that $|J^\flat(\mathbf{U})(b)| \le C\alpha_0 \xi^{-3}$. A free-boundary bond has a missing incident plaquette within two bare spacings. Separation of the first two joined regions therefore places its initial site in joined layer zero. Since $\xi_0 = \xi$, the bound reads

$$\xi_0^3 |J^\flat(\mathbf{U})(b)| \le C\alpha_0.$$

Together with the retained-current bound this gives the strip current radius used above.

4.17.1.12. The local gauges on the joined cubes. For a triple in the structured domain on the full carrier, the pointwise and good-gauge clauses in §2.2.4.1 give the original enlarged local class. Restricting to the active parameter union keeps the same splitting and all the inner stencils. The gauges of the joined class are then obtained from the original gauges. We use the enlarged class $\mathfrak{P}_t^\natural$, whose gauge cubes of index q are all the cubes of side at most $12\mathfrak{M}\xi_q$ that are unions of $\mathfrak{M}$-cubes at that level and lie in $\mathcal{L}_q \cup \mathcal{L}_{q+1}$. Such a cube need not meet $\mathcal{L}_q$.

First recall the supplied truncation argument. Removing the last member from a separated sequence carries $\mathfrak{P}_{k+1}^\natural$ into $\mathfrak{P}_k^\natural$ with the same radii and the same decomposition $\mathbf{U} = e^{i\xi A'} U$. All scaled inequalities can be read in the same original units throughout. For the gauge clause, only a cube q of index $k-1$ which meets the former last region Ω_{k+1} needs attention. Its side satisfies

$$s(\mathsf{q}) \le 12\mathfrak{M}\xi_{k-1} < \mathfrak{M}\xi_k.$$

Cover it by a cube q' of side $2\mathfrak{M}\xi_k$, made of 2^4 cubes at scale $\mathfrak{M}\xi_k$. If $x \in \mathsf{q} \cap \Omega_{k+1}$, every point of q' is within $2\mathfrak{M}\xi_k$ of x. Separation therefore puts q' in $\Omega_k = \mathcal{L}_k \cup \mathcal{L}_{k+1}$. The original gauge clause at q' gives the gauge on q, with

$$\xi_{k-1}|A| \le L^{-1} a_0, \qquad \xi_{k-1}^2 |\nabla^\xi A| \le L^{-2} a_0,$$

where a_0 is its original gauge radius. Thus no loss accumulates under successive truncations.

The same argument applies to the local class on an active union Y of parameter cubes. Here it is necessary to choose q' inside Y. This is possible on the actual nested grids. Put $m = \mathfrak{M}\xi_k$; then m divides w and $\mathsf{w} \ge 2m$. The parameter cubes whose interiors meet q form a rectangular block of cubes, all belonging to Y. In each coordinate the interval of q, whose length is less than m, meets at most two m-grid intervals. If it meets only one, include an adjacent interval within that rectangular block. The block has at least two such intervals in every coordinate. The product of the chosen two-interval unions is the required cube $\mathsf{q}' \subset Y$. It still has side $2m$, so the separation argument is unchanged. The original local gauge clause is therefore applicable to q'.

Now let $\widetilde{\mathsf{q}}$ be any gauge cube of index q for the joined sequence, contained in Y. Fineness gives

$$\widetilde{\mathsf{q}} \subset \mathcal{L}_q^W \cup \mathcal{L}_{q+1}^W \subset \Omega_q^W \subset \Omega_q.$$

Truncate the original sequence at q. In that sequence Ω_q is the last layer, so $\widetilde{\mathsf{q}}$ is one of its gauge cubes of index q. The preceding local truncation argument supplies a real gauge on a cube containing $\widetilde{\mathsf{q}}$, with $\xi_q|A|, \xi_q^2|\nabla^\xi A| \le a_0$. Restrict this gauge to $\widetilde{\mathsf{q}}$ itself. This is an allowed choice of

the cube in the joined gauge clause; it lies in $\Omega_0^W \cap Y$, and every derivative stencil retained there is unchanged. Thus the joined local-gauge clause holds with the original radius.

Together with the pointwise and free-boundary-current estimates above, this proves joined-pair admission from the original enlarged local class on $\Omega_0 \cap Y$. The argument uses the actual standard parameter cubes and the original local-class decomposition. It does not require a holomorphic choice of the real local gauges.

4.17.1.13. Localization with the bond read fixed. Suppose the strip datum $B'[P]$ has been supplied on the joined rows, holomorphically on the required pair domain, with $\|B'[P]\|_\infty \le \beta < \varepsilon_{\mathrm{D,s}} e^{-32\varkappa}$. Its values are fixed while the cube parameters are varied. Include the full local masks of this datum in its carriers, and let $\mathfrak{B}$ be the cubes carrying its possible nonzero rows. Thus these are boundary cubes, with the prescribed fixed enlargement when the row conversion uses an endpoint block. Use the admitted joined pair throughout.

Let N_b be a wall-connected set of parameter cubes, where adjacency means sharing a face. Include enough local margin that the full averaging and frame read at b, with every read stencil, lies in the interior of its union. Hold the parameters on N_b at one and vary those on $S = \mathsf{P} \setminus N_b$. Write

$$F_b(s; P) = \mathsf{Rd}_b(P; \mathbf{H}(s; B'[P])), \qquad R = e^{\varkappa}.$$

Here the read vanishes at zero response and is holomorphic on the response ball. If its bound in the local response norm is C_{rd}, the response estimate gives

$$\sup_{|s_\Delta|<R} |F_b(s; P)| \le A, \qquad A = C_{\mathrm{rd}} C_{\mathrm{D,s}} e^{16\varkappa} \beta.$$

All suprema below use the same admitted pair domain.

For $K \subset S$ define the mixed difference

$$H_b[K; P] = \sum_{A_0 \subset K} (-1)^{|K|-|A_0|} F_b(\mathbf{1}_{A_0}; P).$$

The fixed parameters on N_b are understood in every summand. Finite Möbius inversion gives $F_b(\mathbf{1}_S; P) = \sum_{K \subset S} H_b[K; P]$. The response restricted to a wall component uses only the pair and datum in that component. Since N_b is wall-connected, the read uses its one component. If $K \cup N_b$ has another component, pair the terms in the mixed difference by switching one cube of that component; they cancel. If the component of N_b meets no cube of $\mathfrak{B}$, its datum is zero and its response is zero. Therefore

$$H_b[K; P] = 0 \quad \text{unless } K \cup N_b \text{ is wall-connected and meets } \mathfrak{B}.$$

This reasoning uses the full component locality of the response, not just decay of its kernel.

For $1 < r < R$, the exact Cauchy formula for the difference is

$$H_b[K; P] = \frac{1}{(2\pi i)^{|K|}} \int_{|z_\Delta|=r,\, \Delta \in K} F_b(z_K, 0_{S\setminus K}; P) \prod_{\Delta \in K} \frac{dz_\Delta}{z_\Delta(z_\Delta - 1)}.$$

For $K = \emptyset$ this means $H_b[\emptyset; P] = F_b(0; P)$. Taking $r \uparrow R$ gives

$$\|H_b[K]\| \le A(R-1)^{-|K|}.$$

Each parameter is differenced once, so there is no factorial. The norm here is a supremum before summation.

Let W_K contain $K \cup N_b$ and all its local read and datum masks. Use a fixed bounded enlargement, and write $\ell(W)$ for the tree length on the output cube grid. Keep the geometric comparison explicit:

$$\ell(W_K) \le c_h(|K| + n_b), \qquad n_b = |N_b|.$$

The constant c_h includes the change between the parameter grid and the output grid. The rooted cube count gives constants C_b, c_{e}, independent of the torus and the number of levels, such that at

most $C_b e^{c_{\mathrm{e}} n}$ wall-connected sets $K \cup N_b$ have $|K| = n$. Here C_b depends on the bounded read star. Put

$$n_* := \min\{|K| : K \cup N_b \text{ is wall-connected and meets } \mathfrak{B}\}, \qquad q_a := \frac{e^{c_{\mathrm{e}} + a c_h}}{R-1}.$$

If no such set exists, all terms vanish. Otherwise, for $q_a < 1$,

$$\sum_K e^{a\ell(W_K)} \|H_b[K]\| \le A C_b e^{a c_h n_b} \frac{q_a^{n_*}}{1-q_a}.$$

Group the terms having the same W_K. Their sum depends only on the fields in W_K and retains the boundary cube and the whole read star. On each local pair domain where the component equations and the supplied datum have been admitted with the same bounds, this sum is holomorphic and obeys the same absolute estimate. Locality alone would not extend a bound to local data outside those domains. Reality and covariance of the datum, response and read pass through the mixed differences.

For $\varkappa \ge 1$, one may use $\log(R-1) \ge \varkappa - 1$. For example, when $\varkappa > 1 + c_{\mathrm{e}}$, the choice $a = (\varkappa - 1 - c_{\mathrm{e}})/(2c_h)$ gives $q_a \le e^{-(\varkappa - 1 - c_{\mathrm{e}})/2}$. The strip margin supplies the lower bound on n_*; it must be measured after the read and datum masks have been included. The factor $e^{16\varkappa}$ in A and the fixed read-star cost remain in the displayed estimate and can then be absorbed by that margin. If the parameter partition is the level-t M-cube partition, the response floor is $\mathring{\delta}_0 M \ge 4352\varkappa$, in addition to its other size conditions. Choosing $\varkappa$ proportional to $\mathring{\delta}_0 M$ within this floor gives a tree rate of that order. This final choice does not supply the missing holomorphic datum or its norm bound.

4.17.1.14. The background of an approximate test on the cutoff zone. Let b be a bond of the cutoff zone that occurs in the approximate test of $\square'$. Use bare length units and set $w = M_2 \check{R}_t L^t$, so that the test cubes have side Lw and each of their enlargement layers has width w. By the definition of the cutoff zone, an endpoint of b is within $2w + L^j$ of a test cube in R. Since b is tested at $\square'$, every point of $C = \square'^{\sim 4}$ is within $(L+8)w + 2L^j$ of R. The region R lies inside the one-cell inset of Ω_t. The one-cell enlargement of its hull lies in Z_t. The side of a level-t cell is $M\check{R}_t L^t$. Choose the fixed M with enough room that the preceding distance leaves at least four M_1-layers in both of these margins. For $t \ge 2$ also use the one-cell margin of Ω_t inside Λ_j. This is a margin in level-j cells, with side $M\check{R}_j L^j$. The cube sizes at these consecutive levels are comparable, so the same fixed choice of M leaves room in this margin. For $t = 1$ only the part Z_1 is used. Thus C lies in the top layer of the joined strip sequence.

In that top layer C is a one-part collared region at level t, with collar width M_1 and the full first member. Its joined sequence is the tower of C, since all the members of the strip sequence contain C. The top rows on C carry the prescribed V_t. The new collar rows are formed by the same lifts of those top rows as in the definition of the test background. This identifies the joined datum with the datum of $U_{t,\square'}$. In particular its regular orbit is defined when the strip datum belongs to the real comparison class.

The test reads b inside $\square'^{\sim 3}$, where its endpoint contour blocks are wholly in the top layer of the tower. In both sequences their centres are nodes and the other level-j sites of these blocks are free. The block axial frames therefore fix the same sites in the comparison. The read carriers have distance at least $w - CL^t$ from C^c, which exceeds $3M_1 L^t$. The top spacing in bare units is L^t. Apply the real collar estimate eq. 3.cdii and the endpoint calculation for the strip shift to the strip background and its localization to C. It follows that

$$\varphi(V_j^{\mathrm{loc}}(b) V_{j,\square'}^{\mathrm{bg}}(b)^{-1}) \le C\varepsilon_1 e^{-cM_2 \check{R}_t},$$

with ε_1 the real test radius of the joined strip datum. On the strip support it is bounded by $C_L \varepsilon_j$. The fixed scale floors and then the coupling ceiling give a bound $\delta_j/8$ for this angle. Use also $|H| \le \delta_j/8$ for the strip shift. Where $\vartheta_{\mathrm{co}} < 1$, the angles of both $V_j(b) V_{j,\square'}^{\mathrm{bg}}(b)^{-1}$ and $W' V_j^{\mathrm{loc}}(b) V_{j,\square'}^{\mathrm{bg}}(b)^{-1}$

are at most $(5/3 + 1/8 + 1/8)\delta_j < 2\delta_j$. Their group distances from one are no larger than their angles. Where $\vartheta_{\mathrm{co}} = 1$ the two products coincide. Hence on the cutoff zone the approximate bond factor can be written through W' and the two localized backgrounds on this support.

What is frozen and what is integrated. On Ω^c_{j+1}, step $j+1$ stores V_j together with its constraint. On Ω_{j+1} the action is expanded around $U_{j+1}(\mathbf{V})$. The only variable integrated there is $A = \mathcal{A}^{\mathrm{s}}_j|_{\Lambda_{j+1}}$, conditionally on the stored field $A' = \mathcal{A}^{\mathrm{s}}_j|_{\Omega_{j+1}\setminus\Lambda_{j+1}}$. The measure is Gaussian with covariance $C^{(j)}(\Lambda_{j+1})$, which is the inverse of the restriction of the form $\Delta^{(j)}$ to the bonds of Λ_{j+1}, and its linear term is $-\langle A, \Delta^{(j)} A'\rangle$. The coupling flows only where this integration is carried out, $\varphi_{j+1} \in C^\infty_0(\Lambda_{j+1})$, and it stops on the whole of Z_{j+1}, including $\Omega_{j+1} \setminus \Lambda_{j+1}$. Once the square is completed, the conditional weight appears as a factor inside $\mathbf{T}_k(Z) = \prod_{j<k} \mathbf{T}^{(j)}$, with the regions cut by the component Z ((2.21), (3.23) there; this operation is the product shown for a component on which $\mathbf{R}$ has never acted, and in general the operation is defined by a recursion over the marks):

$$\mathbf{T}^{(j)} = \int dV_j\big|_{\Omega^c_{j+1}} \delta(\mathcal{M}(V_j)V_{j+1}^{-1})\, \mathfrak{G}_j\, \chi\chi^c\, z^{(j)} \int dA'\, \chi\chi^c\, e^{-\frac12\langle A', [\Delta^{(j)} - \Delta^{(j)} C^{(j)}(\Lambda_{j+1})\Delta^{(j)}]A'\rangle}.$$

This operation contains no Wilson weight. That weight belongs to $\exp A_{k,\mathcal{S}}$, the function on which the operation acts; $z^{(j)}$ is explained below. The old R-terms, $\mathbf{R}'_j = \sum_{i\le j_1} \mathbf{R}^{(i)}$, appear alongside $\mathbf{E}_j$ in the regular action $\widetilde{\mathbf{E}}_j$ of the step §4.17.1.45. Here $\mathbf{R}^{(i)} = \sum_X [R^{(i)}(X,\cdot) - R^{(i)}(X,\mathbf{1})]$ is the summand of level i of $\mathbf{R}_j$, and j_1 is the index k_1 of § 4.17 at level j. The young ones, $\mathbf{R}''_j = \sum_{j_1<i\le j} \mathbf{R}^{(i)}$, are handled separately. Put $\delta F := F(U_j) - F(U_{j+1})$. Attach a parameter t to the terms present only next to Z_j, and a parameter s to $\mathbf{R}''_j$ ((3.23)–(3.28) and pp. 270–271 there). Let $z^{(j)} = \prod_c z^{(j)}(c)$ be the factors that come from eliminating the delta functions. In $\mathbf{T}^{(j)}$ their product runs over those coarse bonds c of Ω_{j+1} that lie outside Λ_{j+1}; under the logarithm it runs over those of Λ_{j+1}. Then

$$\log\Big[z^{(j)}\int dA\, \chi^{(j)} e^{-\frac12\langle A,\Delta^{(j)}A\rangle - \langle A,\Delta^{(j)}A'\rangle + \cdots}\Big] - \tfrac12\langle A', \Delta^{(j)} C^{(j)}(\Lambda_{j+1})\Delta^{(j)} A'\rangle$$

$$= \int_0^1 dt\, \langle \delta\mathbf{B}_j - \delta A(x_j(\cdot) - x_j, \cdot) + \cdots\rangle_{s=1,t} + \int_0^1 ds\, \langle \delta\mathbf{R}''_j\rangle_{s,t=0} + \Big(\log[\cdots] - \tfrac12\langle A', \Delta^{(j)} C^{(j)}(\Lambda_{j+1})\Delta^{(j)} A'\rangle\Big)_{s=t=0}.$$

In this identity $\langle\,\cdot\,\rangle_{s,t}$ denotes the normalised mean with respect to the measure that the parameters s, t interpolate. The left-hand side is the unnormalised integral. Its second term is present since the square, once completed, was moved into $\mathbf{T}^{(j)}$. Inside the integral over t, the dots stand for two kinds of terms. Those of the first kind are the terms of the strip, namely the Jacobians together with the differences of all quantities that depend on a shifted variable. Those of the second kind are the differences, taken between the two backgrounds, of the exponents of the integral operations carried by the term. The coupling difference carries the sign it has in $A_{j,\mathcal{S}} = -x_j A - A(x_j(\cdot) - x_j, \cdot) + \ldots$. A cluster expansion as in § 4.5 is applied to each part. The Gaussian normaliser is contained in the last part; it is that part of $E^{(j+1)}$ which carries b^0_{j+1}. On a label it is a determinant: that of a multi-scale operator, compressed to Λ_{j+1} and taken in the background of that label; so by definition it is non-local. It is converted into local terms,

$$\sum_c \log z^{(j)}(c) - \tfrac12 \log\det\big(\mathsf{C}^{\mathsf{T}}\Delta^{(j)}\mathsf{C}\big|_{\Lambda_{j+1}}\big) = \text{number} + \sum_X \mathbf{N}(X, U_{j+1}),$$

$$|\mathbf{N}(X)| \le C e^{-cM d_{j+1}(X)},$$

which Bałaban does by means of a resolvent integral and walks § 4.5, whereas here it is done by sums with alternating signs, taken over the sub-regions $Y \subset X$, whose terms are the diagonal entries of the logarithm of the operator built on Y. Möbius inversion yields the sum rule, and the

decay is due to a sign-reversing involution, which cancels everything except the chains of walks that visit all of X. Only the last two parts give terms with domain $X \subset \Lambda_{j+1}$. These terms are built from walks and fields inside X, so the regions do not affect them. They are of two kinds. The first is $R^{(j+1)}$; it arises from the part with s, to which what $\mathbf{R}$ leaves is added § 4.17. The second is $E^{(j+1)}$, which comes from the last part, where $\mathbf{E}_j$ stands with the old R-terms. These terms are the same for every label. For the regular terms this holds for every such X. For the remainders it holds for X one cell inside Λ_{j+1}, the only place where a label shows them, and this is the margin of §4.17.1.45. Thus the young R-terms go into $R^{(j+1)}$, and the old ones go into $E^{(j+1)}$ and b_{j+1} (2d, 2e). Everything else makes up $B^{(j+1)}$; among it is the part of the quadratic form that is rejected (next paragraph). It amounts to $O(1)$ for each M-cube of level $j+1$ next to Z_{j+1}; this cost is covered by §4.17.1.40, and for that reason no renormalisation of it is required.

What a one-step operation keeps. The conditional form is a Schur complement on the free coordinates. In the following display the factors of $\Delta^{(j)}$ act as its free-coordinate precision $\mathsf{C}^{\mathsf{T}}\Delta^{(j)}\mathsf{C}$. A chain is either a precision walk or a product of a precision walk, a walk of the inverse of the integrated compression, and a precision walk. These chains have connected carriers. A chain is kept if the cells of level $j+1$ that it meets intersect $\Omega_{j+1} \cap Z_{j+1}$ in a non-empty connected set and remain within one layer of that set; a kept chain is then counted with the component $\mathfrak{k}$ of $\Omega_{j+1} \cap Z_{j+1}$ that contains this set:

$$\langle A', [\Delta^{(j)} - \Delta^{(j)} C^{(j)}(\Lambda_{j+1}) \Delta^{(j)}] A' \rangle = \sum_{\mathfrak{k}} \langle A', \Delta^{\mathrm{loc}}_{\mathfrak{k}} A' \rangle - 2 \sum_{X} \mathsf{B}^{\times}(X),$$

$$|\mathsf{B}^{\times}(X)| \le C p_0(g_j)^2 e^{-cM\check{R}_{j+1}} e^{-\kappa d_{j+1}(X)},$$

$$\langle A', \Delta^{\mathrm{loc}}_{\mathfrak{k}} A' \rangle \ge c \sum_{b \text{ in } \mathfrak{k}} |A'(b)|^2 :$$

(the bound on $\mathsf{B}^{\times}$ is for stored fields in range, $|A'(b)| \le C p_0(g_j)$, which they are on the support of the kept tests) a rejected chain has length at least a fixed multiple of the cell side in fluctuation units, up to a fixed additive constant, and the size $p_0(g_j)^2$ of the stored field squared is outweighed by $e^{-cM\check{R}_{j+1}}$. The rule of Bałaban, by which the form "couples only the fields A_j in the same component" (119, p. 258), fails to be local: whether two bonds belong to a common component is settled at a distance from them, and two histories having the same trace can differ on it. The kept form is not a Schur complement but a truncated series. Its lower bound is therefore not inherited and has to be proved. The proof localises to small cubes (Ismagilov–Morgan–Simon) and compares with a genuine Schur complement. *Carriage*: in an integral operation that a term carries, the tests, the gauge factors and the delta functions depend on no background, whereas the forms $\Delta^{\mathrm{loc}}_{\mathfrak{k}}$ and the factors $z^{(j)}$ do. These forms and factors are given as functions of a pair $(\mathbf{U}, \mathbf{J})$ near $\mathfrak{k}$, and they are constructed once and for all. They are evaluated at the current background, which in a term of level k is $U_k(\mathbf{V})$. The background changes with every later step and with every stage of $\mathbf{R}$. Each change produces differences

$$-\tfrac{1}{2} \langle A', [\Delta^{\mathrm{loc}}_{\mathfrak{k}}(U^{\sharp}) - \Delta^{\mathrm{loc}}_{\mathfrak{k}}(U^{\flat})] A' \rangle$$

, where $U^{\flat}$ is the background after the move and $U^{\sharp}$ the one before it, both written in the new variables. Localisation turns these differences into boundary terms. For a piece of a kept form whose carrier is R, the oscillation with respect to the pair is bounded by $C p_0(g_j)^2 e^{-\kappa d^{\flat}_{j+1}(R)}$, measured in the hull length of the carrier; this bound is large, being the square of a field at its threshold. The difference of such a piece at the two backgrounds of a stage of level i is localised as well, and each

of its localised pieces, on a domain Y, has modulus at most $C(\log x_i)^{-(q-3\mathfrak{p}_0-Cr)}e^{-c\,d_k^{\natural}(Y)}$. This is a negative power, because q is chosen after $\mathfrak{p}_0$ and r, with $q > 3\mathfrak{p}_0 + Cr$.

4.17.1.15. The comparison at an admitted real reference. Fix the step and use level-j units. Let A be the complete free-variable precision of the step after eliminating the pivot bonds, including the projected gauge and current terms. The free-variable space is the space on the nonpivot bonds meeting Ω_{j+1}. The integration set I consists of the free bonds meeting Λ_{j+1}. Equivalently it is the set of free bonds meeting the blocks of the level-$(j+1)$ sites in Λ_{j+1}. The stored set E is its complement among the free bonds of the step. In particular a free bond with one end in the integration region is assigned to I.

Take a real reference in the admitted class of the fluctuation theorem, on the entire determining sequence, with these conditioning sets. The complete precision has a lower bound $\gamma\,\mathrm{Id}$ there, with $\gamma > 0$ fixed. The Schur complement

$$S = \mathsf{A}_{EE} - \mathsf{A}_{EI}(\mathsf{A}_{II})^{-1}\mathsf{A}_{IE}$$

then satisfies $S \geq \gamma\,\mathrm{Id}$. Indeed, its quadratic form is the minimum of the full quadratic form over the integrated coordinates with the stored coordinates fixed. For a stored component D the compression of S to its free bonds therefore has the same bound. When the integration set is empty the second term of S is zero.

We can also control the difference between this compression and the chain sum assigned to D. For the precision and for the covariance $(\mathsf{A}_{II})^{-1}$, the absolute sum of the length-m walk kernels is bounded entrywise by

$$C\,2^{-m-1}e^{-\delta|b_- - b'_-|_1}.$$

Their absolute row and column sums are at most $C'2^{-m-1}$, since the endpoints range over the unit lattice in these units. For the three factors of a Schur chain, sum first over the internal bond indices. The resulting row and column bounds are at most the products of the three bounds. At total length n the number of choices of the three lengths is $(n+1)(n+2)/2$. The tails above length r thus have absolute row and column sums at most $C''e^{-cr}$. The same bound for a single precision walk follows directly from its length estimate.

Each walk cell has a carrier of bounded diameter in these units, with a bound fixed by the walk construction. The carrier of a nonzero chain of total length n has diameter at most $C_{\mathrm{cell}}(n+3)$, since successive carriers meet at their common bond. Let W be the side of a level-$(j+1)$ large-field cell, measured in level-j units. Use the closed cells for the retention test, with a common corner counting as contact. Disjoint closed cells of this grid are at sup distance at least W. Thus if the carrier has sup diameter less than W, all the cells it meets touch one another. A chain contributing to the compression on D meets D, since its carrier contains both endpoints of each of its exterior bonds. The cells it meets in the stored strip then form a connected nonempty set in D, and the other cells it meets are at most one touching layer away. Such a chain is retained for D. Thus every omitted term in this compression belongs to the length tail $n \geq W/C_{\mathrm{cell}} - 3$. The tail estimate and the matrix Schur test give

$$\|\Delta_D^{\mathrm{loc}} - S|_D\|_{2\to 2} \leq Ce^{-cW/C_{\mathrm{cell}}}. \tag{4.cdxlii}$$

When this error is at most $\gamma/2$, the kept form at this reference is bounded below by $(\gamma/2)\,\mathrm{Id}$. This argument applies in the full real reference class and on the literal integration and stored coordinate sets just described.

To use this bound when the pair is given only near the stored component, we must compare on small cubes with admissible real references on which the same short chain terms are defined. Such a comparison must match the region traces, the integrated free bonds, and the real pair on the carriers, in a common frame for the retained coordinates. The walk locality identities then match the short terms. The estimate eq. 4.cdxlii controls length tails in an admitted comparison. If K is

the kept matrix in the retained coordinates and $\sum_\nu \chi_\nu^2 = 1$, the kernel of $K - \sum_\nu \chi_\nu K \chi_\nu$ is

$$\tfrac{1}{2} K(b,b') \sum_\nu (\chi_\nu(b) - \chi_\nu(b'))^2.$$

For cutoffs of bounded overlap varying on length h, the factor multiplying $K(b,b')$ is at most $Ch^{-2} d(b,b')^2$. The exponential kernel bounds give uniform row and column sums with this second distance moment. The matrix Schur test bounds the error by Ch^{-2}. Thus patch lower bounds with a fixed margin give the complete lower bound once the comparisons on the actual localized histories have been constructed in the same coordinates.

4.17.1.16. Comparison in complex coordinates. The precision and inverse walk terms are holomorphic in the background and current restricted to their carriers, on the piecewise local classes of the fluctuation expansion. Two realizations give the same coefficient for a decorated walk with the same cell families and parent map if the region and fluctuation-structure traces agree on its common padded hull $[\![\omega]\!]$, at every level. Match the actual free-coordinate and conditioning masks on all their reads in that hull. The first-member trace then gives the same field carrier $[\omega] = [\![\omega]\!] \cap \Omega_0$. The pair on this carrier must be the same, in the same coordinates, and belong to both local classes. This applies factor by factor to a Schur chain.

Suppose the actual later read and its comparison are expressed in one chart about a coercive real reference. Normalize the chart to radius 1 in the background and current norms. If every carrier restriction belongs to its local class throughout the chart and the absolute walk sums obey the uniform row and column bounds with summable length tails there, the kept matrix $Q(z)$ is holomorphic and uniformly bounded in operator norm. Cauchy's estimate along the radial line to z then gives $\|Q(z) - Q(0)\|_{2\to 2} \le C\theta$ for $\|z\| \le \theta \le \frac{1}{2}$. If $Q(0) \ge c\,\mathrm{Id}$, it follows that $\mathrm{Re}(a^{\mathsf{T}} Q(z) a) \ge (c - C\theta)\|a\|_2^2$ on the real retained coordinates. For the localized histories we must construct the real comparisons in these coordinates and verify the common chart with a uniform fraction of the available radius for the prepared and substituted data, including the independent current. The existence of each coefficient on its open carrier class alone does not give that fraction.

4.17.1.17. A real comparison by cutting off the potential. Keep the separated determining sequence of the step which formed the strip, including its original free-coordinate set and its integration mask. Work in level-j units. On an enlarged comparison cube about a retained bond suppose there is a real gauge in which the background is $e^{i\eta_j A}$, with $|A|$ and $|\nabla^{\eta_j} A|$ at most a, and with the transported independent real current bounded by a in absolute norm in level-j units. Take the cube and its whole stencil collar strictly inside Ω_j, so that only layers $j, j+1$ occur there in the forming sequence. The retained form and its comparison must use the same pivots and the background-relative contour quadratic term of the fluctuation operator. In that prescription the real gauge acts on free coordinates by the adjoint at the initial endpoint, an orthogonal change in the counting pairing.

Choose a real cutoff χ equal to one on the middle cube and zero in a neighborhood of the outer boundary, with first difference bounded by C/h for a cube of side $O(h)$. Extend χA and χJ by zero in this gauge on the whole original torus. The first difference of χA is at most $Ca(1 + h^{-1})$. In a plaquette product the linear sum of its bond logarithms is η_j^2 times the discrete curl of χA, so its norm is bounded by $C\eta_j^2 a(1 + h^{-1})$. The product remainder is bounded by $C\eta_j^2 a^2$. Thus the real reference $(e^{i\eta_j \chi A}, \chi J)$ has plaquette defects at most $C\eta_j^2(a + a^2)$, including at the cutoff. It has a single small logarithm on the torus. The scaled potential and its first difference cost at most a further factor L^2 on the adjacent upper layer. The independent current costs at most L^3 there. Outside the collar the reference is flat with zero current. Choosing a small after the comparison width makes this pair satisfy the real curvature, gauge and current conditions of the fluctuation theorem on the original geometry. The current can be cut independently because that theorem takes a real current as a separate argument.

Extend the local site gauge arbitrarily on the torus and transform the reference back. The real pair conditions are invariant under this gauge action, so the reference is still admitted and agrees with the actual read on the middle cube in its original frame. The global reference uses the same region traces and conditioning masks there. Every chain whose endpoints are tested in the inner cube and whose length is less than its buffer to the middle boundary divided by C_{cell}, up to the fixed additive constant, has its carrier in the common region. Its terms agree by carrier locality. On the local read the absolute walk estimates must hold on all carriers of the kept form, including the long ones. With these estimates the remaining length tails in both forms have operator norm at most $C\exp(-ch/C_{\mathrm{cell}})$. Choose h to make these errors and the partition error smaller than the fixed reference gap, with the cutoff support fitting inside the original collar. Thus this cutoff supplies a positive real comparison on the patch once its gauge, mask and current conditions hold. The partition estimate above combines such comparisons with constants uniform in the depth. For a later read, the two-layer bounds must be verified in the forming sequence and in its retained frames, including the enlarged cubes about the external bonds. These comparisons use the reference-weighted form. A change in the ratio of physical and reference weights uses the gauge compensation in eq. 4.d.

4.17.1.18. Reading a retained strip in its original domain. Let D be a component of $\Omega_t \cap Z_t$ as formed by step $t = j + 1$. A later record retains this strip only if no intervening healing, island operation or re-made level of a drop-out has replaced its field. Write $D^{\sim}$ and $D^{\oplus}$ for its one- and two-cell enlargements on the level-t partition. For a retained strip the trace on $D^{\oplus}$ is unchanged in the following sense. The level-t region is the one formed by step t and the regions of levels $1, \dots, t-1$ contain $D^{\oplus}$. This applies to the determining and action readings of level t, with every stage index. The local structure has no radius lift there and uses only the indices $t-1, t$. The retained factors use the pivots, integration mask, and gauge of step t. A factor of the quadratic form reads the field $\mathcal{A}^{\mathrm{s}}_{t-1}$ in these same coordinates. The associated elimination factor depends only on the background.

Take $P = (U, A', \mathbf{J})$ in the structured space of the level-t reading on an address containing the full carriers of the read. Use the pointwise and gauge clauses of §2.2.4.1, including layer zero at the first strip. At its formation this is the reading on either side of the step-t operation that retains the strip. For a later label use the level-t reading for the retained factor on its original carrier. Use the larger of the running radii at $t-1$ and t for each quantity and set $\bar{a}_i$ to their uniform upper bounds over the chosen coupling range, for $i = 0, 1, 2$. The third radius is for the independent current. The pointwise bounds on curvature, potential and current in these two layers cost at most $L^3(1 + \beta_{\mathrm{s}})\bar{a}_i$ in the fixed strip domain. Indeed the pointwise clause of the layered triple assigns a bond, plaquette or difference by its base point. The strip domain may assign it by another of its sites. Consecutive boundaries are separated by more than the diameter of such a stencil, so the two local spacings differ by at most L. The largest power in these norms is the third, for the current.

In level-$(t-1)$ units the level-t cells have side $LM\check{R}_t$. The gauges required in the strip domain are those on the cubes of the walk expansion, of width of order M_1 in their local units, and on the enlarged tiny cubes, of width of order M/L^2 in level-$(t-1)$ units. The latter are required at the endpoints of the external bonds as well as of the integration bonds. A required cube contained in the upper region fits in a gauge cube of width of order M in level-t units inside the upper trace. One can place the containing cube within the block intervals met by its coordinate projections. For a required cube reaching the lower side of the boundary, the containing cube has width of order M in level-$(t-1)$ units. Its collar lies in $D^{\oplus}$ and hence in the level-$(t-1)$ region. The stipulated hierarchy of the walk and cell widths gives room for both choices. These are cubes of the gauge clause of the layered triple, whose bound for $U = e^{i\eta A}$ in that gauge is $\xi_n|A|, \xi_n^2|\nabla A| \le CM\bar{a}_0$. Converting the gauge estimate to the other layer costs at most L^2. At $t = 1$ the level-zero lattice has unit spacing in these units. Axial transport in its local cube gives $|A| \le C\,\mathrm{side}\,\bar{a}_0$ from the plaquette bound, and the unit-spacing first difference is bounded by twice the potential bound.

Choose the fixed radii a_i^{loc} inside the positive strip class $\mathcal{O}^+$ of the original kept operator. Its gauge radius includes the fixed small radius of the walk cubes. The remaining contributions to the radii tend to zero with the coupling ceiling. It suffices to impose

$$L^3(1+\beta_{\mathrm{s}})\bar{a}_i < a_i^{\mathrm{loc}} \quad (0 \le i \le 2), \qquad CL^2M\bar{a}_0 < a_0^{\mathrm{loc}}.$$

For an external elimination bond also require the small averaging chart on its full read set. The two-layer potential and gauge bounds give a chart size $C(L,M)(\bar{a}_0+\bar{a}_1)$ in the upper units, so the separate condition is $4C(L,M)(\bar{a}_0+\bar{a}_1) < r_{\mathrm{P}}(L)$, the pivot chart radius. The floors on M, including that required by the decay rate of the kept chains, precede the choice of these coupling ceilings.

These checks admit the read to the fixed domain of the original kept operator and of its elimination factors. On the positive strip class the kept-form estimate bounds the real part in its original free coordinates, before multiplication by a coupling ratio. In a real comparison the potential may now be cut off in the gauges just obtained. Choose the comparison width h with its interaction collar inside the two-cell trace. If γ is the original real reference gap, take the error in eq. 4.cdxlii at most $\gamma/2$ and the sum $Ce^{-ch/C_{\mathrm{cell}}} + Ch^{-2}$ of the comparison and partition errors at most $\gamma/4$. The free bonds and masks have not changed, so this leaves a lower bound $\gamma/4$ for the old conditioned form in its original coordinates. On its admitted complex domain, the walk and elimination coefficients are holomorphic. For the actual substitutions we must verify the stated layered bounds on these carriers. For a normalized Gaussian with a changed coupling use the compensation in eq. 4.d. 4.17.1.19. The amplified substitution on carried strip factors. Let n be the level of the main step and $j+1<n$ the level at which a retained strip was formed. Consider a quadratic or elimination factor of that strip which is carried through step n. The carriage rule puts its carrier X outside the one-layer enlargement of the region being healed. The carrier is in the exterior region of the healing, and the structure in which the factor is read counts no stage in a component meeting its sites. These are the served targets of the main step. The strip coordinates and the pivots on X are those at its formation.

Let $P=(U,A',\mathbf{J})$ belong to the complex space of the output structure on a saturated localization Y containing the enlarged carrier and the response collars. For the admitted inner variables ξ use the formed inner data $\varsigma[P;\xi]$ of the main step. The belt map gives the reduced increment $\beta = \mathfrak{b}^Y(s;P,\varsigma[P;\xi])$ of the row averages on the belts, with $\|\beta\|_\infty \le \varepsilon_\beta/2$ throughout the complex cube polydisc $|s(\Delta)| < e^{\bar{\kappa}}$. For each wall component w of the localization use the response with cube parameters $s\mathbf{1}_w$ and form

$$(\mathbf{A},\mathbf{K}) = \sum_w \lambda_w(\mathbf{H},\mathrm{j})(s\mathbf{1}_w;\beta)[\mathfrak{p}^{\mathrm{e}}(P)].$$

Here $\mathfrak{p}^{\mathrm{e}}(P)$ is the restriction to the local exterior response class, with the current of that class. Level this shift on the exterior pillars with the pins at the sites of the stored data. Write $\mathfrak{h}^\delta$ for the result restricted to the bonds of X. The argument of the retained factor is $(P|_X) \dotplus \mathfrak{h}^\delta$, with the potential composed by the group product and the current increment added. Its stored fluctuation argument is held fixed.

The response estimate gives decay from the belts for the potential, its first difference and the current in their local units. The response of a wall is supported inside that wall, so independent multipliers cost $\max_w|\lambda_w|$. Pinning increases the bound by a fixed factor C_δ. The wall carriers lie strictly inside Y, so the shift vanishes on the target boundary outside the interior of Y. Put $\alpha_{*,n} = \min_{\iota=0,1}\alpha_{\iota,n}$ and let Σ denote the belts. The bound in the profile used by the target clauses is

$$|\mathfrak{h}^\delta|_b \le c_{\mathrm{sh}}\alpha_{*,n}\, C_\delta a(X) \max_w |\lambda_w| e^{-\delta_1 d_{\bar{\mathbf{B}}}(x_b,\Sigma)}.$$

Here $|\cdot|_b$ takes the maximum of the potential, its first difference and the current, multiplied by the first, second and third powers of the local spacing, respectively. The constant c_{sh} is the fixed

profile allowance in the substitution bound. The gap of a lower clause with index m' absorbs the profile in the units of that clause. In particular, if m is the exterior index at the base point, the gap comparison for $m' \le m$ is

$$L^{-(m-m')}\alpha_{*,n}e^{-\delta_1 d_{\mathbf{B}}(x_b,\Sigma)} \le Ce^{-c\delta_1 M\check{R}_n}\mathsf{gp}(m'),$$

where $\mathsf{gp}(m')$ is the gap supplied by the descent of the layer bounds and the fixed gap constant is included in C. With this profile the substitution into the served target preserves its tower, potential and one-scale clauses whenever $C_\delta a(X)\max_w|\lambda_w| < 1$. The free rim and wide shell used in that comparison hold for both classes of the main step. The stored sites of a served target are outside the boxes, so its pinned transports are among those admitted by the comparison.

To bound $a(X)$, split the response decay between the pointwise profile and the distance from the belts to X. A path crosses a distance at least $cM\check{R}_n$ in level-n units before it can reach the exterior. It then crosses the intervening layers, each of scaled width at least ρ. If n_X is the largest level for which X meets the interior of the healed exterior region $\bar{\Omega}_{n_X}$, this gives

$$2a(X) \le \frac{Ce^{C\bar{\kappa}}\varepsilon_\beta}{\alpha_{*,n}}\exp\bigl[-c\delta_0 M\check{R}_n - c\delta_0\rho(n-1-n_X)_+\bigr].$$

Thus for $a_X = 2C_\delta a(X)$ the whole disc $|\lambda| < 2/a_X$ is available when every λ_w equals λ. Since $\check{R}_n$ grows at least quadratically in the logarithm of the coupling parameter, the belt factor absorbs $\alpha_{*,n}^{-1} \lesssim g_n^{-1}$ uniformly in n. In particular $a_X < 1$ at small coupling.

On these discs the substituted triple lies in the layered space of the factor on its original carrier. The strip-domain comparison above then applies to its holomorphic walk coefficients and elimination factors in the original masks. At $s = 0$ or $\lambda = 0$ the argument is $P|_X$. At the physical point $s = \mathbf{1}$, $\lambda = 1$ the reduced belt datum is the true one. The pinned response gives the pair of a single representative of the prepared critical orbit, restricted to each served carrier. Its transports agree with those of the healed background at the stored sites. This proves the amplified read for the carried strip factors. Factors read inside the healing require the localized inner substitutions.

The idea of R (Comm. Math. Phys. 122 (1989) 175, (0.3)–(0.4)). We split $Z = Z' \cup Z''$. Following that paper (p. 176), Z'' is the union of the components "for which the small factors connected with large field control some number of next steps", and Z' is the union of all the other components (the rule by which the present construction sorts the components into these two sets is given under "Where it acts", below). The density is a sum $\rho(V) = \sum_Z \rho(Z,V)$ over the large-field regions Z ((0.2) of that paper), and $\rho(Z'',V)$ denotes the density belonging to the region Z''. Then

$$(\mathbf{R}\rho)(V) = \sum_Z \rho(Z'',V)\,\frac{\int dV|_{Z'}\,\rho(Z,V)}{\int dV|_{Z'}\,\rho(Z'',V)},$$

$$\int \mathbf{R}\rho = \int \rho.$$

In Z' the law of the field is replaced by the small-field law, and the mass is preserved. This idealised form is not linear in ρ. The form actually used is linear, because its reference law contains the Wilson weight and nothing else.

Where it acts. Let $k_\flat = k - \mathsf{N}_k \ge 1$ (*depth*); this restriction excludes nothing at $k = \mathsf{N}_k$, since by the second condition below a member of the class is then a component of Z_k in which no step has created anything, and no such component exists. A component X of Z_k belongs to the class when three conditions hold. First, for $k_\flat \le i \le k$ the set $X \cap Z_i$ is a single component of Z_i and is small, that is, contained in a cube of $O(1)$ level-i cells (*single boxes*, and at $i = k$ *size*). Second, for $k_\flat < i \le k$, step i creates nothing in it, and it does not absorb a second component, $X \cap Z_i = \Phi_i(X \cap Z_{i-1})$ (*quiet*). Third, it has not been acted on by any operation whose level lies in $[k_\flat, k)$, the lower end point included (*quarantine*). Bałaban imposes two conditions, that the

component be small and quiet (ibid., p. 177); to these two, the exclusion of a joining is added here as a separate condition, named explicitly. Two small quiet boxes that join within the window form a small component without creation, yet its trace one scale lower has two components: a joining does not count as a creation. Let H_i denote the hull, in level-i cells, of $X \cap Z_{i-1}$, and let $B^{[r]}$ be the box B with each face pushed outward by r such cells. Then

$$\Omega_i^{c} \cap X = H_i^{[8]},$$

$$Z_i \cap X = H_i^{[10]}$$

$$(k_\flat < i \le k):$$

the boxes are nested, the two of each level being concentric, and the number of cells along a side of X is comparable to the fixed point of the free evolution §4.17.1.40. As long as $k \le \mathsf{N}_k$ the class is empty, so $\mathbf{R}$ does nothing at the first levels. For $k > \mathsf{N}_k$ the class may be non-empty: the component obtained by free evolution from a single isolated cell created at step $k - \mathsf{N}_k$, with no intervening creation, joining or operation before level k, belongs to it. Up to level k the torus is admissible, $\frac{1}{2}\ell L^{K-i} \ge CM\check{R}_i$ for $i \le k$, as the opening of Prop. 4.56 requires. For a first-passage datum, $x_K \le g^{-2} + B_\sharp$, this condition follows from $\ell \in \mathfrak{L}(g)$ by way of $\check{R}_i \le L^{K-i}\check{R}_K$, a consequence of the upper flow bound; it is a lower bound on ℓ. Hence no cell, no box and no neighbourhood of a box wraps around the torus.

4.17.1.20. Restriction to a component. Let C be a union of components of the final region Z_i of a step, and let Y be its input region. The hull, layer, and boxing operations in this step restrict to C. Indeed, each cube of the hull of Y meets an input component. Their union is connected and belongs to Z_i, so the cube and the input component belong to the same final component. The enlargement of a cube by any of the layers used in the recursion is also connected and lies in Z_i. It therefore belongs to C precisely when that cube belongs to C. Finally, when a small component is replaced by its box, the box lies in Z_i and is connected to the component it replaces. The replacement can thus be made before or after restricting to C. Applying this argument at each boxing pass and test round shows that the restricted output is the one obtained from $Y \cap C$ and the recorded failures in C. In particular, if C contains no creation of that step, the output on C is given by the eight-layer hull and by boxing the ten-layer hull of $Y \cap C$, respectively.

4.17.1.21. Tracing an eligible component. Write $\mathcal{S}'_s$ and $\mathcal{S}_s$ for the labels just before and after the operation of level s. We use the nesting of Prop. 4.58 on these labels. At a fixed earlier index i, the regions Z_i decrease as these labels advance from $\mathcal{S}'_i$. A step leaves earlier entries alone, and the three rules for an operation only enlarge their integrated regions. Fix $h = k_\flat \le i \le k$ and a cell of $G_i = Z_i(\mathcal{S}'_k) \cap X$. For $i \le s < k$ the cell lies in a component of $Z_s(\mathcal{S}'_s)$. Healing that component would remove the cell from Z_i. Making it an island would have the same effect if $i < s$. In the remaining cases an operation on that component would give it a mark. If the mark ceased to stand, a later healing or island would have integrated the cell at level i. If it still stands, the marked component lies in the component X that contains the cell. This contradicts the exclusion of marks at levels $h, \dots, k-1$. Thus no intermediate class component contains the cell. Its memberships in the regions at i, and at $i-1$ when $i \ge 2$, are the same in $\mathcal{S}'_k$ as in $\mathcal{S}'_i$.

The entire component of $Z_i(\mathcal{S}'_i)$ through that cell survives in $Z_i(\mathcal{S}'_k)$. To see this, at each intermediate operation the whole component still lies in the same component of the top region as the chosen cell, by nesting and connectedness. The operation leaves that top component alone. Induction proves the assertion, and the surviving component is contained in X. Hence G_i is a union of components of the original output of step i. For $i > h$, the step's input restricted to G_i is G_{i-1}. The absence of creations for $h < i \le k$ now lets us use the preceding restriction argument at each of those steps. All these steps have $i \ge 2$, since $h \ge 1$. The argument allows the first step's creation set to be defined separately.

For clarity, measure lengths in bare units and set $a_i = M\check{R}_i L^i$, the side of a level-i cell. For a box B, write $B^{[s]}$ for its enlargement by a distance s in the sup norm in its lift. A negative s means moving each face inward by $|s|$. The oldest component G_h is a nonempty box by the small-component boxing rule and the survival just proved. Inductively its successor is a box. Its hull H_i on the next grid satisfies $G_{i-1} \subset H_i \subset G_{i-1}^{[a_i]}$, by rounding the endpoints in each coordinate to the level-i grid. A box is fixed by the boxing operation. Thus the two restricted outputs have the form

$$O_i := \Omega_i^c \cap X = H_i^{[8a_i]}, \qquad G_i = H_i^{[10a_i]}, \qquad G_k = X. \tag{4.cdxliii}$$

Here and below Ω_i, Z_i without a label refer to $\mathcal{S}'_k$. Each H_i is nonempty by eligibility, which requires a predecessor through the waiting window. In particular, X has at least 21 cells along each side. With the small-box cutoff of 100 cells per side, it has at most 100.

4.17.1.22. The boxes used in preparation. Let $u_i = ML^i$ be the side of an M-cube at level i in bare units. In the scale choice used for the preparation, let $k_0 + 1$ be the last index with $a_{k_0+1} = u_k$, with $h < k_0 \le k - 2$. Thus $a_i \le u_k$ up to $k_0 + 1$, and $a_i \ge Lu_k$ thereafter. The construction uses the following distances from the original small-field region. For $h < i \le k_0$ take distance $5a_i$ from Ω_i. For $k_0 < i \le k$ take distance $5u_k + w_i$ from Ω_{k_0+1}, where

$$w_{k_0+1} = 2u_k, \qquad w_k = 0, \qquad w_i = \sum_{q=i+1}^{k} u_q \quad (k_0 + 2 \le i < k).$$

In each case $Z_i''(X)$ is the union of cells of X all of whose points have at least the indicated distance. The change of scale allows the later boxes to stay on the scale u_k.

For $0 < s \le 8a_i$, the points of X at distance at least s from Ω_i form $O_i^{[-s]}$. The interior of O_i is disjoint from Ω_i. Every face of O_i lies in the closure of the part of Ω_i between O_i and G_i, since G_i extends two cells beyond O_i in every direction. Thus the distance inside O_i is the least distance to one of its faces, which gives the erosion formula. It follows from eq. 4.cdxliii that

$$Z_i''(X) = \begin{cases} H_i^{[3a_i]}, & h < i \le k_0, \\ H_{k_0+1}^{[3u_k - w_i]}, & k_0 < i \le k. \end{cases} \tag{4.cdxliv}$$

The first box is a union of level-i cells. For the second, the faces of H_{k_0+1} lie on the grid with side u_k. Since L is odd, those faces also lie on the grid with side u_i, and $3u_k - w_i$ is a multiple of u_i. The second box is therefore a union of M-cubes of level i. These grid facts justify passing from the set of points at the specified distance to the union of cells in the definition.

The earlier boxes satisfy $H_i \subset Z_i''(X) \subset O_i \subset G_i$. The next hull contains G_i, so the nest increases through the change of scale. At the later levels the centre is fixed, and w_i decreases from $2u_k$ to zero. The boxes remain inside O_{k_0+1}, which itself is contained in all later O_i. Thus $G_h \subset Z_{h+1}''(X) \subset \cdots \subset Z_k''(X)$. The separation from G_h to the exterior of $Z_{h+1}''(X)$ in X is at least $3a_{h+1}$. At early stages, $Z_i''(X)$ is separated from the exterior of $Z_{i+1}''(X)$ in X by at least $7a_i$, since $G_i = H_i^{[10a_i]}$ is already inside the next box. For $k_0 < i < k$, the separation is $w_i - w_{i+1}$. In particular the late separations have the scale of the M-cubes, which explains the smaller margins used for the prepared backgrounds.

With the cutoff of 100 cells per side, $G_{k_0+1} = H_{k_0+1}^{[10u_k]}$ has sides at most $100u_k$. Hence the sides of H_{k_0+1} are at most $80u_k$, and those of $Z_k''(X)$ are at most $86u_k$. The central integration below adds one more layer of M-cubes. Its box therefore has sides at most $88M$ in level-k units.

The operation. (0) *The frame sum*, described first although it belongs inside (3). In each component the identity $1 = |W_4|^{-1} \sum_{r \in W_4} 1$ is inserted after the integration over the box and before the tree gauge of (3). Consequently no frame sum is attached to a component that leaves at (2) or during the stages. In the summand of r, every object of (3), (4) and § 4.17 that belongs to X is formed in the frame r: the reference law with its denominator, the two trees, the test on

B, and the last-shell test. If a component leaves after the tree gauge, its frame sum stays with it, and an island keeps, in each summand, the cut-off and the delta function belonging to the frame of that summand. Formed instead in a single frame r_0, these make the bracket of X integrate to $|W_4|^{-1}\sum_r \mathfrak{a}_r\, \mathsf{D}_X^{(r_0)}/\mathsf{D}_X^{(r)}$ instead of $|W_4|^{-1}\sum_r \mathfrak{a}_r$. Here $\mathfrak{a}_r$ denotes that part of the summand of r which is independent of the box, and $\mathsf{D}_X^{(r)}$ denotes the denominator of $\mathfrak{s}_X$ formed in the frame r. The reason for keeping the frame sum is that neither the test on B nor the last-shell test is gauge invariant. Each of them enters only by way of decompositions of unity performed within a single gauge-fixed measure. Let m be the measure before the tree gauge, and let $\mathsf{a}_r, \mathsf{b}_r$ be its parts that pass, respectively fail, these tests in the frame r. Then $\mathsf{a}_r + \mathsf{b}_r = \mathsf{m}$ for every r, and hence $|W_4|^{-1}\sum_r(\mathsf{a}_r + \mathsf{b}_r) = \mathsf{m}$. With the drop-outs kept instead in a single fixed frame r_0, the total is $\mathsf{m} + (|W_4|^{-1}\sum_r \mathsf{a}_r - \mathsf{a}_{r_0})$. The average is taken so as to obtain covariance under the lattice isometries; trees break this covariance. (1) *Stages*: for $j = k_\flat, \dots, k-1$, one value after another, the stored variables of the outer shell of $Z_{j+1} \cap X$ are integrated out as in a small-field step. Before this, tests at the sharper threshold $\delta'_j := g_j A_1 p_1(g_j)$ are made, formed with backgrounds localised in X. What remains is a box Λ^{pr} of side at most CM: it is the set $Z''_k(X)$ of the nest of §4.17.1.1 enlarged by one more layer of M-cubes, and this layer is the shell of level k. In it the levels $k_\flat, \dots, k$ are stacked in thin shells, the shell of level j carrying the field V_j. Together these fields form the datum V'' attached to the prepared determining set $\mathbf{B}''$; its background is U''_k. At the innermost position lies the core $C_{k_\flat} = X \cap Z_{k_\flat}$, whose side, measured in the unit of level k, is at most $CM\check{R}_{k_\flat} L^{-\mathsf{N}_k}$. (2) The test asks whether the exterior field V_k admits an extension into Λ^{pr} whose curvature is less than $2\varepsilon_k$. If an exterior field satisfies $|\partial V_k - \mathbf{1}| < \varepsilon$, then it does admit an extension, one with $|\partial V_k - \mathbf{1}| < CM^2\varepsilon$. To see this, set the field equal to $\mathbf{1}$ inside after choosing an axial gauge on the surface $\partial^+\Lambda^{\mathrm{pr}}$. Hence "no regular extension" means that some exterior plaquette has $|\partial V_k - \mathbf{1}| \geq cM^{-2}\varepsilon_k$, and this pays as in §4.17.1.40 (p. 193 there). (3) V_k is integrated over Λ^{pr}. Taken together, the parts from the test (2) up to the division into the two classes § 4.17 form the *main step* of the operation; the stages that precede it and the exponentiation that follows it are counted separately. This integration is the first move to alter the density. Integrals against any bounded F that is independent of V_k on the box are left unchanged by it. Level by level, from the top down, it resolves the bare chain $\prod_j \int dV_j\, \delta(\mathcal{M}(V_j)V_{j+1}^{-1})$, $\int dV_i(c)\, \delta(\mathcal{M}(V_{i-1})(c)V_i(c)^{-1}) = 1$. What remains is a free Haar integral,

$$\chi_k\, \chi_{k,\Lambda} \int dV_{k_\flat}\big|_{C_{k_\flat}} \chi\, \mathbf{T}_{k_\flat}(C_{k_\flat}) \int dV''\big|_{\mathbf{B}''\cap(\Lambda^{\mathrm{pr}}\setminus C_{k_\flat})}\, \chi''_k\, e^{A''_k(U''_k)}$$

Here $\chi_{k,\Lambda}$ is the test of (2); χ stands for the plaquette tests of level $k_\flat$ carried by the term on $\Omega_{k_\flat} \cap C_{k_\flat}$; and χ''_k, A''_k are the tests and the action that (1) leaves. The integral is regarded as a density that is constant in V_k on the box. The field that is expanded is V''. It is expanded around the averages of the minimiser U_0 below, each average taken at its own level:

$$V'' = e^{ig_k B} V_0 \ \text{ on the fluctuation bonds } \mathbb{B}_0 = \mathbf{B}'' \cap (\text{shells}),$$

$$V_0 = (\mathcal{M}^j U_0 \text{ on the shell of level } j)_{k_\flat \leq j \leq k}.$$

Thus B is a multi-scale field on bonds of every level from $k_\flat$ to k, with a single scaling g_k and a single test $|B| < \delta'_k/g_k$. This is the field B in the prepared-component operation. The gauge of this field is fixed along a tree T_0 in $\mathbb{B}_0$, whose bonds come from all these lattices, one lattice for each shell. For two nested boxes $P_1 \supset P_2$, the tree is made up of axial contours which leave from a single initial site and go around P_2. The family of trees has two properties (pp. 195–196 there). First, the family is stable. Suppose one enlarges P_2 to a box $P'_2 \subset P_1$ and deletes the contour of each site of $P'_2 \setminus P_2$; then what is left is the tree of $P_1 \setminus P'_2$. Bałaban describes this property

as important, and boxes are needed because of it. Second, the tree of a shell uses up the gauge freedom at every site of the shell except one. For this reason, for each inner box on which a gauge is fixed, one external bond crossing its boundary is added, and one more is added for the outermost box. Through these extra bonds the trees of the shells become a single tree, and it fixes the gauge entirely, with Jacobian one. The core operation $\mathbf{T}_{k_\flat}(C_{k_\flat})$, which contains the failed tests, is at no point unfolded. One further test, the *last-shell test*, compares with the vacuum and constrains $V_{k_\flat}$ between the core and $\mathbb{B}_0$. It requires

$$|\partial U_{k_\flat,\square}((\mathbf{1},V_{k_\flat}))-\mathbf{1}|<\tfrac{1}{2}\varepsilon_{k_\flat}\eta_{k_\flat}^2$$

on the test cubes of that region, where $(\mathbf{1},V_{k_\flat})$ equals $\mathbf{1}$ on the side of $\mathbb{B}_0$. (4) In the run with its own choices, $\theta_k=x_k$. For each term τ, its mass $m_\tau=\int\tau\,dV_k|_{\Lambda^{\mathrm{pr}}}$ multiplies the reference law. Of the two factors of this product, the level-k variable $V_k':=V_kV_\Lambda^{-1}$, where V_Λ is the element of the critical orbit of Prop. 4.59 that equals $\mathbf{1}$ on the tree of δ_{ax}, occurs only in the reference law: in its numerator as the argument, and in its denominator as the variable of integration. Let $U_{k,X}$ denote the background localised in X, and let $\chi(\Lambda^{\mathrm{pr}})$ be the cut-off $\mathbf{1}\{|\frac{1}{i}\log V'(b)|<M_0\varepsilon_k$ on the bonds of the box$\}$, in which M_0 is a constant chosen large after M. Let δ_{ax} be the tree gauge of $\mathbb{T}^{(k)}\cap\Lambda^{\mathrm{pr}}$, taken on a tree that contains all the sites of this set together with the external bond of T_0 into the box; that bond is part of the tree because, without it, a constant gauge transformation of the box is left unfixed. Let ϕ_X be a cut-off function that equals 1 well inside X. Then

$$\mathfrak{s}_X(V_k)=\frac{\delta_{\mathrm{ax}}(V_k')\,\chi(\Lambda^{\mathrm{pr}})(V_k')\,e^{-x_kA(\phi_X,U_{k,X}(V_k'V_\Lambda))}}{\int dV'|_{\Lambda^{\mathrm{pr}}}\,\delta_{\mathrm{ax}}(V')\,\chi(\Lambda^{\mathrm{pr}})(V')\,e^{-x_kA(\phi_X,U_{k,X}(V'V_\Lambda))}}.$$

If one of the tests of (1)–(3) fails in a component, that component drops out §4.17.1.1: it remains live, and the failure counts as a creation. This can happen to the same component repeatedly. Each occurrence counts as a creation and is followed by a wait of at most N_k+1 steps.

The purpose of the stages, and the reason for a sharper threshold. Continuing the field by least action costs a constant factor: for exterior data with $|\partial V_k-\mathbf{1}|<\varepsilon$ one has $|\partial V_\Lambda-\mathbf{1}|\le C(M)\varepsilon$, and $|\partial U_0-\mathbf{1}|\le C(M)\varepsilon_k\eta_k^2$ near the box. For every value of the coupling, the stages reduce the component from side $M\check{R}_k$ to a box of side $O(M)$. Hence $C(M)$ is a constant fixed before γ. On the shell of level j it is overcome by the factor $L^{-(k-j)}$ by which a level-k field scales when viewed from level j. On the outermost shells it is overcome by $\check{R}_k^{-c}$, because $1+\log_L\check{R}_i$ levels are compressed into the box, namely the levels from the last level i with $L^{k-i}=\check{R}_i$ up to level k. Consequently U_0 belongs to the domain of the carried tests. It also belongs to the analyticity domains of the terms, insofar as the domain of a term lies inside the component or at a distance from the box; the remaining terms are treated in § 4.17. In the words of 122 (1989) 175, p. 195, "it is the reason why we have done the preliminary integrations". As in Lem. 4.57, the tests made at a stage have to imply the earlier ones. Here this must happen $\mathsf{N}_k=\check{R}_k$ times in succession, and the losses together amount to a fixed fraction. If two backgrounds satisfy the same constraints on a region, their difference is the response to the difference of their data, and this response decays. Let $U_{k,X}^{(n)}$ denote the background after n stages, localised in X. Put $j=k_\flat+n$, and let β_{s} be a fixed small fraction, written β by Bałaban. Then, on the support of the tests of stage $n+1$ and on the shell of level $i\le j$,

$$|\partial U_{k,X}^{(n)}-\mathbf{1}|\le|\partial U_{k,X}^{(n+1)}-\mathbf{1}|(1+c\beta_{\mathrm{s}}2^{-(j-i)})+c\beta_{\mathrm{s}}2^{-(j-i)}\varepsilon_i\eta_i^2,$$

where the error term is

$$C\delta'_j e^{-\delta_0 \operatorname{dist}} \eta_i^2 \le C\,\tfrac{\delta'_j}{\varepsilon_j}(1+(j-i)^{1/2}) e^{-c(M/M_1)(j-i)}\varepsilon_i\eta_i^2$$

. For M large, the decay $e^{-c(M/M_1)(j-i)}$ across the shells dominates $1+(j-i)^{1/2}$, and $2^{-(j-i)}$ remains. The ratio $\delta'_j/\varepsilon_j = (A_1/A_0)(\log x_j)^{-(\mathfrak{p}_0-\mathfrak{p}_1)}$ dominates the fixed constants, and at this point smallness of A_1/A_0 suffices as well. After n stages the test requires $|\partial U^{(n)}_{k,X} - \mathbf{1}| < (1-\beta_{\mathrm{s}}(1-2^{-(j-i+1)}))\varepsilon_i\eta_i^2$ on that shell. On the outermost shells, where the collars of the stages overlap, this requirement is relaxed by a factor $L_\flat^2$ for each overlap, where $L_\flat$ is an integer with $2 \le L_\flat < \frac{1}{2}L$ that is chosen together with L; such a choice requires $L \ge 5$. Let $k_\sharp + 1$ be the last of the levels at which an $M\check{R}$-cube, measured in units of level k, has side precisely M; in formulas, $M\check{R}_{k_\sharp+1}L^{k_\sharp+1-k} = M$. The collars of the stages with $j \le k_\sharp$ are disjoint, and the collars of the later stages overlap. On the shell i the factor is $L_\flat^{2(i-k_\sharp-1)_+}$. It depends on the shell only, not on the stage, and it becomes larger with each successive shell until it reaches $\check{R}_k^c$. In the region not covered by the shells, the bound is expressed in the scale j of the stage and equals $(1-\frac{1}{2}\beta_{\mathrm{s}})\,c_l\,L_\flat^{2e}\varepsilon_j\eta_j^2$, where $c_l = 3$ adjacent to Ω_k at the last stage and $c_l = 1$ elsewhere. Far from the box, the curvature of the least-action continuation U_0 can be as large as $(2+c)\varepsilon_k\eta_k^2$, and the test of the last stage must be implied there as well. Here $e = 0$ for $j \le k_\sharp$. For $j > k_\sharp$ one takes $e = (j-l-1)_+$ on $\Omega_l \setminus \Omega_{l+1}$, $k_\sharp < l \le j$, and $e = j - k_\sharp - 1$ between the shells and $\Omega_{k_\sharp+1}$. This is the form of 122 (1989) 175, (1.24), where the level is denoted k_0 and the base L_0. On a layer $l < j$ this bound remains below $\varepsilon_l\eta_l^2$, the scale of that layer. In passing from the scale $j+1$ to the scale j one gains L^{-2} and pays $L_\flat^2$. On plaquettes read by both stages, the later threshold leaves a margin for the geometrically decaying response. The crossing plaquettes of the prepared interface require the comparison below. The sharper threshold enters in two places. In the first, the new fluctuation test has to imply the old fluctuation tests of step $j+1$, at δ_j and $2\delta_j$. This holds because $CL\delta'_j = CL(\log x_j)^{-(\mathfrak{p}_0-\mathfrak{p}_1)}\delta_j \le \frac{1}{2}\delta_j$ for γ small, and it puts no new condition on the constants chosen earlier. In the second, at the main step, δ'_k has to remain a small fraction of $\varepsilon_{k_\flat}$, which is the curvature threshold of the core level. In this estimate the thresholds of two levels may differ by $\varepsilon_j/\varepsilon_i \le C(1+(j-i)^{1/2})$, the bound valid for every pair of levels §4.17.1.45. Restrict to the common support of the carried tests χ_k, the tests of (2) and (3), and the tests and delta functions that stand under the core operation; the latter make the data stored in the core regular. On this set, and provided $C(M)\check{R}_k^{-c} \le c$ on the outermost shells, the final regularity threshold follows on its inset, with the seam implications discussed below. The equality does not reach ∂X: adjacent to X^c, the background localised in X is constrained bond by bond on the bare lattice. There the test therefore demands $|\partial V_k - \mathbf{1}| < C\varepsilon_k\eta_k^2$ of the block field itself, while the carried tests provide only $2\varepsilon_k$. All of this holds under the condition

$$C\,\mathsf{N}_k^{1/2}\,\frac{p_1(g_{k_\flat})}{p_0(g_{k_\flat})} + C(M)\,L^{-\mathsf{N}_k}\mathsf{N}_k^{1/2} \le c\,:$$

the first term is δ'_k measured relative to $\varepsilon_{k_\flat}$, including the allowance $\mathsf{N}_k^{1/2}$. Since $\mathsf{N}_k = \check{R}_k \approx (\log x_k)^r$, it is a condition on the exponents, $\mathfrak{p}_1 < \mathfrak{p}_0 - Cr$, together with a ceiling on g_k. The second term is a level-k field viewed from level $k_\flat$, so N_k is taken large.

4.17.1.23. The prefinal reads at the old wall. Let $q = j+1 < m$ and $a_q = M\check{R}_qL^q$ in bare units. Write S_X for the level-j average of the prospective background localized to X, in the frame of the approximate collar test. In an uncompressed stage the new prepared face is five level-q cells from the old Ω_q wall. At $q = k_0+1$ it is seven cells away. For $q > k_0+1$ the prepared box is outside Ω_{k_0+1}, hence outside Ω_j; the ordinary separation from Ω_j^c to Ω_q is at least eight level-q cells. At every prefinal stage this last separation also bounds the clearance to the older determining layers on the exterior side. The clearance on the interior side from the wall to Ω_{q+1} is at least eight level-$(q+1)$

cells. Since $a_{q+1} \geq a_q$, the four-cell wall neighborhood lies in $\Omega^c_{q+1} \cap X$, which is inside the two-cell top inset of X. The two groups of ordinary approximate tests have bases in $(\Omega_q^{\sim 2} \setminus \Omega_q) \cap X$ and $(\Omega_q \setminus \Lambda_q^{\sim}) \cap X$. Their bases lie within two level-q cells of the wall, since in this quiet component Z_q is the two-cell enlargement of $\Omega^c_q \cap X$. The four test layers of the localization, with the endpoint blocks of every bond it reads, add less than one level-q cell. This follows from $L^2 M_2 \leq M$ and the fixed block reach. Thus the complete reads lie within three cells of the wall, with clearance from the new prepared face, the older core, the next ordinary layer and X^c.

Use this region with an additional fixed comparison band on each side, of total reach less than four cells from the wall. The ordinary global center at step q and the preceding stage center have the same rows there: the level-q rows on the inside and the level-j rows on the outside. Earlier promotions change only rows beyond the original Ω_j wall, with the associated one-step completions there. The comparison band misses those rows and their blocks by the ordinary separation. The two problems agree on the corresponding localized datum with these two scales. The joined comparison and averaging on the full endpoint blocks bound the difference of their axial readings by $C_L \varepsilon_\star e^{-cM \check{R}_q}$. Use the ordinary strip shift on the bonds on which that substitution is made. Its physical real bound on those bonds is $C_L \varepsilon_j e^{-c\check{R}_q}$.

The prospective stage has level q throughout these test cubes and their enlargements. The localized test-cube datum is the lift of the same V_q there. Its background has the same axial read at the common nodes. Comparing it with the prospective background on the full $\square'^{\sim 4}$ box gives

$$|S_X(b)(V^{\mathrm{bg}}_{j,\square'}(b))^{-1} - \mathbf{1}| \leq C_L \varepsilon_\star e^{-cM_2 \check{R}_q}.$$

The distance from the endpoint blocks to the comparison boundary is a fixed fraction of a test layer, in level-q units. This is the local comparison for the actual test centre, with V_q fixed on its whole halo.

At a bond with neither endpoint in Ω_q the relative collar test gives $2\delta'_j$ against S_X. For a bond read by the completed ordinary strip test, compare instead the ordinary center to the preceding-stage center and then to S_X by the real fixed-target path of §4.17.1.27. Across the old wall the coarse row joining the two centres is an outward row of the old member and a retained row after the promotion. Its value is $V_q(c)$ throughout the path. The two centres are old nodes of levels j and q. The physical increment of this outward row is zero. Its reduced increment still reads the changing internal links of the exterior block. Use that increment in the response and restore both node values as in the two-block calculation below. The restoration of the node gauges in the one-step average leaves the identity at the old level-j node and v_j^{-1} at the level-q node, with $|\mathsf{v}_j - \mathbf{1}| \leq C_L \delta'_j$. The additional exterior contour of the ordinary strip frame uses only internal bonds of the exterior block. This block is entirely in the new exterior collar, and those nonpivots are tested there. The regular mean therefore bounds that contour change by $C_L \delta'_j$. This gives the comparison in the inherited frame with both endpoint factors included. At an old-wall crossing the physical link itself is controlled by the completed ordinary test at δ_j, including the original real strip substitution. The new collar test need not read that crossing. Any adjacent factor on an old ordinary Gaussian bond was removed by the ordinary whole-term identity, with its original cutoff and the retained strip factors. That bond is absent from the free variables of the prepared collar. The sum of the center errors is at most $C_L \delta'_j + C_L \varepsilon_\star e^{-cM_2 \check{R}_q} = o(\delta_j)$, so both groups of ordinary approximate factors equal one on their complete reads. The argument uses the direct exterior-only collar mask.

At the first stage put $h = m_\flat$. The surviving level-h density tests at this first stage have bases in $Z_h \cap \Omega_h \cap X$. The stage-zero guard recovered in §4.17.1.25 implies the other bottom density tests outside $\Omega_q^{\sim}$, by localization on their own complete four-layer boxes. The bases outside Z_h lie in Λ_h, two level-h cells from Ω^c_h, and the exclusion of $\Omega_q^{\sim}$ keeps the full boxes in $\Omega_h \setminus \Omega_q$. The comparison with the pure level-h test tower there costs at most $C\varepsilon_\star e^{-c\check{R}_h}$ in level-h units, within

the $\beta_{\mathrm{s}}/2$ margin of the stage-zero bound. The retained bottom tests read the frozen core: its gap to the first prepared face is at least $3a_q$ and their halos reach less than a_q.

4.17.1.24. The comparison of the centers at the last stage. Put $j = m-1$, let $Y = Z''_m(X)$, and write

$$K = (\Omega_m^c \setminus Y) \cap X.$$

At the last stage the approximate collar test compares the actual V_j to the j-fold average S of $U_{m,X}^{(\mathsf{N}_m)}$ on its nonpivot mask. In the direct graded rule the mask consists of bonds with an endpoint in K and neither endpoint in Ω_m. The incident-bond convention additionally tests crossings into Ω_m. In the direct rule those crossings use the completed ordinary strip test. Denote the corresponding preceding-stage average by S^-, the ordinary strip center by $V_j^{\mathrm{bg,loc}}$, and the ordinary test-cube center by $V_{j,\square'}^{\mathrm{bg}}$. We use the actual averaging constraints and keep the preceding-stage guard during these comparisons.

The ordinary approximate tests in the fifth and sixth groups have bases in $(\Omega_m^{\sim 2} \setminus \Omega_m) \cap X$ and $(\Omega_m \setminus \Lambda_m^{\sim}) \cap X$, respectively. Their tested bonds are those of $\square'^{\sim 2}$ other than the pivots. Their centers are formed on $\square'^{\sim 4}$. The interior bases are at least one level-m cell from the exterior of X. The exterior bases lie in O_m and within two level-m cells of Ω_m. Each added test layer has width $M_2\check{R}_m$ in level-m units. The complete reads therefore remain at distance at least $cM\check{R}_m$ from ∂X, including the blocks of their end points. The prepared core Y lies in $\Omega_{k_0+1}^c \cap X$, which lies in the old live region $Z_{m-1} \cap X$. By eq. 4.cdxliii this old region lies at least eight cells inside Ω_m^c. Thus a test-cube box can meet the old wall and stays clear of the prepared seam and the tower collar at ∂X. The prospective joined sequence has top level m throughout the test-cube box.

On that box the actual top rows of $U_{m,X}^{(\mathsf{N}_m)}$ have values V_m. Its joined datum for the test-cube localisation is therefore exactly the one induced by the lift of V_m. The localised background is the ordinary test-cube background. For a real datum below the ceiling of the joined comparison, eq. 3.cdi and eq. 3.cdii compare these backgrounds in their common block axial reading. In the units of level m the read is at distance $cM_2\check{R}_m$ from the boundary of its test-cube box. Consequently

$$|S(b)(V_{j,\square'}^{\mathrm{bg}}(b))^{-1} - \mathbf{1}| \le C\varepsilon_\star e^{-cM_2\check{R}_m}$$

on the stated footprint, with $\varepsilon_\star$ a bound on the small regular datum. This application reads the ordinary coarse density test and the retained rows. It does not require the discarded sharp bound at the artificial bare rim of X.

For this real datum bound, the preceding-stage support already controls the tested holonomies before the last enlargement. Levels below j keep their rows. The determining set of level j loses rows. Its second-kind rows still use the unchanged layers $j-1, j$, so the remaining tested plaquettes have their old holonomies. For a tested plaquette of level m with a corner in a carried density cube, that test bounds its actual V_m holonomy. The density cubes on $\Omega_m^{\sim 4}$ cover the plaquettes near the old seam. In the other case the averaging blocks of a newly tested plaquette are in the preceding member of level j, by the last prepared separation, and outside the old Ω_m. Here the fine plaquettes are formed from the old determining rows, and the exact one-step average gives the coarse bound. At the exterior tower a tested holonomy is either the identity or the lifted top holonomy. These are bounds at the respective levels of the datum. They do not divide the top plaquette deviation by the square of the fine spacing.

To compare S^- with $V_j^{\mathrm{bg,loc}}$, use the region between an inner and an outer box. For the outer box take X inset by a quarter of a level-m cell, rounded on the grid of M_1-cubes at that level. The old exterior inside X is a box separated from X^c by two cells by eq. 4.cdxliii. For the excluded inner box take $(\Omega_m^{\sim 2})^c \cap X$, with this enlargement in level-m cells. The outer boundary band is in the old Ω_m, and the inner boundary band is in $\Lambda_j \setminus \Omega_m$. The earlier stages alter rows only beyond the inner band, towards Z_j. The new gauge draws of the last stage start outside $\Omega_m^{\sim 3}$. On the annulus both backgrounds therefore have the same regions and the same determining rows, including the

top data used on its two boundary bands. Join at level m on the outer band and at level j on the inner band. Both localisations give the same datum. For a read of either group with both ends in Ω_m, use the localized strip center only on the actual strip read and substitution mask. For a read unaffected by that substitution use the ordinary global center. It has the same determining rows on the annulus. The block axial frame on the full read blocks is common, and the distance to the annulus boundary is of order $M\check{R}_m$. With $L_j(b)$ denoting the applicable ordinary center, the comparison gives

$$|L_j(b)(S^-(b))^{-1} - \mathbf{1}| \le C\varepsilon_\star e^{-c\check{R}_m}.$$

For the change from S^- to S, use the finer determining set at the averages of the prospective background, then change the freed level-j rows to their actual values. The two constraint sets are nested at the induced datum. A critical point for the larger constraint set is critical for the smaller set there. The common rows, including the exterior tower rows, do not change. On a nonpivot freed row the approximate collar test bounds the increment by $2\delta'_j$. For a freed pivot, both blocks of its coarse row are outside the old Ω_m. Each nonpivot in the double block is controlled by the collar test or belongs to the common fine rows. This includes the rows crossing the prepared seam, whose outside block is in K. The two fine fields have the same V_m average on that coarse row. The contour argument in §4.17.1.27 places the actual pivot in the small branch, and inversion of the averaging equation bounds its increment by $C(L)\delta'_j$. A pivot crossing the old Ω_m seam is absent from the finer determining set in the convention excluding inward bonds. The resulting plain datum increment is supported in the collar. The real response supplies the reduced datum and the node factors, including any factors at a seam. On the common axial reads inside the old Ω_m the response bounds $S^-(b)S(b)^{-1} - \mathbf{1}$ by $C(L)\delta'_j$. This argument is made after the approximate collar test and before the sharper collar split.

On a read of either group in the old Ω_m, add these three bounds to the carried or completed fluctuation bound δ_j, with the ordinary strip shift on its actual mask. The exponentially small terms and $C(L)\delta'_j$ fit in the remaining δ_j of the approximate threshold $2\delta_j$. A nonpivot read with an end point outside the old Ω_m has that end point in K. For a bond with neither endpoint in Ω_m, use the collar test and the test-cube comparison to obtain $2\delta'_j + C\varepsilon_\star e^{-cM_2\check{R}_m} < 2\delta_j$. Both tests exclude the geometric pivots on this overlap.

For a crossing of the old wall in the direct graded rule, the full exterior endpoint block lies in K, and the interior endpoint is in the first stored ordinary strip layer. The completed strip test there gives the bound at δ_j in the original plain coordinate, without changing the physical link or its soft gauge factor. Compare only the centres L_j and S on the full two blocks by the mean-contour axial reading used below for the global collar chart. The exterior contour of the ordinary frame is determined by the internal bonds of the exterior block. The direct collar test does read these internal bonds. Its bound controls that contour without assuming an additional collar bound on the crossing itself. On the common retained centre pins the comparison gives

$$|L_j(b)S(b)^{-1} - \mathbf{1}| \le C_L\delta'_j + C_L\varepsilon_\star e^{-c\check{R}_m}$$

in the inherited frame. Together with the test-cube error and the original strip bound this is less than $2\delta_j$. The two-block comparison below uses the actual retained centre nodes and the original exterior contour. When using the incident-bond convention and the crossing itself lies in its mask, the direct collar bound applies in that convention's prescribed frame.

For the inset split the finer path supplies the local collar response at a fixed admitted prospective datum. The clearances above place the complete footprints of the two groups in its comparison region, including the interior endpoints of tests based outside Ω_m. The inherited strip quadratic form uses the original strip variables.

4.17.1.25. The preceding guard on the prepared seam. The stage-zero plaquettes lie in $\Omega_h \setminus \Omega_{h+1}$. At any stage with $h < j < m$, every prepared shell lies in Ω_m^c. The deep exterior clause is in $\Omega_{i_0+1}^c$,

where $i_0 + 1 \le j$, and the other exterior clauses are in $\Omega_l \setminus \Omega_{l+1}$ with $l \le j$. Consequently every earlier guard reads only $X \cap \Omega_m^c$, which is two level-m cells inside X by eq. 4.cdxliii. The artificial bare rim occurs only in the final guard.

Consider the implication from stage m to $j = m - 1$ on the ordinary real collar chart. On a shell of index $i < j$ already present at j, the geometric factor and curvature scale are unchanged. The later coefficient is smaller by $\beta_{\mathrm{s}} 2^{-(j-i+2)}$. The weighted response from the changed collar rows is at most

$$C_L \frac{\delta'_j}{\varepsilon_j}(1 + \sqrt{j-i}) e^{-c(M/M_1)(j-i)} \varepsilon_i L^{-2i}.$$

Here the ratio of thresholds contributes $1 + \sqrt{j-i}$ and the shell separation gives the exponential. Choose M/M_1 so their product is bounded by a constant times $2^{-(j-i)}$, then use δ'_j/ε_j to fit the reserve. Any overlap factor on this fixed shell is the same at both stages and is at least one. On a plaquette wholly in the new shell $Z''_m \setminus Z''_j$ the factor is unchanged and the coefficient decreases from $1 - \beta_{\mathrm{s}}/2$ to $1 - 3\beta_{\mathrm{s}}/4$. Outside both nests the ratio of the two thresholds is at most

$$\frac{\varepsilon_m}{\varepsilon_j} \frac{\max\{L_\flat^2, 3\}}{L^2}.$$

The factor 3 occurs at $l = j$. The adjacent reference couplings differ by a bounded increment, so their threshold ratio tends to one in the small-coupling range. These exterior comparisons have a fixed fractional margin. On admitted real data the collar response fits these reserves, by its weighted bound on the old shells and the small ratio δ'_j/ε_j in the exterior. All these reads remain in the inset.

A plaquette can cross a face of Z''_m while lying wholly in $\Omega^c_{k_0+1} \setminus Z''_j$. Choose a normal and a tangent edge away from the corners of the face, using the half-spacing faces of the centered blocks. The separation of the prepared boxes puts the whole plaquette outside Z''_j, and the clearance from Ω_{k_0+1} puts it inside the old deep exterior region. The preceding guard reads it. The final shell and exterior clauses both require containment, so neither reads it. It is also outside the later original layers used by the other exterior clauses.

At such a plaquette write $T_j(p)$ for the preceding threshold and $E_j(p)$ for the bound on the curvature change from the collar response, in bare plaquette units. We must show that the prospective curvature is below $T_j(p) - E_j(p)$ on the support on which the preceding guard is removed. The small-paying-energy estimate below gives this comparison on the part of the support to which it applies. In the two joined sequences the plaquette has the old and new scales j and m under the largest-corner convention. The weighted profile at p is bounded, in either sequence, by

$$C\left(\varsigma_* + \check{R}_m^2 \varepsilon_m e^{-c\delta_{\mathrm{c}} M \check{R}_m}\right) = o(\varepsilon_j).$$

Indeed the old rows are read from the compatible field, and the new rows use its retained averages. The distance to the floor uses the same prepared-window separation. The two bare curvature bounds gain respectively L^{-2j} and L^{-2m}. Their sum is $o(T_j(p))$ and bounds the change in any common real frame. This proves the preceding seam test on the low-energy branch.

In an inset split let χ_{in} be the literal final clauses restricted to plaquettes whose corners are all in X with one full level-m cell layer removed. The preceding reads omitted by these clauses are the deep exterior plaquettes straddling $\partial Z''_m$. Put $F_j = L_\flat^{2(j-k_0-1)}$ and let $\kappa_\times$ test each of these plaquettes at $(1 - 3\beta_{\mathrm{s}}/4) F_j \varepsilon_j L^{-2j}$ in the prospective background. The datum for that test is held fixed in the collar integration. If χ_{in} is the final inset test, the complementary factor of their product is

$$1 - \chi_{\mathrm{in}} \kappa_\times = (1 - \chi_{\mathrm{in}}) + \chi_{\mathrm{in}}(1 - \kappa_\times).$$

Both terms belong to one regularity stop before the collar integration. Under the payment hypotheses a failure in the second term is impossible at small paying energy by the profile estimate above.

The threshold leaves a reserve $\beta_{\mathrm{s}}F_j\varepsilon_j L^{-2j}/4$ for the old-chart response. On the passing branch the fixed-target response estimate below fits that reserve throughout the admitted real collar box, so the preceding seam test is one there. This implication uses the reserve and the collar response. The small-paying-energy argument concerns failure of $\kappa_\times$.

There is also a direct bound for these crossings on the admitted real inset chart at the final stage. Translate a crossing plaquette p a bounded number of bare spacings into an exterior cell at one of its outside corners, keeping its orientation. The translated plaquette lies in the deep exterior and in the inset. The separation from Z_j'', the old wall, and the outer boundary lets both plaquettes lie in the smaller part of a fixed-size level-j regularity cube. Its enlargement is in the prospective member of level j. The local gauge on this cube applies across the level-m face. In that common gauge the difference of the linear plaquette curls is at most $C\varepsilon_\star L^{-(2+\alpha)j}$ by the first-difference Hölder bound. The quadratic and higher terms in the products of the four links vary by at most $C\varepsilon_\star^2 L^{-3j}$, by the bound on their first differences. The inset test bounds the defect of the translated plaquette by

$$(1-\tfrac{1}{2}\beta_{\mathrm{s}})L_\flat^2 F_j\varepsilon_m L^{-2m}.$$

Divide the three bounds by $F_j\varepsilon_j L^{-2j}$. The last displayed bound has ratio at most $(1-\beta_{\mathrm{s}}/2)(L_\flat/L)^2(1+o(1))$. The two errors tend to zero, since $j=m-1$ and $m\ge \check R_m$, with $\check R_m$ growing at least as the square of the logarithm of the inverse coupling. This gives the reserve of $\kappa_\times$ once the real prospective datum has been admitted. The fixed-target response then transfers it to the preceding guard.

An earlier transition has its own crossing reads. In particular, with $h=m_\flat$, the first prepared face lies strictly in $\Omega_h\setminus\Omega_{h+1}$. A bare plaquette astride that face is tested at stage zero. Neither containment clause of the next guard tests it. The final-stage Hölder estimate uses $j=m-1$ to make its translation error small compared with the tested threshold. At the first face that argument does not supply the reserve.

For a transition from j to $j+1$, use the actual list of preceding reads. At a newly omitted crossing the preceding coefficient is $(1-\beta_{\mathrm{s}}/2)F_j\varepsilon_j L^{-2j}$, with $F_j=1$ in the uncompressed range and $F_j=L_\flat^{2(j-k_0-1)_+}$ thereafter. In a split with an added crossing test, impose $(1-3\beta_{\mathrm{s}}/4)F_j\varepsilon_j L^{-2j}$ on the fixed prospective datum. This leaves $\beta_{\mathrm{s}}F_j\varepsilon_j L^{-2j}/4$ for the old response. The first face has the separation from the bottom core and the old wall needed for the local paying-energy comparison. On the complete crossing carriers the small-energy argument bounds the prospective defect by $C(\sigma+\check R_m^2\varepsilon_m e^{-cM\check R_m})L^{-2j}$, with $\sigma=c_*\delta_j'\check R_m^{-4}$. This fits the crossing test. Its failure on the otherwise passing prospective branch belongs to the same regularity stop on the old prefix. On its passing branch eq. 4.cdxlv fits the reserve on the whole admitted real collar chart and gives the preceding inequality there.

At the first transition put $h=m_\flat$, $q=h+1$ and $Y=Z_q''$. The original stage-zero guard tests plaquettes contained in $\Omega_h\setminus\Omega_q$. All of these lie in the inset of X. For one contained in Y, the first prepared shell tests it at $(1-3\beta_{\mathrm{s}}/4)\varepsilon_h L^{-2h}$. For one contained in Y^c, use the new deep exterior bound $(1-\beta_{\mathrm{s}}/2)\varepsilon_q L^{-2q}$. Here $h<k_0$, so $i_0=h$ at the new stage and the exterior power of $L_\flat$ is zero. A plaquette with corners on both sides uses the added crossing test at the first shell threshold. In all three cases the new bound leaves at least $\beta_{\mathrm{s}}\varepsilon_h L^{-2h}/4$ below the old bound. For the exterior case use $\varepsilon_q/\varepsilon_h=1+o(1)$ and L^{-2}.

The passing prospective guard fixes an admitted real orbit at the outgoing datum. Hold that datum fixed and use §4.17.1.27 with target V_q on the full approximate collar ball. The old curvature can change by at most $C_L\delta_h' L^{-2h}$ on the first face and on the adjacent layer-h stencils. On the covered layer the same weighted comparison applies to its full stencils, using the old units there. This error fits the reserve. Thus the old stage-zero guard equals one on the real chart for the passing graded branch. The earlier value of that guard is still used in assigning the incoming stage-zero outcome. The removal in the collar integral follows from the comparison on its whole real chart.

For an operation using these additional tests through the whole window, assign a newly added crossing of $\partial Z''_{s+1}$ to shell s. Retain it in the subsequent guards with the same coefficient as that shell. Its first coefficient is $1-3\beta_{\mathrm{s}}/4$. From the transition j to $j+1$ with $j>s$, its coefficient drops by $\beta_{\mathrm{s}}2^{-(j-s+2)}$. The stencil at this old face has scale at least L^s, and the separated faces give the same weighted distance to the newly changed rows as for the adjoining shell, up to a bounded stencil enlargement. For each intervening layer the path crosses a width of at least a fixed multiple of M in its own units. The decaying form of eq. 4.cdxlv therefore gives a defect change bounded by

$$C_L\delta'_jL^{-2s}e^{-c(M/M_1)(j-s-1)}.$$

The adjacent frame comparison costs at most $C(1+\sqrt{j-s})$ in comparing ε_j with ε_s. Choose the shell separation and then the coupling floor as in the original ladder. The change fits the decrease of the coefficient at every transition. Thus the already assigned crossings are carried with the earlier shell tests until the main integration.

For comparison of the last-stage change alone with the literal final test, let r be the product of its omitted indicators on the same prospective datum. The literal continuation is $\chi_{\mathrm{in}}r$, and the inset continuation is $\chi_{\mathrm{in}}\kappa_\times$. Their two differences are the sectors $\chi_{\mathrm{in}}r(1-\kappa_\times)$ and $\chi_{\mathrm{in}}(1-r)\kappa_\times$. One may refine each literal branch by multiplying it by $\kappa_\times$ and by $1-\kappa_\times$, leaving that branch's kernel and stage count on both pieces. Summing the two pieces recovers the original labelled measure. To change the continuation rule itself one must compare the two kernels on the difference sectors. The later implication for $\kappa_\times$ is on the main-step support. An earlier stop belongs to a different branch.

The inset test can also define the split of a separate operation from its first formation. Put $G=\chi_{\mathrm{in}}\kappa_\times$ on the real pre-collar fibre, counting an undefined tested background as a failure. Use the old prefix kernel on $G=0$ and the admitted continuation moves on $G=1$. Both are positive kernels with unit mass when written as the real moves, before their weights are expressed by the collar integral. Thus the two branches exhaust the incoming measure. A bare insertion multiplies the incoming bare measure before applying the same kernels. For example a curvature source replaces $\rho_0(U)dU$ by $e^{A(w,U)}\rho_0(U)dU$ and uses the tests and reference laws of the unsourced run. The stage count on $G=0$ is the preceding count, and failure of the product makes a single mark. The mark's own mass omits its failing test. A later containing fibre can use that failure for one payment when the complete witness is available there. The move identities give an exact weighted integral with labels assigned by G. To identify its positive branch with the localized stage integral, we must account for every retained test on its actual chart. An indicator on the fixed outgoing datum can stay outside the collar logarithm, as the final top-density factor does. An indicator on an integration variable can stay in the expansion if it is fixed in the real integration coordinates throughout the parameter domain, has a fixed carrier, and accepts the smaller coordinate ball used in its Gaussian tail estimate. For example, on a plain strip bond with reference S_{o}, an approximate factor with cube centre D tests $|e^{ig_ja_b}S_{\mathrm{o}}D^{-1}-\mathbf{1}|<2\delta_j$. If the centre error is at most $c\delta_j$ with $c<1$, the factor accepts the ordinary ball $|g_ja_b|<\delta_j$. This is a one-bond factor when the centres are fixed on that fibre. A test I_S with active slots S that accepts the product ball of radius h has

$$1-I_S\le\sum_{b\in S}\mathbf{1}_{\{|z_b|\ge h\}}.$$

The absolute Gaussian tilt on its carrier therefore gives a tail factor $|S|e^{-\gamma_2h^2}$ times the normalization and mean costs of the tilt. For several fixed selectors I_α, use their complete carriers in every binary cut, and let S_α be their sets of active coordinates. Suppose that at most ν of the sets S_α contain any one bond, counting each selector only once. For a family A of failed selectors choose one bond from each S_α. Then

$$\prod_{\alpha\in A}(1-I_\alpha)\le\sum_{\substack{b_\alpha\in S_\alpha\\ \alpha\in A}}\prod_{b\in\{b_\alpha:\alpha\in A\}}\mathbf{1}_{\{|z_b|\ge h\}}.$$

The set of bonds on the right has size at least $|A|/\nu$. Apply the stage Gaussian tilt once per distinct bond. On a stage chart with the real-contour Gaussian bound this gives the tail

$$\left(\prod_{\alpha\in A}|S_\alpha|\right)e^{-ch^2|A|/\nu}$$

in addition to the Gaussian normalization cost and the bounds on the analytic vertices. In the tilt the positive quadratic form is diagonal on the selected coordinates, so its size per coordinate is independent of the multiplicity. If no active coordinate enters a selector, carry its real value outside the Gaussian estimate.

For a bond selector attached to an original test cube, the sets of tested bonds lie in the two test layers of that cube. A bond can belong to only a fixed number of such enlarged cubes. Restrictions to the integration mask can decrease this number. The product of a repeated selector with itself can be counted once. For a single stage, the cardinality of each such set grows at most as a fixed power of $\check{R}_m$. At the stage fluctuation threshold h is a fixed fraction of δ_j'/g_j, so the factor $\log|S_\alpha|$ is absorbed by ch^2/ν at weak coupling. This count uses only the original test-cube reads. If the inverse chart introduces new active coordinates, use the resulting supports and prove the overlap estimate on them.

Fixed Borel selectors in these coordinates require no continuation as functions of z. Keep them on the real contour, and use the locally uniform integrable Gaussian majorant for holomorphy in the analytic parameters. Their compatibility with the factorization uses their full carriers. For a preceding curvature guard on the active collar, we must either show it holds on the complete chart or put it in this fixed-domain form and prove that it accepts the reference ball. A bound only on the support of the literal prospective guard gives neither property for the inset rule. If its domain moves with the analytic parameters, the real tail estimate leaves the transported integral and its bound to be proved.

For the remaining inset-positive evaluations use the real collar path at fixed prospective datum. The seam estimate concerns the prepared interface inside X. The face-lift calculation at ∂X supplies its own restriction.

4.17.1.26. The lower density and contour tests on the inset. In the ordinary step $t=j+1$ use the query rule in which a collar bond has both ends in the explored region of its round. Since that region only grows, a bond crossing the final small-field boundary $\partial\Lambda_t$ has not been queried in the collar. Its inner threshold in the ordinary mean estimate is the rim threshold $\theta_c\delta_j$. In a rule that queries incident crossings as well, the accepted ball must fit all the resulting tests, including $\delta_j^\flat$ on a queried pass. The stored coordinates in either case are the complement of the actual integrated nonpivots.

The ordinary labelled fluctuation split retains the signs of the queried outcomes. For explored bonds E^{T}, failure set I, explored rim cells E^{H}, and failed rim set $\mathsf{R}^{\mathrm{bord}}$, its factors include

$$\prod_{b\in I}\chi_b^1\prod_{b\in E^{\mathrm{T}}\setminus I}\chi_b^0\prod_{c\in\mathsf{R}^{\mathrm{bord}}}(1-\mathrm{lo}(c))\prod_{c\in E^{\mathrm{H}}\setminus\mathsf{R}^{\mathrm{bord}}}\mathrm{lo}(c).$$

Keep also the failed-cube factors and the unexplored bond factors of the ordinary split. An eligible component of the collar operation misses every ordinary creation set at the unfolded levels. A failed queried bond puts its endpoint cells in that set. A failed rim test puts its rim cell there, and a failed cube puts its coarse hull there. Their incident reads and the cube test halos lie in the same enlarged ordinary component as the creation. By nesting, such a component reaching the stage component would put its creation inside it. Thus only the passing queried factors occur on the eligible collar carriers. The failed factors in the frozen core keep their original signs.

Apply the test implications on the successful real support in their original order. Use the prospective regularity and approximate collar tests, the exact retained averages, and the ordinary completed fluctuation factors. These last factors control the inherited strip variables read by the belt tests,

including the old-wall crossings. The sharp exterior mask concerns a different stock of nonpivots. Remove the preceding regularity, ordinary density, contour, and two approximate belt groups on the full reads where the corresponding implications have been proved. Keep the final top density, the soft gauge density, the carried fluctuation factors, and the separate collar and rim factors. Keep any other positive guard on its inverse read until its own implication is established. An active guard belongs inside the exact real collar integral, while a fixed-datum factor can be taken outside. The sharp collar split follows these comparisons.

To apply the ordinary fluctuation factors, let L_b and G_b be the localized and global ordinary strip centres and put $e^{iH_b} = G_b L_b^{-1}$. Write $W' = e^{iA'_j(b)}$ for the real strip coordinate after the ordinary cutoff substitution. The physical link on a substituted bond is

$$V_j(b) = W' e^{i(1-\vartheta(W'))H_b} L_b, \qquad V_j(b) G_b^{-1} = W' e^{-i\vartheta(W')H_b}.$$

In the unchanged zone use the original coordinate. On the plain strip $\vartheta = 1$. In the cutoff zone $\vartheta = 0$ through angle $4\delta_j/3$ and $\vartheta = 1$ from $5\delta_j/3$ onward. If $|H_b| \le \delta_j/8$, the hard angle tests at thresholds at most $29\delta_j/24$ are unchanged. They agree below the start of the cutoff, and above it the change of angle is at most $\delta_j/8$, so both fail. For an approximate test with cube centre D, put $X_b = L_b D^{-1}$. When $\vartheta < 1$ and $|H_b| + |X_b - \mathbf{1}| < \delta_j/3$, both $W'X_b$ and $W' e^{i(1-\vartheta)H_b} X_b$ have chord distance less than $2\delta_j$ from the identity. When $\vartheta = 1$ the two arguments are equal. This proves the approximate test identity on the cutoff mask with its centre reserve.

Let $h < j < m$ and $q = j + 1$. The lower density cubes have bases in $(\Omega_j^{\sim 4} \setminus \Omega_q^{\sim}) \cap X$. The full four-layer halo of a base extends by less than one level-j cell. The eight-cell gap to Ω_{j-1}^c and the exclusion of $\Omega_q^{\sim}$ put this halo in $\Omega_{j-1} \setminus \Omega_q$. It lies in the top inset of X because it lies in $\Omega_q^c \cap X$. It misses the old prepared box Z_j''. For $j \le k_0$ this follows from its five-cell distance to Ω_j. At $j = k_0 + 1$ the distance is seven cells. At later levels Z_j'' is outside Ω_{j-1}. Hence the whole density box is in the old prepared layer j. Use that layer's actual determining rows at the old target.

For $q \le k_0 + 1$, the halo can meet the new prepared box Z_q''. A plaquette wholly inside that box is in the new shell and is tested at $(1 - 3\beta_{\mathrm{s}}/4)\varepsilon_j L^{-2j}$. This includes any such plaquette crossing the original Ω_j wall. A plaquette wholly outside the box uses the deep exterior bound $(1 - \beta_{\mathrm{s}}/2)\varepsilon_q L^{-2q}$, since $i_0 = j$. A plaquette astride the new face is wholly in $\Omega_j \setminus \Omega_q$. Indeed that face is five level-q cells from the old Ω_q wall, or seven when $q = k_0 + 1$, and the gap to Ω_j^c is eight cells. The preceding guard therefore reads this plaquette and the new crossing test supplies the shell bound on it. In all three cases the new bound leaves a fixed fractional margin below $\varepsilon_j L^{-2j}$.

For $q > k_0 + 1$, the halo misses both prepared boxes. When $j = k_0 + 1$ both faces are at least five level-j cells from Ω_j, and for $j > k_0 + 1$ both boxes are outside Ω_{j-1}. The halo is now in the prospective layer q. On plaquettes wholly in one of the two original layers at the Ω_j wall the exterior bounds give

$$|\partial U^+(p) - \mathbf{1}| \le (1 - \beta_{\mathrm{s}}/2) \max\{3, L_\flat^2\} \varepsilon_q L^{-2q}.$$

For an astride plaquette translate it a bounded number of bare spacings into the original layer j in the same prospective comparison cube. In a common real gauge eq. 3.cdxxxiii and eq. 3.ccclxvii bound the change in the curl by $C\varepsilon_\star L^{-(2+\alpha)q}$. The variation of the terms of order at least two in the plaquette logarithm is $O(L^{-3q})$. In the compressed range, $q \ge m - O(\log \check{R}_m)$, while $m \ge \check{R}_m$. With the frame comparison in the waiting window, both errors are $o(\varepsilon_j L^{-2j})$. Since $L_\flat < L/2$, the resulting bound has a fixed fractional margin here as well.

The fixed-target real response transfers the resulting bound to the preceding background at a cost $C_L \delta'_j L^{-2j}$. On the full density localization box the preceding background has the actual level-j determining datum. Its localization with the lifted V_j on the pure level-j tower is precisely the background used by the density test. The inner plaquettes of the test have the three-small-cube margin to the boundary of that localization. The joined comparison bounds the additional error in

level-j units by $C\varepsilon_\star e^{-c\check{R}_j}$. Both errors fit the fractional reserve, so the original lower density test passes on the inset-positive real collar chart.

The contour indicators of the old exterior belt use the order-q blocks based between the first and third layers outside Ω_q. Those blocks lie entirely in the collar. The new gauge insertion starts beyond the third layer, on the remaining exterior collar blocks outside Z_q''. All their internal links are tested exterior nonpivots. There are no finer determining nodes in these blocks after promotion, so the prospective axial frame has trivial mean contours. On the local approximate collar ball the links differ from their prospective axial reference by $O(\delta_j')$, also after changing the stage centre. The mean contour map on the full block has a bounded derivative, so these indicators pass at their original ε_j threshold. The soft density on the same contours stays in the integral.

At a prefinal stage the level-q density test has bases in $(\Omega_q^{\sim 4} \setminus \Omega_{q+1}^{\sim}) \cap X$. Its small-cube halo and the fixed row stencils fit in $\Omega_q^{\sim 5}$ and miss Ω_{q+1}, since $a_{q+1} \geq a_q$. They are in the promoted level-q member. Thus the factor reads the fixed V_q and may stand outside that collar integration. At the following executed stage of the same component its bases are precisely the lower density bases, on the actual halo just treated. On an intervening stop it keeps its real value on the recorded outgoing graph. The final top density remains with the fixed top field.

Thus on the passing graded collar branch the old lower density and contour factors can be removed by identities of real integrands. The ordinary completed fluctuation factors keep their original strip coordinates, and the new sharp factor uses the free exterior mask. The bottom-core and fixed-outgoing selectors stay on their real arguments. This reduction uses the original chart and the crossing clauses of the graded rule. The next estimates must admit the remaining analytic weights on the complex collar section with these masks.

At the final stage set $j = m - 1$. For an old approximate cube test whose halo crosses Ω_m, distinguish the actual collar mask and the inherited strip mask as in the two belt comparisons. For the remaining old approximate tests meeting the small-field integration region, apply the implication inside the original ordinary-step integral, using its Gaussian cutoffs on the variables integrated there. The later stage has no independent copy of those variables. If an earlier integral already filed a factor involving those tests, use its actual resulting factor until it has been identified on the retained coordinates.

4.17.1.27. The real finer datum and the collar path. At a transition from level j to $q = j + 1$, put $Y = Z_q''$ and let K be its exterior collar in $\Omega_q^c \cap X$. Fix an admitted prospective real datum and its regular critical configuration U^+ in the frame of the approximate collar test. Choose the common stored rows in that frame, which stays fixed in the comparison. The prospective datum is held fixed while the finer variables vary in the collar. Use the fixed small regularity ceiling of the background theorem, with room for constants depending on L. Let V^0 be the datum obtained by reading U^+ on the preceding determining set. All common rows have their prescribed values. The two joined sequences have the same bare domain and agree except for the enlargement at level q. An old level-j inward bond has an end in the old Ω_q, hence also in the enlarged member. It is absent from the new no-inward determining set. The lower inward masks agree. This is the nested restriction condition for the no-inward determining sets. The old curvature and current scales are no larger, so U^+ is regular also in the old units. A tested plaquette of the old datum at level $q \geq 1$ has a corner in the old member at level q. Its full order-q carrier lies in the member at level $q - 1$ by the gap between the members. Its holonomy is the plaquette of $\mathcal{M}^q U^+$, including the one-step completions of the second-kind bonds. The average bound gives an old datum radius of at most a fixed multiple of the regularity ceiling of U^+. At level zero use the bare curvature bound. Also, the constraints of the old set at V^0 imply those of the new set, since the new rows are obtained by composition on their old fine blocks. It follows that U^+ is critical for the old set at V^0.

Keep the inherited coarse rows at their prescribed values. For each newly imposed coarse row c, both endpoint blocks are outside the old Ω_q, by alignment on the level-q grid. They are inside the

old member of level j. At the first stage the new face is at least three level-q cells from the bottom core. At subsequent stages the gap between the prepared faces exceeds the width of the full double block. Every nonpivot in the double block either meets K and is read by the approximate collar test, or belongs to the common fine rows on the other side of ∂Y. The actual fine field and the induced fine field $\mathcal{M}^j U^+$ therefore differ by at most $2\delta'_j$ on the nonpivots in the frame of that test. Their common coarse value is $W = V_q(c)$.

To check the actual pivot's branch, use the straight corridor product q as its coordinate, with every other fine bond fixed. In each of the two logarithmic cases of the real averaging formula the coarse value is

$$F(q) = \exp_q\left(\sum_a \alpha_a \log_q H_a\right), \qquad \sum_a \alpha_a = 1 - L^{-3}.$$

Here $\exp_q, \log_q$ are the round exponential and principal logarithm on SU(2), with the group logarithm transported by right translation from the identity. The anchors H_a are the transports avoiding the middle bond. On the regular branch their end pieces are the averaged block contours. On the other logarithmic branch use the literal contours. The L straight transports through the middle bond give zero in the logarithmic sum, which accounts for L^{-3}. If neither logarithmic case applies, $F(q) = q$.

Write e for the regularity radius of U^+. The level-j plaquette defects of its induced field on the double block are $O_L(e)$, by the average bound in the member of level j. Sweeping the fixed contour stencils shows that their transports lie within $C(L)e$ of the central transport, and hence within $C(L)e$ of W by the regular averaging formula. Changing the nonpivots by $2\delta'_j$ moves each literal transport by at most $C(L)\delta'_j$. The averaged end contours have the same bound, since each stays in its regular mean chart and reads no pivot. Thus $d(H_a, W) \le C(L)(e + \delta'_j)$ in either formula. If $F(q) = W$ in a logarithmic case, the tangent sum has norm less than π. Its norm therefore equals $d(q, W)$, and the triangle inequality gives

$$d(q, W) \le (1 - L^{-3})\big(d(q, W) + C(L)(e + \delta'_j)\big).$$

The remaining case gives $q = W$ directly. This puts the actual pivot within $C(L)(e + \delta'_j)$ of the induced pivot, since the other bonds of the corridor are already close. Taking the fixed regularity ceiling sufficiently small puts the full double block in the regular case of the averaging formula. In a fixed double-block gauge of the induced field, the derivative in the middle bond is then close to its flat value $L^{-3}I$. The regular one-row inverse gives the sharper bound $C(L)\delta'_j$ for the pivot increment using the prescribed coarse value and the tested nonpivots.

Interpolate the nonpivot logarithms and solve the pivot equation along the interpolation, keeping W fixed. Each double block contains only its own pivot. The regular inverse is uniform on the small one-row chart, so the row logarithms and their derivatives along the path are $O_L(\delta'_j)$. The endpoints are the induced and the actual old datum. The common rows stay fixed. This path lies in the real continuation polydisc about V^0. The old critical orbit therefore exists along the path, with initial orbit that of U^+. This construction starts at the fixed prospective orbit and applies to the full real product ball on which the released nonpivots satisfy the approximate collar bound. For a point of the ball use the regular implicit inverse at the induced field. Its uniform radius and derivative bound give the required pivot values on the whole ball. This constructs the old datum without using the preceding guard on that ball.

Write the old orbit on this path as $(e^{i\mathcal{H}(B)}U^+)^{u_B}$ in bare units, with B the plain determining logarithms relative to V^0. The real Landau response to a row at its top y_c has value and covariant first-difference bounds with factors ξ_y^{-1} and ξ_y^{-2}, respectively, times $Ce^{-ad_{\mathbf{B}}(y,y_c)}$. Here the metric and the tops belong to the preceding joined sequence. The derivative is taken in the plain row logarithm, so its input is the velocity just bounded by $C_L\delta'_j$. The top sum at this rate is bounded uniformly on the separated sequences, and at most eight rows use any one top. Thus on the old

level-j plaquette carriers at the new prepared face,

$$\xi_j\|\mathcal{H}\| + \xi_j^2\|\nabla_{U^+}\mathcal{H}\| \le C_L\delta'_j, \qquad \xi_j = L^j.$$

This estimate sums in the actual metric, with the same bound at the first stage and at the last stage. If the affected stencil is a distance D from the changed row tops, keep half the rate in the sum. The bound at a stencil whose local scale is at least ξ_s is then $C_L\delta'_j e^{-aD/2}$ in the norm with weights ξ_s, ξ_s^2.

The scaled plaquette estimate on this complete stencil gives the following bound for the difference of defects between the old field U^- and the prospective field. The real node gauge preserves the defect norm.

$$\Big|\,|\partial U^-(p) - \mathbf{1}| - |\partial U^+(p) - \mathbf{1}|\,\Big| \le C_L\delta'_j L^{-2j}. \tag{4.cdxlv}$$

For small coupling this is less than $\beta_{\rm s}F_j\varepsilon_j L^{-2j}/4$, the reserve left by the prospective crossing test.
4.17.1.28. The global real collar coordinates. Fix the prospective real datum with its global and local critical orbits admitted. Set $q = j+1$. Write $S_{\rm g} = \mathcal{M}^j U_m^{(n+1)}$ for the averaged global background of the integral, and $S_X = \mathcal{M}^j U_{m,X}^{(n+1)}$ for the center of its approximate collar test. The two joined problems have the same determining rows and data in the interior of X; the difference comes from the outer joining collar. Use the prescribed block axial readings with the same retained node data. On the full blocks these readings include the node factors of the real response.

In bare units let $a_m = M\check{R}_m L^m$. The collar K lies in $\Omega_q^c \cap X \subset O_m$ of eq. 4.cdxliii, which is two level-m cells inside X. Include the order-j average carriers of the fine rows, the full double blocks of the new coarse rows, and those of any inherited coarse row whose averaging stencil reads a changed fine bond. These finite stencils add only CL^m to the distance from K. The old groups of tests at the original Ω_q seam use their full four-layer test-cube enlargements. Before the final stage the preceding wall comparison gives their clearance. At the last stage use the corresponding level-m calculation. For the collar coordinates themselves the full endpoint stencils have the stated clearance at every stage by the prepared-face separations. Their prospective scales are q and, across ∂Y, j. The separation from the preceding prepared face, or from Z_h at the first stage, keeps these carriers out of finer layers. Weighted lengths to the joining collar are at least $cM\check{R}_m$, since no layer has spacing greater than L^m. The real joined comparison, followed by averaging on these blocks, gives

$$\sup_b \Big|S_{\rm g}(b)S_X(b)^{-1} - \mathbf{1}\Big| \le C\varepsilon_\star e^{-cM\check{R}_m} = o(\delta'_j)$$

on the collar read set. The last equality uses the frame drift and $\check{R}_m \ge (\log(\theta_m - c_5))^r$, with $r \ge 2$. The same bound is smaller than δ'_j times any fixed negative power of $\log\theta_j$.

For the same actual nonpivot value the two coordinates are related by the exact product

$$V_j S_X^{-1} = (V_j S_{\rm g}^{-1})(S_{\rm g}S_X^{-1}).$$

Consequently the global sharp cutoff at δ'_j implies the local approximate cutoff at $2\delta'_j$. On the positive local approximate branch the global nonpivot increment is bounded by $3\delta'_j$, which fits the same regular chart before the sharp split. The actual middle bond in each double block is the same in both charts, since the other physical bonds are fixed and the unique regular pivot solves the same constraint with target $V_q(c)$.
4.17.1.29. The sharp guard in the two charts. On the nonpivot bonds put $H = (1/i)\log(S_{\rm g}S_X^{-1})$ and write $V_j = e^{ig_jB_{\rm g}}S_{\rm g} = e^{ig_jB_X}S_X$. Then

$$e^{ig_jB_{\rm g}} = e^{ig_jB_X}e^{-iH}.$$

In each chart let h be the density of Haar measure in exponential coordinates, with the same normalization. Right translation gives on the free bonds

$$dB_{\mathrm{g}} = \prod_b \frac{h(g_j B_X(b))}{h(g_j B_{\mathrm{g}}(b))}\, dB_X.$$

The scale factors $g_j^{\dim G}$ cancel bond by bond. The pivot densities are evaluated on the same solved physical fields. They multiply both sides of the Haar identity, since the retained row targets and the graph of the regular inverse are the same in the two charts.

On the free collar variables the global sharp guard in the first chart is the fixed product ball $\max_b |g_j B_{\mathrm{g}}(b)| < \delta_j'$. In the second chart it is the indicator of this same inequality after substitution. The local sharp guard tests $\max_b |g_j B_X(b)| < \delta_j'$. Either guard implies the local approximate test on these bonds by the centre comparison. To compare the two sharp guards, use the uniform derivative of the logarithm on the regular small chart. For $h_X = C \sup_b |H(b)| = o(\delta_j')$,

$$\big|\max_b |g_j B_{\mathrm{g}}(b)| - \max_b |g_j B_X(b)|\big| \le h_X.$$

In particular, where the guards disagree both maxima lie within h_X of δ_j'. This band already has a bond of size at least $\delta_j'/2$ in either chart, the size used in the sharp-test energy estimate. On the common real fibre the four products of the two guards and their complements sum to one. In changing charts each product travels with its density. A comparison of the labelled operations must also account for the two disagreement terms and the variables their branches keep.

On the failed global branch the cutoff substitution can be checked bond by bond. Write W' for its new coordinate, and use the cutoff ϑ at scale δ_j'. The physical local and global readings are respectively

$$W' e^{i(1-\vartheta)H} \quad \text{and} \quad W' e^{-i\vartheta H}.$$

Here H is the fixed shift of the two prospective centres on the real fibre. The joined estimate gives $|H| \le \delta_j'/8$. Below the start of the cutoff, at $4\delta_j'/3$, the global reading equals W'. Above that start its angle is at least $4\delta_j'/3 - |H| > \delta_j'$. Thus its sharp failure is exactly the complement of the sharp ball in W'. For the approximate local reading the two chord tests in the old and new coordinates agree where $\vartheta = 1$. Where $\vartheta < 1$ both pass by $5\delta_j'/3 + |H| < 2\delta_j'$. Apply this identity on the actual transformed mask, with the derivative of the cutoff map in its Haar factor and with unchanged coarse targets for the pivots.

The domain of a test and the set of independent collar coordinates must be distinguished. The direct graded rule tests a sharp ball on its free exterior nonpivots. The inherited strip coordinates, including the old-wall crossings, keep their ordinary tests in their original chart. Its local sharp failure keeps that prefix before the shift. Under the incident-bond convention, the sharp mask can also include a bond crossing into the old Ω_m. Such a bond belongs to the inherited ordinary chart. Write S_{o} for its reference. The global sharp factor there tests the logarithm of $(V_j S_{\mathrm{o}}^{-1})(S_{\mathrm{o}} S_{\mathrm{g}}^{-1})$, with V_j read in the inherited chart. There is no new integration coordinate for that bond. The whole sharp indicator is the free-ball indicator times the product of the sharp readings on the other bonds of its mask. The ordinary strip bounds at scale δ_j do not by themselves imply these readings at scale δ_j'.

For the final collar, on a crossing of the old Ω_m wall this inherited bond lies in the ordinary plain strip. The bases of both passed and failed ordinary cube tests are inset by a full level-m cell. In level-j units this cell has side $LM\check{R}_m$. The read reaches at most $2LM_2\check{R}_m + 1$ beyond the base, including the incident endpoint convention. This is less than one cell by the choice of M. Hence these masks do not read the crossing bond. Its inside endpoint is in the stored boundary strip. The ordinary bond map on this plain part is just the expression of the physical link relative to the local strip centre, with Haar measure. The explored collar factors belong to the ordinary interior test

mask, and the ordinary rim test excludes the stored strip bonds. The newly completed fluctuation test and the inherited approximate test can still read the crossing on their stated masks.

There is a direct way to keep an additional sharp read on an inherited free bond. Let ρ_b be the smallest retained ordinary upper threshold at that bond, including its factors in the cube and rim tests. Suppose that on its actual tested fibre

$$\left|\tfrac{1}{i}\log(S_{\mathrm{g}}S_{\mathrm{o}}^{-1})\right| + \delta'_j < \rho_b.$$

On the global sharp ball the triangle inequality for the group angle makes all these ordinary upper factors at b equal to one. On this plain strip use the physical group variable with its Haar density. With the ordinary centre fixed in the inherited coordinates being changed, holding the fresh variables fixed makes the re-centering a right translation bond by bond. Thus the new sharp read can be written as a fixed ball in that inherited coordinate, with the exact change in its conditional density. The completed tests on the other bonds remain factors of the original integral. For application we must check the displayed centre bound on the complete crossing stencils, the fixed-centre property on this joint fibre, and the analytic bounds of the resulting density on the strip discs. In particular the difference of the ordinary and prospective centres, rather than the difference of the two prospective centres, enters this bound.

On the ordinary reads with both ends inside Ω_m the preceding comparison gives this difference at order $O_L(\delta'_j)$ in a common axial frame. That size fits any of the retained ordinary thresholds, which are fixed fractions of δ_j. The estimate for the approximate test on a crossing used a direct test of V_j against the prospective centre. It leaves a frame comparison to check for the present re-centering at a crossing. The node factors at both ends of that bond must be those of the inherited coordinate.

Let $x_- = b_-$, $x_+ = b_+$, and let y_-, y_+ be the centres of their two complete level-m blocks. Write $T_W(y, x)$ for the one-step mean contour of a level-j field W in such a block. Its axial reading of the crossing is

$$\mathcal{R}_b(W) = T_W(y_-, x_-)W(b)T_W(y_+, x_+)^{-1}.$$

For any gauge u the covariance of the mean contour gives

$$\mathcal{R}_b(W^u) = u(y_-)\mathcal{R}_b(W)u(y_+)^{-1}.$$

Thus the comparison can be made through the factors at the two block centres. If the two complete read blocks lie in the common joined annulus with its matching rows, the joined comparison controls the real potentials there. At the old wall of the quiet component the two blocks and their order-j carriers are within CL^m of the wall. The outer band is separated from that wall by the quiet-box margin, and the inner boundary lies past the enlargement by two cells of the old member. These margins place the two blocks in the common interior of the annular comparison. The old exterior block lies in the old member of level j, and the clearance from the prepared box puts both blocks in the new member of level m. Orient the crossing from the exterior block to the interior block and write $c = \langle y_-, y_+\rangle$ for the coarse bond between their centres. It is an outward row of the old member at level m, so it is retained even when the fine inward rows are omitted. It becomes an interior row after promotion of the exterior block and has the same value $V_m(c)$. The old exterior centre is a node of layer j by its internal level-j rows. The old interior centre is a node of layer m. Both complete blocks lie inside the common part of the two joined sequences away from their joining bands. Their rows and the levels of these nodes are therefore unchanged in the annular comparison. The average factorization on the full two-block carrier controls the level-j links and the factors at the two centres. At the interior centre of the old sequence the restoring gauge has value $w(y) = v_{j+1}(y)^{-1}$. In the averaged comparison its product with the level-j factor is $w(y)v_j(y) = \mathsf{v}_j(y)^{-1}$, since $v_{j+1}(y) = v_j(y)\mathsf{v}_j(y)$. The exterior centre lies in the old layer j, even though it lies on the level-m lattice. There the product is the identity, as it is at the exterior fine node before auxiliary axialization. The one-step means have uniformly bounded derivatives on the same regular blocks. Applying the last identity to both comparisons with the joined reference shows

that the axial readings of the ordinary and preceding backgrounds differ by at most $C_L\varepsilon_\star e^{-cM\check{R}_m}$ on that carrier. For the comparison with S_{g}, start the real response on the old determining set at the datum induced by the prospective field, in its prescribed frame. The physical row increment $\beta(c)$ is zero throughout the interpolation. The reduced increment $\beta_{\natural}(c)$ can be nonzero because its outward-row conversion reads the changing internal links of the exterior block. Use the response to $\beta_{\natural}$ and restore at each old node y by $v(y)^{-1}$. The datum of the uncorrected response is the desired physical datum turned by v, so this restoration fixes the prescribed value of c and returns both node frames to the inherited ones. At the two centres the average factorization now leaves the identity at the old layer-j node and v_j^{-1} at the old layer-m node, as in the annular comparison. The latter is $O_L(\delta_j')$ from the identity by the local response on the full carrier. This gives the same bound for the difference of the two axial readings. Use a fixed residual gauge for the response to start at the chosen prospective representative. Both restored node values are then prescribed for the whole path.

The original strip frame has a further contour at the exterior endpoint. The ordinary joined strip has nodes at all level-j sites of that block. Its level-j internal bonds keep the actual values of V_j, which determine the old contour from the block centre to the endpoint. The axial condition is imposed at the nonnodes of the ordinary interior blocks. An internal path has no pivot, since each pivot lies in a corridor between distinct blocks. The interior endpoint is axial already. On the prospective block the contour is the identity. The difference of the exterior contour from the identity is therefore bounded by $C_L \max_e |V_j(e)S_{\mathrm{g}}(e)^{-1} - \mathbf{1}|$, where e runs only over the internal bonds of that exterior block. For the native collar mask the changed exterior block next to the old wall lies wholly in the active collar. The members consist of whole blocks, and the clearance from the old wall to the prepared face is greater than the width of this block, also at compressed levels. Every internal contour bond of the exterior block is therefore in the passed approximate test. That test and the comparison of the two prospective centres bound the maximum by $C_L\delta_j'$. This uses the internal paths even when the sharp test on the crossing fails. Undoing the exterior contour gives the desired bound in the inherited frame on the old-wall crossings just described. If using a sharp mask with additional inherited reads, we must check their complete carriers and admit the resulting conditional density in the complex stage space. In this auxiliary axial comparison the stored fields keep their original values. In a physical re-centering of a crossing nonpivot, solve its old coarse constraint for the pivot at the same fixed target. The native exterior block bound and the inherited ordinary bounds put the two-block read in the original regular pivot chart, where the change of the solved pivot is bounded by a constant times the change of the nonpivots. Keep its elimination factor and the Jacobian of the original strip substitution. For a crossing in the ordinary plain strip the old rim factor excludes that strip bond. A completed ordinary fluctuation test can read it, at threshold δ_j; its factor at the crossing is then one on the re-centred sharp ball by the centre bound above.

The induced datum argument also applies to the global critical background itself. Read the global prospective configuration on the global old determining set. Its old units are no larger than its prospective units. As in the localized argument, the complete tested carriers give an admitted old datum and the nested constraints give criticality at that datum. Interpolate the nonpivots of the global chart and solve the corresponding pivots. The modified rows are at level j; the point response sum in level-m units is bounded uniformly in the number of components and in the torus. Thus the real global first background in the collar integral is the regular old orbit on this path. The localized old guard can be checked at each of these physical row values by the localized path estimate. Its value was not used to continue the old orbit along the chart.

At the final stage the inherited strip is kept in the ordinary coordinates. Some of its rows lie close to ∂X, where the estimate comparing S_{g} with S_X need not hold. An inherited double block that reads a changed collar bond was already included in the interior comparison. The ordinary and preceding global backgrounds on the rest of the strip can be compared on a common annulus.

Use an outer box obtained by enlarging X by half a level-m cell and rounding on the top tower grid. Remove the inner box $(\Omega_m^{\sim 2})^c \cap X$. The outer band is in the unchanged top layer, including the neighboring cells outside X. The inner band is in the old layer j. The earlier stages change rows over the old components inside $G_{m-1} \subset H_m$. Even their full row carriers stay inside the removed box by the six-cell gap. The two boundary bands have the widths required for the joined comparison. At the physical collar value, the ordinary and preceding global problems read the same rows and data throughout this annulus. Its interior contains the ordinary strip rows touching the old Ω_m and their full double blocks, including those reaching across ∂X. This gives the comparison of the ordinary orbit in its own gauge on those stencils. The inherited Schur complement and the retained rim and collar indicators are evaluated in the original variables of the strip.

4.17.1.30. The real endpoint triples. At a stage of the depth-m problem set $q = j + 1$ and put $e_l = \check{R}_l^2 \varepsilon_l$. This allows the complete averaging footprints at the original exterior walls of a compressed stage. The tests with sharper thresholds keep those thresholds.

The input at a point of a history includes the fields of the operations still carried by it. A datum plaquette uses the actual determining links and, for a completed bond, the average of the lower field on its full double block. These values agree with the fields in the tests by the retained averaging constraints. In the convention excluding inward rows these plaquettes exhaust the datum tests. For each test place in a stopped component use its least-level departure. If the component is untouched, or the full footprint misses the inset of its stage test region, the ordinary density test supplies the bound. The same ordinary test is used at untouched higher levels and on the unchanged action top. An inner footprint in a tested shell uses the last positive stage test at that departure. At a restored core the bound comes from the retained reference cutoff and the surrounding ordinary tests.

For a departure at the sharp collar split after n integrations, put $j' = i_\flat + n$, where i is the level of that operation. The retained positive stage test is $\chi_i^{(n+1)}$. A level-j' test in its inset with a corner in the collar uses also the retained approximate bound at $2\delta'_{j'}$. In the translated coordinates this bound is on the reconstructed field of the localized collar chart. The failed sharp indicator is carried as a separate factor. The ordinary test supplies a footprint outside the inset. At the promoted level the retained coarse row is fixed by its averaging constraint. In the direct exterior collar rule, a retained determining link of level j' has no endpoint in the next old member. A completed bond uses both full blocks outside the corresponding next member. Thus the determining reads use the collar bound on its exterior slots and the retained values on the other slots. The original strip tests remain the suppliers for the old-wall fluctuation reads.

These choices use the tests carried at the relevant moment. Before the first stage use the untouched datum. While a positive stage test is carried it supplies the ordinary assignment. After removal and before integration the collar assignment uses the new positive stage test and the approximate collar test on the old collar variables. The new ordinary assignment uses the new positive stage test on the promoted datum. A standing departure below the current waiting window keeps its earlier determining reads and averaging completions. Gauge moves conjugate the holonomies. A refresh with the inner datum retained leaves its test values in that inner slot. Where restoration replaces the field, the tests of the restored datum provide the new bound.

The witnesses on the complete footprints give $2\psi_l \varepsilon_l$ for the datum defect. Here ψ_l is $O(1)$ for an ordinary witness or a restored core and is bounded by $C(\log \theta_l)^r$ on the remade shells. The latter bound uses $L_\flat^2 < L$ and the compressed interval of length at most $\log_L \check{R}_{k_0+1}$, with the frame comparison of the running scales. Thus each test gives a bound Ce_l directly. Fix an entering point on these retained tests and on the constraints with coarse target V_q. This is the input for varying the collar. To remove the preceding guard on an enlarged support, use the separate comparison in §4.17.1.25.

Let U_{in} denote the regular global old configuration at that input. The datum defects are below the fixed real existence ceiling at weak coupling. Apply the real profile estimate in its layer form.

In bare units it controls $L^{2\lambda(p)}|\partial U(p)-\mathbf{1}|$ and $L^{3\lambda(b)}|J^0(U)(b)|$ at each corner or endpoint by the profile there, where λ of a stencil is its largest corner layer. For the datum bounds just obtained the profile has the form

$$C\sup_l e_l \exp\bigl[-\delta\, d_{\mathbf{B}}(x,\mathcal{L}_l)\bigr], \qquad \mathcal{L}_l=\Omega_l\setminus\Omega_{l+1}.$$

The place of a tested level-l plaquette is in $\mathcal{L}_l$, and its corners lie in layers $l-1,l$. From layer s the path to this read crosses the intervening layers, giving distance at least $c(|l-s|-2)_+$. The frame bounds make e_l/e_s grow at most polynomially in $|l-s|$. Hence the profile in layer s is at most $C'e_s$. The zeroth layer uses the bare datum tests. Apply the same profile on both stage sequences.

In the prospective datum all holonomies below level j are unchanged. At level j, the new first-kind row set is a subset of the old one, and the second-kind completions still use the same level-$(j-1)$ layer. At level zero there is no completion from a finer layer. Above level q the original row values and masks are retained. For a completion at level $q+1$, its full two-block read stays in the old Ω_q, by the old gap from Ω_{q+1} to Ω_q^c. Thus the enlargement at q does not change that completion. At higher levels neither layer of the completion changes.

Every tested holonomy at level q equals the plaquette of $\mathcal{M}^qU_{\mathrm{in}}$ on the relevant complete stencil. A determining row that met the old Ω_q keeps its value. Each newly imposed row has both blocks outside the old Ω_q and within the old level-j member. Its retained constraint reads the old determining V_j on these two blocks. For a second-kind bond the two blocks are outside the prospective member at q and in the preceding layer, so they also use the old level-j values. In either case the identity with the average follows from the actual retained constraint or its one-step completion. For each tested plaquette the order-q carrier stays inside the unchanged level-j member by the separation of the prospective sequence. The level-j profile and the adjacent-scale conversion give bare curvature at most Ce_jL^{-2j} on that carrier. Averaging there gives $C(L)e_j\le C'(L)e_q$ for the datum defect at the promoted level. The artificial face lift of the localized problem does not enter this global calculation. We have thus obtained the levelwise datum estimate for the fixed prospective global orbit and, by the weighted maximum, its normalized curvature and current bounds with Ce_s in layer s.

For the varied old datum, begin at the averages of this prospective configuration on the old determining set. For an old level-l tested plaquette, $l\ge 1$, its order-l carrier is inside the old member of level $l-1$. The prospective scale on this carrier is at least $l-1$. In changing its units to $l-1$ the powers $L^{-2(s-l+1)}$ absorb the frame variation in e_s/e_{l-1}, so averaging gives a defect bounded by $C(L)e_{l-1}\le C'(L)e_l$. At level zero the bare profile gives the estimate directly. Now vary the actual old collar coordinates in the regular fibre chart. Only level-j rows move, by $O_L(\delta_j')$ including the reconstructed pivots. Only tests of levels j and q can read these rows, either directly or through a one-step completion. On their full double blocks the regular average and the product of the four group factors change by $O_L(\delta_j')$. This is smaller than the datum allowance Ce_l at these adjacent levels. The old orbit on the varied fibre has the same layerwise bound from the weighted maximum. These are bounds for the two endpoints from the entering datum profile of the history. In using them through the stages, take the profile from the actual retained tests at each entrance, as in the levelwise datum bound. Repeatedly multiplying the adjacent comparison constant would not give a uniform profile.

Consider now any stage clause of scale s for either real endpoint. In a prepared layer and in an untouched higher layer its reading set is in the actual member at scale s. In the compressed clause of an original layer i, the assigned scale is $s=j$ for the old stage and $s=q$ for the prospective one. On the remade component the actual member at that scale contains the reading set, since the prepared box is outside Ω_{k_0+1}. For a reading on an unchanged part, use at least its original scale i. The loss of scale $s-i$ is at most $\log_L \check{R}_{k_0+1}$, by the compression identity. Thus one can use the actual member at scale $a\le s$ with $a=s$ except for this possible compression loss. Use the same

calculation at an earlier address whose determining regions are contained in the endpoint sequence, with the compression interval of that address.

For the pointwise bounds at scale s, changing from the scale a costs at most $L^{3(s-a)}$. This accounts for the physical current, whose scale power is three, as well as the curvature, whose power is two. At the plain triple $A' = 0$, so the two potential clauses hold identically. For each of the tower clauses, the actual level-p tower on a localization domain is formed by intersecting the stage sequence, truncated at p, with its localization tower. Hence it is subordinate, even if p exceeds the layer of the read. The restriction identity eq. 3.cccxciii identifies its real background at the own averages with a gauge copy of the restriction. It therefore has the same curvature and the same current at every full current stencil. In level-p units the current gains $L^{3\mathsf{p}}$ relative to bare units. This gives the scale required in the tower clause, since its allowed factor $L^{s-\min(\mathsf{p},s)}$ is at least one. The curvature factor in that clause simplifies to L^{-2s}.

For a local gauge cube of side $C_{\mathrm{g}}ML^s$ wholly in the actual member of level a, use the gauge estimate at $b = \max\{0, a-1\}$. The halo of thickness $8\rho L^b$ lies in Ω_b by separation, or in the ambient bare torus at $a = 0$. The powers $L^{-2(l-b)}$ and $L^{-3(l-b)}$ for its actual layers l absorb the frame drift. Thus the curvature and current in those units are bounded by Ce_a on their complete halo stencils. The side in level-b units costs $O(ML^{s-b})$, and conversion of the potential and its first differences costs at most $L^{2(s-b)}$. The normalized gauge bound is $CML^{3(s-b)}e_a$. Use the torus side condition $2C_{\mathrm{g}}ML^s + 16\rho L^b < \mathsf{s}_T$. The fixed curvature ceiling and the product of the gauge radius in level-b units with Ce_a fit the smallness requirements at weak coupling. Restrict the resulting gauge to the prescribed read set.

The frame bounds across the waiting window give $\check{R}_{k_0+1} \le C(\log\theta_s)^r$ on the compressed interval, and $e_a \le Ce_s$ there. Consequently the pointwise and tower bounds, normalized at the nominal scale, are at most $Cg_s(\log\theta_s)^{\mathfrak{p}_0+5r}$, and the gauge bounds are at most the same quantity times M. The stage choice $q_{\mathrm{rad}} \ge \mathfrak{p}_0 + 7r + 1$ for $\alpha_{0,s} = C_0 g_s(\log\theta_s)^{q_{\mathrm{rad}}}$, and the positive coefficient floor $1 - 4\beta_{\mathrm{s}}$ for the choice $0 < \beta_{\mathrm{s}} < 1/4$ in the allowed window, put the plain triples inside half the radii for small coupling. At earlier hereditary addresses use their wide subordinate sequences, the full gauge cubes, and their fixed positive coefficient floor and nonnegative lifts. The same bounds fit the smaller adjacent running radius, with its bare-level value at level zero, and the half radius of the fixed local regularity clause. This verifies the real clauses on the specified carriers.

4.17.1.31. The complex substitutions in the collar integral. Keep the real factor U fixed and use independent complex potential and current coordinates. The source for the old critical problem is the nonlinear datum increment on the full double blocks of the collar. Solve the regular one-row inverse at the applicable background. For a free field B this gives the completed logarithmic datum $B' = g_j \mathsf{C} B - \mathsf{h}\widetilde{\mathsf{D}}(g_j \mathsf{C} B)$. Take its corresponding reduced datum for the reduced response. On the complex chart the inverse gives $\|B'\|_\infty \le C_L g_j \|B\|_\infty$, so the source in the box $\|B\|_\infty < Cp_0(g_j)$ is within the small response bound. Using the nonlinear row is necessary for the equality at the physical endpoint.

For the current increment the reduced first variation has a local linear term in addition to its supported parts. Write $D_{\mathrm{lin}}B' = \hat{Q}^{\mathsf{T}}\mathsf{a}B'$ for this row term. The supported bracket of the raw response is $\mathbf{F}^\flat + D_{\mathrm{lin}}B'$. Gate each row of the linear term by the product of the switches in a connected set containing its complete source and output stencils. Include the plain-data and parent carriers in this set. The neighbor margins and the one-step row charts give bounded size on the aligned standard grain. Denote the resulting linear term by $D_{\mathrm{lin,s}}B'$. It agrees with $D_{\mathrm{lin}}B'$ at full switches, and a nonzero row term lies in one active wall component. In the current formula use

$$\mathbf{J}_s = \mathsf{f}(-i\xi\ \mathrm{ad}_{\mathbf{H}})^{-1}\big[\mathbf{J} + (\mathbf{F}^\flat + D_{\mathrm{lin}}B') - D_{\mathrm{lin,s}}B'\big].$$

The raw formula gives exactly the current of the perturbed real configuration at full switches. At a cut the supported bracket and the gated linear term use only their respective components. The inverse f^{-1} acts bond by bond, so the increment from $\mathbf{J}$ is supported on those components. The

product of the bounded number of switches costs a fixed factor in the current bound. Use this continuation to form the component increments j_c alongside the localized potential increments. In the weighted current estimate write $D_{\mathrm{lin,s}} = D_{\mathrm{lin}}G_s$, where G_s multiplies each source row by its carrier product. The increment from $\mathbf{J}$ is the inverse f applied to $\mathbf{F}^\flat + D_{\mathrm{lin}}(I - G_s)B'$, plus $(\mathsf{f}^{-1} - I)\mathbf{J}$. The local row bound for $\hat{Q}^{\mathsf{T}}$ and the fixed switch cost bound the added row term in cubic current units. The small exponential chart bounds the last term by the weighted response times the current radius. The gauge turn has the same estimate for the additional factor $\mathrm{Ad}(u) - I$.

For a wall component $\mathfrak{w}$, evaluate the response with cube switches $s\mathbf{1}_{\mathfrak{w}}$. Call its potential $\mathbf{H}_{\mathfrak{w}}$ and its current increment $\mathsf{j}_{\mathfrak{w}}$, where the increment is the current in the displayed formula minus the input $\mathbf{J}$. Use the same component parameter in both output sums,

$$\mathbf{A} = \sum_{\mathfrak{w}} \lambda_{\mathfrak{w}} \mathbf{H}_{\mathfrak{w}}, \qquad \mathbf{K} = \sum_{\mathfrak{w}} \lambda_{\mathfrak{w}} \mathsf{j}_{\mathfrak{w}}.$$

The independent input current is kept in its original slot. The component parameter multiplies the response after solving the equations. This is the interpolation used in the common radius budget.

Use one levelled triple on the union of the carriers of the inherited reads, restricting it to each reader's address. If $W = e^{i\eta_t \mathbf{A}}\mathbf{U}$ is the unlevelled configuration, take $u(y) = v[P; \mathbf{A}](y)^{-1}$ at the pillar top y, using the same switched potential $\mathbf{A}$ that defines W. At a stored site a of this pillar take

$$u(a) = \tau[\mathbf{U}](a)^{-1} u(y) \tau[W](a).$$

Indeed $\tau[W^u](a) = u(y)\tau[W](a)u(a)^{-1} = \tau[\mathbf{U}](a)$. Write $\mathbf{A}^\circ$ for the relative logarithm in $W^u = e^{i\eta_t \mathbf{A}^\circ}\mathbf{U}$. Use the same analytic gauge in the current substitution

$$\mathbf{J} + \mathbf{K}^\circ = \mathrm{Ad}(u)\,(\mathbf{J} + \mathbf{K})\,.$$

At the physical endpoint the corrected configuration and current agree with those of the actual old critical orbit in its adapted frame. The transport identity keeps the spectators of each earlier term in their prescribed frames. Each inherited term uses its own attachment. The new crossing test reads the fixed prospective datum and adds no pin.

On the integrated strip fields the substitution in an inherited potential uses the scalar multiplier $\lambda_{\mathfrak{w}} s(\square_b)$. It multiplies the far argument and serves as the switch for an unchanged near argument. The real cutoffs act in their integration charts. Keep the inherited Schur form and take the difference of its two evaluations as a potential on these discs. Its two evaluations use the same stored variables. The shift of the local free coordinate has a separate source radius of the form $c(\log \theta_j)^{-e_y}\delta'_j$. In the local sharp rule, keep the free collar coordinate B_X in its original real product ball $|g_j B_X| < \delta'_j$. For a free shift y use the global increment

$$g_j B_{\mathrm{g}}(B_X, \mathsf{y}) = \frac{1}{i}\log\!\left(e^{ig_j B_X} e^{-i\mathsf{y}}\right)$$

on each released nonpivot, and then complete the pivot at the fixed coarse target. For the physical value of y, take $e^{-i\mathsf{y}} = V_X V_{\mathrm{g}}^{-1}$ with V_X, V_{g} the local and global centres in the same frame. This is the orientation for left link logarithms. Its bound is $C\varepsilon_t(\log\theta_t)^C e^{-cM\check{R}_t}$ in a component of level t. In its waiting window θ_j and θ_t are comparable with one logarithm. The exponential therefore puts the actual shift inside the source disc at every stage, including the bottom. On a complex section its source is the localized shift map formed on that section.

On the real free-source disc the trial global angle is at most $\delta'_j + |\mathsf{y}|$ in this same ball. Combining with the actual centre comparison gives the approximate bound $2\delta'_j$ on its full free mask. The old completion and rim tests act on the original strip coordinates. At fixed admitted prospective datum the guard implications, including the crossing reserve, apply on this entire real ball. This permits the use of the same integration domain for all the real trial shifts. At the physical shift it gives the original local sharp integral. The source is then continued in the integrand while retaining those real integration coordinates.

On the passing local-sharp branch the smooth stage Haar factor has a separate calculation. Write $z = g_j B_X$ and $z_{\mathsf{y}} = g_j B_{\mathrm{g}}(B_X, \mathsf{y})$. For the Haar density h normalized at zero, the change from dz_{y} to dz has logarithm

$$L(z, \mathsf{y}) = \log h(z) - \log h(z_{\mathsf{y}}).$$

Indeed right translation preserves Haar. The logarithms are taken on the fixed small chart where h is nonvanishing. Its evenness gives $L(0, \mathsf{y}) = -\log h(-\mathsf{y}) = O(|\mathsf{y}|^2)$. The difference $L(z, \mathsf{y}) - L(0, \mathsf{y})$ vanishes at either zero argument. Integrate the mixed derivative along the two segments in the product-logarithm chart to bound it by $C|z||\mathsf{y}|$. On the fixed real ball $|z| < \delta_j'$ and the independent shift disc this is at most $C(\delta_j')^2 (\log \theta_j)^{-e_y}$. On an enlarged complex section use the actual bound $g_j B_*$ for $|z|$ on that section.

When two moves use the same free link, let z_0, z_1, z_2 be its successive logarithms in their actual order. The two smooth log factors add to $\log h(z_0) - \log h(z_2)$. Subtract its centre at $z_0 = 0$, with the intermediate value $z_1(0)$ induced by the first map. Keep the centre once on the shift carrier. After substituting the localized shifts its series has two or more shift factors for a single zero-centred translation, while the difference has at least one. For the composition use the ordered product-logarithm chart and the same rooted union of the shift carriers. A cutoff Jacobian between the smooth changes is carried as its own factor.

For the global sharp branch keep B_{g} as the variable of the fixed sharp ball on the free nonpivots. Its real local approximate test on those bonds is then identically one. In comparing with the analytic integral having a free shift source, the candidate for this fixed ball is the source value zero with its integration variable identified with B_{g}. The physical integral with a local sharp guard instead uses B_X as the variable of the fixed ball and the actual shift in the analytic factors. The cutoff stays fixed in both representations on the free coordinates. In the direct graded rule the sharp mask is confined to the free exterior nonpivots. The inherited crossing coordinates remain in the ordinary strip integral with their completed tests. A test on the broader incident mask gives a separate real kernel. If the full sharp mask also reads an inherited bond, we must show that its exact pulled-back indicator is among the fixed real factors of the analytic integral, or prove it equals one on the support being integrated. In the expansion with Gaussian tails each real cutoff uses its prescribed carrier and accepts the corresponding smaller ball. Freezing the real datum alone leaves those carrier and tail checks to be made. The failed global branch uses its own real strip map with the transported tests. Where that map has a cutoff, its derivative enters the density in addition to the Haar factors.

4.17.1.32. Substituting the physical shift in the stage logarithm. Keep the shift y independent while forming the analytic logarithm of the collar integral on the fixed real domain. On the admitted graded section the physical value at an exterior nonpivot b is

$$H[P](b) = \sum_W H(b; W; P|_W).$$

Each summand reads a decoupled response to the localized difference of data. Its full carrier W joins b to the boundary of the localization. At an ordinary strip the resulting lower bound on the length is $d_j(W) + 1 \geq \check{R}_j$ in the strip units. In a stage it is $d_t(W) + 1 \geq \check{R}_t$ in the component units. In the respective units the pieces have bound $C(\alpha_{0,j} + \alpha_{1,j}) e^{-cM(d(W)+1)}$. This construction requires the actual endpoint centres and their decoupled reads on the common graded section. The scalar annular bound on their difference alone would give no such carrier assignment.

Let $F_X(\mathsf{y})$ be a carrier term of the free-shift logarithm. For a shift piece indexed by $a = (b, W)$ write $h_a = H(b; W; P|_W) e_b$. The contribution using a finite nonempty set A of shift pieces is

$$\sum_{J \subset A} (-1)^{|A|-|J|} F_X \left(\sum_{a \in J} h_a \right).$$

Assign it to $X\cup\bigcup_{(b,W)\in A}W$, with the fixed enlargements of the stage reads. Each nonzero difference uses only the shift slots read by F_X. If the full deformation $\mathsf{y}=\sum_{a\in A}t_a h_a$ is admitted for $|t_a|<R_a$, $R_a>1$, Cauchy's estimate bounds this mixed difference by the bound for F_X on the deformation disc times $\prod_{a\in A}(R_a-1)^{-1}$. Indeed the alternating sum selects exactly the Taylor terms of positive degree in every t_a.

The exponential bounds on the response pieces and their lower length allow part of the decay to be spent on the larger union carrier. In the stage sum use the rooted closing load

$$\sup_{\Delta}\sum_{a=(b,W)\colon c(b)=\Delta}\frac{e^{Cr_{\natural}\varrho_{\mathrm{a}}\#W}}{R_a-1},$$

where $c(b)$ is the anchor cell of the shift slot and the exponent is the graded carrier price. Denote this load by $\varepsilon_{\mathrm{cl}}$. The dilation radii must fit in the free-shift disc and satisfy $CN^*\varepsilon_{\mathrm{cl}}\le 1$, where N^* bounds the number of anchor cells of one component. Use the native stage collars and the island hulls as exempt boxes, with the stage separation, bounded hull multiplicity and adjacent grades differing by at most one. The separated-component packing estimate applies to the tree of X with its prescribed trace enlargement. Include the full anchor reads in checking this enlargement. If the tree Γ is counted at level m and the operation is at level t, the weighted count of anchors, with weight $\epsilon^{(D-1)_+}$ at wall distance D, is bounded by

$$N^*\left(1+\frac{4|\Gamma|L^{m-t}}{\mathsf{N}}+\frac{|\Gamma|+1}{L\mathsf{N}}\right),\qquad 0<\epsilon\le c.$$

The weight is one for a directly read anchor at wall distance at most one. A fixed larger wall distance costs only a fixed inverse power of ϵ. In component units this gives $CN^*(1+d(X)/\mathsf{N})$ for the directly read anchors. For graded trees keep the indicated scale conversion when charging the length. For fixed X the sum over subsets of shift pieces is bounded by the product of one plus their weighted Cauchy costs. Its logarithm is at most the sum of those costs. The anchor count thus gives a bounded prefactor and a loss $O(1/\mathsf{N})$ in the spatial rate. In summing over terms refiled at the same enlarged carrier, use the anchored tree attachment count and the summed-to-pinned norm estimate of the stage expansion. The spatial rate losses add over the N stages, whereas the bounded prefactors multiply individual stage amplitudes before those amplitudes are summed.

Keep $F_X(0)$ on X. The nonempty anchored differences sum to $F_X(H[P])-F_X(0)$ by telescoping, first for finitely many pieces and then by absolute convergence in the closing norm. The resulting terms, with these enlarged carriers, are the ones passed to the next stage and to the source oscillation norm. The integration domain and the real factors in the stage law stay those used in forming the free-shift integral.

If the inherited crossing coordinates are re-centred, write $\mathbf{z}$ for the old combined strip and collar coordinates and $\widetilde{\mathbf{z}}$ for the coordinates with fixed sharp balls. The ordinary centre can depend on the new collar variables even when it is fixed in the inherited variables being translated. Its first derivative in those collar variables contributes to the linear part T of $\mathbf{z}$ in the new coordinates. For old precision D, the corresponding quadratic becomes $\mathsf{T}^{\mathsf{T}}D\mathsf{T}$, with any constant shift accounted for in the mean and the scalar. If $D\ge\gamma I$ and T has a bounded real inverse, the new real floor is at least $\gamma\|\mathsf{T}^{-1}\|^{-2}$. Its covariance is $\mathsf{T}^{-1}D^{-1}\mathsf{T}^{-\mathsf{T}}$. These identities show where the crossing correction enters the Gaussian estimates. In particular the linear mixing need not carry a small coupling factor. We must bound its local matrix entries and the nonlinear remainder on the declared sections, including the cut and switched sections, before using the stage expansion for this re-centred density.

Use the ordinary endpoint frames for the substitution in the strip coordinate. In physical logarithmic units write $h(\beta)=\frac{1}{i}\log(S_{\mathrm{g}}S_{\mathrm{o}}(\beta)^{-1})$, where $\beta=g_jB$. The response in reduced row coordinates has a coupling-independent analytic radius. To use that radius here, suppose the completed row map, the ordinary strip reference and the two endpoint readouts give this same fixed-radius property for h on the section, say $\|\beta\|_\infty<R$, with $\|h(\beta)-h(0)\|_\infty\le CR$ there. Cauchy's estimate

along the line through β then gives

$$\|h(\beta) - h(0) - \mathsf{L}\beta\|_\infty \le 2CR^{-1}\|\beta\|_\infty^2, \qquad \|\beta\|_\infty \le R/2,$$

where $\mathsf{L} = Dh(0)$. The logarithm of $e^{ig_j a_{\mathrm{new}}} e^{ih(g_j B)}$ gives the old strip coordinate. Bound all the combined coordinates by T, including the ordinary slots left untouched. Take $g_j T \le R/2$ and the product logarithm in the small chart. If $\|h(0)\|_\infty \le g_j d$, then after subtracting $a_{\mathrm{new}} + \mathsf{L}B + h(0)/g_j$ the remaining scaled coordinate r satisfies

$$\|r\|_\infty \le C g_j (R^{-1}T^2 + T(T+d)).$$

The first term is the Cauchy remainder and the second comes from the product logarithm. The remainder is supported on the re-centred slots. If D has bounded absolute row sums, the change from this remainder in the quadratic is bounded by $CN_{\mathrm{cr}}[(T+d)\|r\|_\infty + \|r\|_\infty^2]$, where N_{cr} counts those slots. The log of the Haar quotient costs at most $CN_{\mathrm{cr}} g_j^2 (T+d)^2$ in the small exponential chart, since the log density has zero first derivative at the identity. For fixed R and logarithmic T, d these remainders are small per crossing. Localization still requires the complete carriers and decay of the coefficient maps.

For example, a uniform derivative bound $|\partial_c h_b| \le Ce^{-\mu d(b,c)}$ on the fixed source disc gives a second derivative bound on its half-disc by Cauchy in one coordinate. Interchanging the coordinates gives both exponentials, so that their geometric mean bounds the same derivative:

$$|\partial_{c'}\partial_c h_b| \le \frac{2C}{R} e^{-\mu[d(b,c)+d(b,c')]/2}.$$

The second-order remainder of h_b is bounded by C/R times the square of the corresponding weighted sum of $g_j|B_c|$. Divide by g_j in the scaled coordinate and include the product logarithm as above. The source radius is needed here for the centre map and its derivatives. The old entries are still evaluated within their original strip discs.

On a fixed real ordinary chart the input to this centre map can be formed in physical units. Solve the one-row pivot equations on their fixed regular charts. On the joined sequence a row reads a retained row, or the lift of a named parent row. The latter is the identity or the oriented parent link, so it is holomorphic in the parent link on the same fixed geometry. Take logarithms relative to the ordinary datum at zero and form the reduced row input. These local operations preserve a fixed small disc where the regular row and lift charts have uniform room. Use the holomorphic critical family of the ordinary joined sequence at its admitted real datum. Read the averaged endpoint contours in the ordinary strip frame. This gives the centre germ at that fixed real reference, using the real identification of the critical family at its physical data. The annular comparison supplies its value at zero. To use this construction on cuts, each parent row and the complete endpoint stencils must remain in the prescribed carrier, and the ordinary reference itself must be provided by the compatible cut rule. Exponential real comparison of two references does not give the exact local dependence required of that rule.

For the ordinary localized branch at depth $q = j+1$ the strip join is formed on $W_q = Z_q \cap \Lambda_j$, with the corresponding cell intersections. Use $W_1 = Z_1$ at the first ordinary step. For $q > 1$ this region lies in the original Ω_j. The earlier preparations change members at levels at most j only within the old live sets contained in Z_j. Those changes miss W_q. The preceding sequence has yet to change the members at levels q and above. Thus the joined row masks agree, including which collar rows are lifts. Their values on the real fibre come from the actual inherited and completed physical datum. With that datum and the same first-member action they give the same localized critical orbit.

Form the input at the supplied global prospective pair restricted to the first member of the ordinary join. The ordinary join is finer than the prospective sequence: each joined member is contained in the original member of its level, and the stage enlarges the latter. An inward bond omitted from the joined set has an endpoint in the next joined member. That endpoint lies in

the next prospective member, so the bond is also absent from the prospective no-inward set. The removed-row condition in the restriction argument is therefore satisfied. Extend variations at fixed joined averages by the unchanged exterior configuration. The original averages remain fixed, and every interior bond of a plaquette straddling the true first member is fixed by a joined bare row. The action difference of the extension equals the difference of the restricted action. Thus on the real critical slice the restriction is critical at its own averaged datum. The complete boundary blocks use their original collar levels on the prospective pair.

Use the tower transport of the complex configuration on these alignment collars. Let D_* be the averaged datum of the unaligned restriction on the ordinary joined rows, and let D_o be the target ordinary joined datum in its aligned frame, formed from the physical collar variables and their retained rows. With $g = g[\mathbf{U}]$, the source at the unaligned response pair is

$$b_o(c) = \frac{1}{i}\log\bigl(D_o^{g^{-1}}(c)D_*(c)^{-1}\bigr).$$

The restricted pair used in the response keeps the independent current on complete stencils and the restricted-action variation on its true incomplete stencils. On the fixed regular physical row charts the inverse pivot map changes the prescribed rows by at most $C_L\|\beta\|_\infty$. The aligned zero-increment comparison and the bound on the complex tower transport then give $\|b_o\|_\infty \le C_L(\varepsilon_1 + \alpha_1 + \|\beta\|_\infty)$ on those charts. Here ε_1 bounds the real datum and α_1 the scaled complex potential on the alignment collars. Where the ordinary row targets are formed on this same chart, a fixed small physical source radius and small coupling put this input in the reduced response disc. The real response with the endpoint factors identifies the ordinary localized centre at full parameter values.

In the physical row conversion use the nonlinear one-row correction at $V = \mathcal{M}^j\mathbf{U}$. It is holomorphic at complex V in the admitted double-block chart and keeps the coarse value $\mathcal{M}(V)$ exactly. Only the rows released by the stage are replaced by that completed field. The inherited inward crossing and its ordinary pivot do not add coordinates to the no-inward ordinary datum. Its other actual rows and its lifted parents retain their prescribed reads. If r_{piv} is the physical radius of the regular inverse, take a smaller fixed radius inside r_{piv} so that the bound for b_o, multiplied by the constant of reduction, is below half the native response radius. The terms $\varepsilon_1 + \alpha_1$ fit the other half of this allowance at weak coupling. The fixed disc here is for the centre map. The inherited actions are evaluated on their own running discs.

On the prospective pair take the running bounds on the full ordinary read and on the original parent blocks of the artificial rows. Use ε_* for the real plaquette radius in layer units, α_* for the complex potential and first difference, and γ_* for the independent current. The full tower averaging estimate puts each parent and endpoint average within $C_L\alpha_*$ of its unitary value in the same frame, uniformly in the tower depth. After real gauge on a full one-step block, the logarithms of the real reference are $O_L(\varepsilon_*)$. The complex change and a fixed reduction of the physical source disc therefore keep the pivot and contour maps inside the one-step analytic charts. In particular the complete pivot derivative is near its flat invertible value on these discs. This supplies the uniform chart room for the fixed-size collar source. It also bounds the derivative of the endpoint mean on the output of the response, after reducing the source disc by the fixed response constant. For the complex gauge identities use the one-step covariance on each complete double block. In its small reference gauge let t bound the link logarithms and let $\varkappa_{\mathrm{end}}$ bound the condition numbers of the gauge at the coarse endpoints. The condition is

$$\varkappa_{\mathrm{end}}\bigl(e^{4(L-1)t} - 1\bigr) < \omega_*.$$

The tower transport bound keeps $\varkappa_{\mathrm{end}}$ bounded. The running radii and a fixed reduction of the source disc put t below the resulting threshold. This checks covariance for the actual complex contours and pivots. For the collared first member form the alignment and parent averages on their full original collars before restricting the gauge to the chosen first member.

Put $b_* = \varepsilon_{\mathrm{D,s}} e^{-32\varkappa}$, the reduced source and current radius of the switched response. Choose the physical collar radius so that its contribution to $\|(b_o)_\natural\|_\infty$ is at most $b_*/4$. In addition, take it small enough that the response estimate times the derivative bound for the endpoint read fits in half the fixed contour and product-logarithm chart. The source from the base is bounded by $C_L(\varepsilon_* + \alpha_*)$, including the conversion. The restricted pair has current radius at most $C_L(\gamma_* + \varepsilon_* + \alpha_*)$: use the independent current on its full stencils and the variation of the restricted plaquettes on the true boundary. For the latter estimate the complex curvature bound and the bare-layer units give the three powers of the bare spacing in the current norm. At sufficiently small running radii the base part and the current thus fit below $b_*/4$ and $b_*/2$, respectively. The joined gauge condition follows by the local truncation and restriction of the enlarged gauge cubes. These are bounds on one fixed-real-factor section, with independent current. They allow the whole fixed collar source disc before introducing the old running argument multipliers.

For the ordinary joined class the pointwise bounds on the prospective pair pass to the smaller layer spacings. Use the complete prospective gauge cubes as in the ordinary strip restriction. If a cube of the join lies in a coarser prospective layer, cover it by the allowed larger cube in the two adjacent prospective layers and restrict its real gauge. This uses the enlarged family of §2.2.4.1 on the prospective carrier. For the ordinary response at depth $q = j + 1$ use the join of the strip and the original sequence on $Z_q \cap \Lambda_{q-1}$, with parts of levels $q, q-1$. At $q = 1$ the join has the single part Z_1. Use the first member of the actual ordinary operation. The full first member and the version trimmed to the collared first member give different boundary actions. On a fixed joined section use the independent current on complete stencils. At an incomplete stencil of the first member use the first variation of the restricted action. There are at most six retained plaquettes at a bond, and such a boundary bond is in the bare layer of the separated join. Thus its bare current is bounded by the curvature radius there. This is the same restricted current prescription as in the ordinary strip comparison. The joined response uses the torus and native walk floors at this depth. The ordinary kept strip quadratic uses the separate conditioned one-step walks. The full-depth collar form uses the native full-depth operators.

When a comparison changes the first member itself, the change of its boundary current is local. For nested first members $D^- \subset D^+$, let $J_{p,\mathbf{U}}$ denote the contribution of a single retained plaquette to the first variation in bare units. At a bond of D^- the physical currents differ by the sum of $J_{p,\mathbf{U}}$ over plaquettes incident to that bond and retained only in D^+. This is an identity for the first variations of the two actions. It extends holomorphically on the full plaquette stencils. When transporting the independent increment as well, subtract this sum from the current on D^+; the increment relative to the physical current is preserved. In the bare current norm a single subtracted plaquette contributes at most $C|\partial\mathbf{U}(p) - \mathbf{1}|$. Indeed the first-variation formula is the traceless part of the holonomy transported to the bond, with the bare factor ξ^{-3} canceled by the current norm. If the admitted bound for this plaquette is a_ℓ in the prospective layer-ℓ curvature units, this contribution is at most $C a_\ell L^{-2\ell}$. Sum over the actual omitted plaquettes, at most six at any bond. The layer-zero bound suffices for a changed stencil in that layer; the factor L^{-2} is available when its bound comes from layer one. The running curvature ceiling therefore gives the same small fixed current radius for either first-member choice. On a fixed first member, binary switches preserve its true boundary current and its original plaquette list.

Use the fixed joined sequence in the switches of the reduced response. The plain datum is formed once by the row formula above. The cut removes operator terms on this geometry and keeps the original boundary current. In an active wall component the response reads the reduced datum at the first neighborhood of its response sites. Plain-data conversion reads through the second neighborhood and the outer ends of those rows through the third. The four neighborhood margin contains the complete stencils. For the walk terms use the closed padded hull of the trail. It includes the output blocks and their four-neighborhood with a one-bare-spacing stencil margin. The switch carrier includes every closed cell meeting that hull. Thus a true-boundary current read

on a surviving term uses only the incident retained plaquettes of the original join inside the active cells. Only these used current entries enter the trace comparison.

For this comparison use an aligned standard switch grid at depth q, with side a multiple of the order-q block and with the native response floors. The comparison uses the same grid and native tags in both settings. If the guard is filed on a coarser nested stage grid, take the parent image of those tags. The lift is the identity when the fine endpoints have the same parent. Otherwise it is the directed link between their two parents. The fine endpoints lie in the full blocks of those parents. A released inner parent that is a pivot lies in the corridor between two order-q blocks. These are the blocks containing the fine endpoints of its lift. The four-neighborhood margin of a surviving row includes both endpoint cells, hence those complete blocks by grid nesting. For a held parent keep its actual prescribed link and its carrier. The outer parents are level-q links and keep their coarse targets. A parent block can extend outside the joined first member. Use the original prospective pair on that part of the active cell. Thus the trace comparison uses the pair and the row and parent masks on the full active carrier in addition to the joined traces on the first member.

On a generating carrier use the fixed-point equations on the surviving walk terms. For a component $\mathfrak{k}$ let $Y_{\mathfrak{k}}^{\circ}$ be the sites over its walk terms. The potential response is supported over $Y_{\mathfrak{k}}^{\circ}$ and the shifted multiplier $\lambda + \mathsf{a}B'$ at rows of its first neighborhood. In the component equations one can set B' to zero at the unused rows: the margin statement gives the same response and the same supported first variation. Every local nonlinearity and every weighted difference in the contraction proof then uses the stencils in the four-neighborhood margin. The surviving walk bounds are bounds on these carriers. Thus the contraction runs on the supplied local pair and its complete stencils. This comparison requires the enlarged gauges on the carrier of each surviving term.

Keep the cells of both endpoint blocks of the crossing at switch value one. They are the same cell or adjacent cells, so the read belongs to one active component. For the perturbed averaged field T, let v be the accumulated node factor. At a retained node put $u(y) = g(y)v(y)^{-1}$. The order of the factors restores the aligned datum from the pulled-back datum turned by v. For an auxiliary axial read at a nonnode x in the block of y, set $u(x) = u(y)T(y,x)$. This makes the contour of T^u the identity. If the read instead has a stored transport $T_0(y,x)$ in the aligned inherited frame, use

$$u(x) = T_0(y,x)^{-1}u(y)T(y,x).$$

Indeed $T^u(y,x) = u(y)T(y,x)u(x)^{-1} = T_0(y,x)$. When the data have been aligned by g, use the aligned transport $T_0(y,x) = g(y)T_{0,\mathrm{old}}(y,x)g(x)^{-1}$. At a retained exterior fine node use its own node correction, since it is a top of the old sequence. The ordinary exterior contour can enter as an auxiliary link read and is undone on return to the inherited chart. These formulas are local on the two complete endpoint blocks. To compare two cuts, match the restricted pair on the surviving walk hulls and their four-neighborhood margin. Match also the ambient parent and pivot reads there. The latter equality gives the same plain source on the rows of the conversion and hence the same reduced source on the rows read by the fixed-point equations. The true-boundary plaquettes are those of the original first member on both cuts. Thus the two component equations have the same coefficients, source and restricted current. Uniqueness in the small response ball identifies the resulting read. At full switches the real response and the same restoration identify the ordinary centre. The pair, plain source and endpoint maps above therefore give the cut rule on the fixed standard partition. On the common graded cells we use the native walk construction below, with the same complete row traces.

Distinguish the fields integrated by the stage from the datum that sets the prospective base. The stage keeps the prospective average fixed while the collar nonpivots and their completed rows vary. These motions enter the response as source coordinates at a fixed pair. On its admitted section a variation of one physical collar coordinate β_c changes a bounded set S_c of plain rows. This includes a lift if its named parent uses that released coordinate. Let S_c^{+} include the finite row neighborhood used by reduction. The regular inverse and the one-step seam conversion give a reduced increment

of size $C_L|\Delta\beta_c|$ supported on S_c^+. For a crossing b, take its two complete endpoint blocks as the read set K_b. Apply the weighted response difference bound with weight $e^{-\mu d(\cdot,K_b)}$. It bounds the increment on K_b by $C_L e^{C\varkappa} e^{-\mu d(K_b,S_c^+)}|\Delta\beta_c|$. The mean contour and relative logarithm are holomorphic on fixed smaller charts there. Dividing by the increment gives

$$|\partial_{\beta_c} h_b| \le C e^{-\mu d(y_b,y_c)}.$$

Both endpoint blocks lie in the adjacent-scale geometry. The endpoint change of units and the number of such coordinates at a pillar are bounded in terms of L. The symmetric distance sum gives weighted row and column bounds at a reduced rate. The switch product for the two endpoint cells costs at most a fixed factor. In the scaled logarithm the factor g_j from $\beta_c = g_j B_c$ cancels the output factor $1/g_j$. The constants in this derivative bound are uniform as the prospective pair ranges over the joined section used for the ordinary joined response. The retained determining values used in that section are the prospective averages of the same complex pair. If another entry uses those values in a different role, verify its admission on its original domain.

At the real prospective datum with the free increment zero, the actual rows of D_o and D_*^g agree. This is an analytic chart anchor. The sharp and other retained tests remain in the real integral on their original arguments. On a released row, this uses the zero nonpivot increment and uniqueness of the pivot at the prospective coarse value. The plain logarithmic difference is then carried by the original artificial boundary rows. In particular if the alignment writes $D_*^g = e^{iB_1} D_o$, the source at the unaligned pair is $-\operatorname{Ad}(g(c_-)^{-1})B_1(c)$. The finite neighbourhood used by reduction keeps it in the boundary collar. The crossing reads lie inside the original quiet window away from this collar. The weighted response bound therefore gives exponential smallness of the zero-increment change there, uniformly in the switches with the endpoint guard fixed. This uses the prospective frame for the zero response, where the exterior contour of the induced datum is the prospective axial contour. For the complex version let W_* be the level-j average of the supplied prospective configuration before one-step axialization. The prospective datum on the real fibre is the stock of retained determining rows, including the top coarse targets. The prospective background has precisely these averages. Define the target on every common row of level q by the corresponding average $\mathcal{M}^q\mathbf{U}$. At a released row use W_* in the regular pivot inverse, with coarse target $\mathcal{M}(W_*)$. At an artificial row use the prescribed lift of the same parent value. Put $q = j+1$. At the inner face of the ordinary join the level-j parent carriers lie near $\partial\Lambda_j$. For $q \le k_0$ the prepared box begins five coarse cells inside the old exterior; for $q = k_0+1$ it begins seven. The quiet exterior extends eight cells beyond the hull of G_j. Hence the full inner alignment collar and its parent blocks lie inside Z_q''. The margin before inserting this band is at least one coarse cell. Their lifts use the held level-j rows. For $q > k_0+1$, the prepared box is inside the old exterior of level k_0+1. The carried box G_j includes the two-cell enlargement of that exterior. The inner band at $\partial\Lambda_j$ is now in the released collar. Its lifts use the completed level-j field there. At depth one there is no inner band. The parents on the outer face are level-q rows and use the fixed coarse averages. If a free increment is expressed in the prospective axial frame, pull it back by the adjoint of the inverse gauge factor at the start of its bond. The gauge fixes the coarse centres, so the one-step covariance gives the same coarse target in both frames on the admitted double block. The one-row inverse is zero at zero free increment. This gives the induced rows there in the same frame on the entire section.

These are all the rows of the joined target. On the real fibre the common values agree with the actual retained datum, the released values are the completed collar datum, and the lifts give the ordinary joined datum by its defining rule. The complete averaging blocks of the common rows stay in the join. A common row meeting a join collar of level r has that collar's level. If its endpoint in the original layer is in the full collar band, that band is in the original layer r. An endpoint beyond the band is at distance at least $\mu_{\mathrm{col}} L^r$ from the collar endpoint, where $\mu_{\mathrm{col}} \ge L^2$ is the joining width. The row would then have level at least $r+2$. The separation of the original members would put its collar endpoint in the member at level $r+1$, which is disjoint from the collar. The

alignment fixes both endpoints of a row at level r. This uses the same geometric test for complex and real fields.

A held determining row in the analytic target is read as the prospective average. That value equals its prescribed group datum on the real fibre. A stored value can also occur as a spectator of an old factor. Keep that separate occurrence in its original slot, including when it is Borel. Thus the common rows agree at zero collar increment, even as the prospective pair varies. Only the artificial boundary rows can supply a zero-increment source. The finite reduction stencil enlarges that support once. The current on the original restricted action stays in the base of the response and is not a separate input increment.

For a crossing oriented from the old exterior into the old interior, let τ_-^*, τ_+^* be the two prospective mean contours of W_*, from the block centres to the fine endpoints. Use $S_{\mathrm{g}} = \tau_-^* W_*(b)(\tau_+^*)^{-1}$ as the prospective analytic link. If the response is zero, the ordinary read with inverse node factors gives $W_*(b)(\tau_+^*)^{-1}$, since the exterior fine site is an old node. Express the ordinary read in the common frame by multiplying on the left by the same τ_-^*, with the inverse prescription for the reversed bond. At zero response it is now exactly S_{g}. On the real prospective axial chart $\tau_-^* = 1$, so the frame choice leaves the physical ordinary read unchanged. This continuation uses only the two complete blocks. It is applied to the link read and does not change the independent current in the response. With targets formed from the same complex pair and the same stored data, the tower transport, pivot completion, response and mean contours are functions of that pair. Two splittings of the pair give the same read by uniqueness of the regular response on the admitted domain.

With this common-frame prescription and the row identification, the zero-increment change on complex sections comes only from the original join boundary. The uniform decay bound for the switched response gives $\|h(0)\|_\infty \le C(\varepsilon_* + \alpha_*)e^{-cM\check{R}_q}$ at the guarded crossings, where the complex bound uses both the real curvature and complex potential radii. The old-wall read is at distance of order $a_q = M\check{R}_q L^q$ from either ordinary alignment band, by the eight-cell inner clearance and the two-cell outer clearance. At the fixed depth q this gives the indicated weighted distance after including the complete blocks. Here $\check{R}_q$ grows like $(\log\theta_j)^r$, with $r > 1$, and $g_j^{-1} = \theta_j^{1/2}$. After division by g_j the error is still smaller than any fixed inverse power of $\log\theta_j$. Thus the offset fits the smaller crossing tier in the Gaussian mean.

For the substitution in the inherited density, pull the prospective link back to the ordinary frame. For the orientation above this gives $S_{\mathrm{g}}^{\mathrm{o}} = (\tau_-^*)^{-1} S_{\mathrm{g}}$. The ordinary link is $S_{\mathrm{o}}^{\mathrm{o}}$, before the multiplication by τ_-^*. Reverse either link by inversion for the opposite orientation. In the displayed orientation the relative logarithm in the ordinary frame is conjugate to the common-frame logarithm by $(\tau_-^*)^{-1}$. This factor depends on the background pair and is fixed as the independent collar coordinates vary. A restored interior transport common to both centres cancels from their relative group element. The new coordinate a_{new} is in the ordinary frame. If a coordinate was first introduced in the common frame, conjugate it by $(\tau_-^*)^{-1}$ when pulling back the physical link. This pullback is the identity at the real axial anchor. The old coordinate is given by the small logarithm of

$$e^{ig_j a_{\mathrm{old}}} = e^{ig_j a_{\mathrm{new}}} S_{\mathrm{g}}^{\mathrm{o}} (S_{\mathrm{o}}^{\mathrm{o}})^{-1}.$$

Here the reconstructed nonpivot values are used in the inverse pivot map at the original coarse target. At fixed collar and coarse data the Lebesgue Jacobian is $\mathrm{j}(g_j a_{\mathrm{new}})/\mathrm{j}(g_j a_{\mathrm{old}})$, where j is the Haar density in exponential coordinates. Keep it with the reconstructed row in the inherited integral.

The old-wall crossing is in the far part of the plain strip. At its formation, with $q = j + 1$, the collar of Λ_q is separated from the old wall by the ordinary coarse layers. The ordinary rim masks exclude the strip. The failed-cube cutoff halos have their bases inset by one coarse cell and stay inside Ω_q even with the two smaller halo layers and a bond reach. Thus none of the three birth near masks contains the crossing. The condition uses those original masks even if a later stage

tests the crossing sharply. Its endpoints belong to adjacent level-q blocks, one on either side of the old wall. A level-m row can read this fine bond only if its double block contains both endpoints. The only such row joins the two block centres. Its inverse pivot uses the full double block and the prescribed coarse target. On the quiet geometry both blocks are clear of the old integration collar and of the cut-off test enlargement. Their stored bonds are in the ordinary boundary strip, away from the rim tier. The fine exterior links are ordinary determining values. Thus the local inverse pivot and its Jacobian on this double block read far stored variables and prescribed group values. A direct boundary read of this coordinate and its occurrence in the conditional polynomial of the strip use the old far analytic argument. Evaluate both at a_{old}. The near strip fields and the real island arguments keep their original coordinates. The ordinary completion includes this nonpivot bond with its stored threshold $\mathbf{1}_{\{|g_j a_{\mathrm{old}}|<\delta_j\}}$. The direct sharp mask tests the free exterior collar nonpivots and leaves this crossing in the ordinary strip integral. If an enlarged mask also tests the crossing, its new factor is $\mathbf{1}_{\{|g_j a_{\mathrm{new}}|<\delta'_j\}}$. On its passing branch the triangle inequality for the real angle gives $|g_j a_{\mathrm{old}}| \le |g_j a_{\mathrm{new}}| + |h|$, with h in the ordinary frame. Hence the old factor is one if $\|h\|_\infty + \delta'_j < \delta_j$. Use this inequality on the whole fixed real collar box. The uniform row derivative of h, integrated along the segment from 0 to $g_j B$, gives $\|h\|_\infty \le C_L \delta'_j + \|h(0)\|_\infty$ on that box. The ratio δ'_j/δ_j and the boundary estimate give the inequality at weak coupling, including on the edge of the box.

For the simultaneous change, hold the collar coordinates and the coarse targets fixed. The ordinary centre depends on the exterior determining rows and the coarse targets. The prospective centre has the same fixed targets, and its finer determining set excludes the old inward crossings. Thus neither centre uses a crossing nonpivot being changed. Translate all those nonpivots by their respective right factors. For each coarse row solve one pivot with all the nonpivots of its double block at their new inverse values. Two rows can share internal links, which are free or prescribed. Each row uses only its own pivot. This gives the simultaneous inverse and the product density.

The new ordinary completion tests the stored coordinate. In the component-local run, on a plain strip bond this is the original logarithm relative to its local strip centre. Let d_{lg} bound the angle between this centre and the old global centre on the actual test domain. The global relative angle is at most $\delta_j + d_{\mathrm{lg}}$ on a local pass and at least $\delta_j - d_{\mathrm{lg}}$ on a local failure. Use this reserve when removing the ordinary approximate bond test: the additional angle from the global centre to the approximate centre, together with d_{lg}, must be less than δ_j. A failure-energy estimate using the global angle can use the lower bound $\delta_j - d_{\mathrm{lg}}$. A factor with the literal global sharp threshold keeps its own indicator where it is not implied. In the enlarged mask, on the new sharp ball its original relative angle is at most $\delta'_j + \|h\|_\infty + d_{\mathrm{lg}}$. If this is less than δ_j, both old completion indicators are one on that passing support. The bound uses the ordered product of the two centre shifts in the same real frame. Carry the actual local completion indicator on both branches of the component-local operation. For the direct mask keep the crossing in the native strip slot a_{old} with its ordinary ball. The sharp balls then apply only to the exterior collar variables. If a crossing outside the sharp mask is translated for a chart calculation, use the inverse translation inside the old indicator. The new radius gives no bound on that untested coordinate. Only in the enlarged mask, where the crossing also passes the new sharp ball, is the old completion redundant by the displayed inequality. On the passed ordinary cube mask, the approximate test uses two different supplies of the δ_j bound on its nonpivot reads. A bond with no endpoint in Λ_{j+1} has the bound from its recorded split indicator. A bond with an endpoint there has it from the cutoff of the ordinary Gaussian integral. On this mask the strip change is the ordinary one. The centre reserve above puts both groups below the approximate threshold $2\delta_j$. The second group is outside the large-field operation. Thus removal of the approximate factor is an identity on the support of the whole term, with those exterior cutoffs present. Earlier regularity tests are removed where the corresponding stage comparison gives their value one. This product uses one choice of sharp centre. A comparison of both sharp masks also

retains their two disagreement sectors. A version of the operation retaining any of those tests still carries its original inverse argument. On a local sharp failure retain the untransformed prefix with its local indicator. On a global sharp failure use the transported real tests and density.

With $q = j + 1$, the inherited free mask comes from $\Omega_q^{(j)*}$. The stage test uses $(\Omega_q^c \setminus Z_q'')^{(j)*} \cap Z$. The star uses incident bonds and deletes the pivots for the corresponding region. The overlap therefore consists of crossings between Ω_q and $\Omega_q^c \setminus Z_q''$, subject to the stage's restriction to Z and both pivot exclusions. Keep only the crossings present in the selected stored strip stock. These are the additional inherited reads in the broader sharp mask.

For a quiet inherited crossing in the broader incident mask, the approximate pass also removes the ordinary upper cutoff on the sharp-failure branch. The approximate chord test on that mask gives angle less than $2\arcsin(\delta_j')$ in the local stage frame. The quiet-crossing estimate bounds the separation of the local and ordinary centres by $C_L\delta_j'$ using the internal approximate passes. It applies on both outcomes of the sharp test on this crossing. Thus its ordinary angle is less than $2\arcsin(\delta_j') + C_L\delta_j' < \delta_j$ at weak coupling. The plain ordinary upper indicator is one throughout the approximate-pass support for this crossing. In an ordinary cube test this removes the crossing's factor from the product. Any complement of the whole cube test still uses the other factors.

For the global failure change of variables, the raw identity transports the approximate pass to the chord ball in each new relative coordinate W_b' and keeps the sharp threshold at angle δ_j'. Order the finite tested mask and partition the complement of the sharp pass by its first failing bond. In each part the earlier bonds lie in the sharp balls, the failing bond has angle in $[\delta_j', 2\arcsin(\delta_j'))$, and the later bonds lie in the approximate balls. These are fixed real factors on this mask. The free V_j collar stock uses the determining bonds in the exterior, which have no endpoint in Ω_q. The crossing has one integration slot in the inherited stock even when it enters two tests. Its cutoff Jacobian and the solved pivot of its row remain in the same density. This partition concerns the approximate-pass part of the global failure kernel. The other real factors retain their native arguments.

The density correction here is taken at the actual enlarged radii. Let A and B_* bound the scaled strip and collar arguments, including their multipliers when they occur in the substitution. Write $H_* = C(B_* + d)$, so $|a_{\mathrm{old}} - a_{\mathrm{new}}| \le H_*$. The normalized Haar density has a nonvanishing analytic extension on the fixed small chart and its logarithm has zero linear term. The log of the free-slot quotient is therefore at most $Cg_j^2(A + H_*)H_*$ in absolute value. For the pivot factor compare the full coarea densities at the old and new nonpivot arguments with the same coarse target, in the original row chart. In Haar frames each is the inverse determinant of the derivative in the solved pivot. On a reduced fixed physical disc this derivative is invertible and its log determinant has bounded first derivatives. Insert all translated nonpivots of the double block before evaluating the inverse. The change of the solved link, and the log ratio of the row densities, are bounded by $C_L g_j H_*$. The fixed number of fine links of a double block is included in C_L. Count the row once. The unchanged density and the ratio give the original coarea factor at its inverse argument. If the density is written with the centre determinant and the linearizing derivative, their product with the pivot Haar factor represents this same coarea density. To check the normalization, differentiate $\widetilde{\mathsf{Q}}_V(\psi_V(B)) = LQ_VB$ at fixed nonpivots in the unconstrained pivot direction, then set $Q_VB = 0$. For one private row c at its pivot p, this gives

$$(D_p\widetilde{\mathsf{Q}}_V)(\psi_V(B))D_p\psi_V(B) = L\mathsf{m}_c(V).$$

On the fibre the output logarithm is at the coarse target, so its derivative at the identity is the identity. The first factor on the left is the actual row derivative in Haar frames composed with the pivot exponential derivative. The latter has determinant $h(B_p')$, where $B' = \psi_V(B)$. Taking determinants identifies the coarea factor as

$$|\det(L\mathsf{m}_c(V))|^{-1}|\det D_p\psi_V(B)|\,h(B_p').$$

The analytic continuation uses the determinant sign fixed at the real anchor. In the convention using m_c for elimination, the factor L^{-3} is the row's fixed output normalization. It cancels in a ratio with the same row. The full coarea factor is evaluated once at the fully composed inverse argument.

The double block is the fixed root of this ratio. Its crossing increments read the same two complete blocks of the row. On a face with this root active, the restrictions to its active component give the same nonpivot list, target and pivot solve as the full face calculation. For a parent read outside the joined first member, use the completed collar value for a released link and the original prospective average for a held one. Include that parent carrier and the neighboring rows of the naturalization in the read before restricting the switches. These parent values are common to the source and the row chart. Form the response from the completed prospective collar first. Its restriction to the face uses the same source values at the rows of the response. Then use its output in the pivot solve at the inverse strip arguments, with the target held fixed. When the crossing gate is off the two evaluations of the determinant coincide. The difference of their logs is one holomorphic rooted read. Apply the rooted Cauchy estimate with the double block fixed and attach the response carriers at this root. The one-slot Haar quotients use their own endpoint roots.

The recentered free crossing is plain. Its group map is a right translation at fixed collar variables, so it has unit Haar Jacobian before passing to exponential coordinates. The cutoff derivative occurs on the original ordinary transition shell. At a fixed real shell argument it is the rank-one determinant in the ordinary shift. Its log is of size $C(\varepsilon_j/\delta_j)e^{-c\check{R}_{j+1}}$ with the original carrier decay. Its old switched version holds the shell argument fixed and multiplies the difference from the zero argument by the old near-field switch. This costs its switch radius. A varying smooth cutoff argument in another composed map requires its own real treatment.

On a fixed real part of the global sharp-failure domain the new cutoff has scale δ'_j. Hold its transformed argument W'_b real and write the inverse factor, up to the fixed right translation, as $W'_b \exp[-i\vartheta(W'_b)H_b]$. Its Haar Jacobian is

$$J_b = 1 - d\vartheta_{W'_b}(W'_b iH_b).$$

In left-trivialized coordinates factor out the adjoint of the exponential. It has determinant one and fixes iH_b, leaving a rank-one perturbation. The derivative of the cutoff is supported in the transition annulus and has norm at most C/δ'_j. Thus the principal log J_b is holomorphic in the shift on the independent shift disc once $C|H_b|/\delta'_j < 1/2$. Its absolute bound there is $2C|H_b|/\delta'_j$. This continuation leaves the real cutoff argument and the fixed selectors in the Haar integral. In the inherited frame the old relative link is $W'_b e^{-i\vartheta(W'_b)H_b} S_{g,b} S_{o,b}^{-1}$, where $S_{g,b}$ is the prospective global centre and $S_{o,b}$ the old strip centre. If a frame map is needed, transport W'_b, H_b together and keep ϑ evaluated at the original real W'_b. For fixed W'_b, its logarithm is holomorphic in H_b and the admitted relative centre logarithm h_b of $S_{g,b}S_{o,b}^{-1}$. The bound in angular units is $C(2\arcsin\delta'_j + |H_b| + |h_b|)$. Use the independent shift margin for H_b and the original strip margin for the other arguments. The old pivot is then evaluated at these inverse arguments on its original chart.

If the admitted shift is expanded in carriers that all contain the same complete bond read, take its weighted absolute tree sum $\|H_b\|_\mu$. Each product in the series for $\log J_b$ has a carrier given by the union of its factors, whose tree length is at most the sum of their lengths. The weighted logarithm sum is therefore at most $2C\|H_b\|_\mu/\delta'_j$ when $C\|H_b\|_\mu/\delta'_j \le 1/2$. At the physical quiet crossing the carrier of the shift also reaches the distant boundary, so its spare decay pays this inverse radius. At fixed prospective centres the Jacobians multiply on the free slots. If an ordinary crossing centre reads the new collar coordinates, form the collar change first. Its reconstruction does not read those old crossing coordinates, and the full derivative is triangular.

The fixed physical radius for the relative logarithm gives $\|a_{\mathrm{old}}\|_\infty \le C_L(T+d)$ on the smaller section above. Here $T = O(p_0(g_j))$ bounds the unamplified strip and collar fields. Form the inverse

on this box. Its use in a switched far argument must fit the old radius $\varrho_{\mathrm{st}}\mathfrak{b}_b$, with $\mathfrak{b}_b$ of order $p_0(g_j)$ in these units. The direct field and the displacement will use separate fractions of this radius. The response of the triple uses its own margin. The reductions concern only slots integrated in the stage. Each carried far slot has its full output radius. The Gaussian operators use their own cut parameters.

Let $\Phi(s,\lambda)$ be a switched weight with the inverse arguments. Its perturbation at fixed switches is $\Phi(s,\lambda)-\Phi(s,0)$, where zero sets all amplitude parameters to zero. This is the difference to which the rooted estimate with a zero at vanishing amplitude applies. For one factor per wall-component take a mixed difference using a separate amplitude for each component. Cauchy's formula then gains one inverse radius for each such amplitude, once the common cut satisfies component deletion. A component carrying only the fixed join boundary can affect a difference in a nonlinear weight even when it carries no collar amplitude. In the rooted estimate include that boundary among the source cells and use its own small weight for such a component. Compare the zero-amplitude value with the prescribed reference value in a separate term. When comparing two far arguments at the same pair and fixed remaining arguments, Cauchy's estimate along their line bounds the difference by the old envelope times the displacement divided by the remaining radius. In particular a residual shift $h(0)/g_j$ in this comparison is paid by the boundary offset, with any multiplier on its slot included in the displacement.

On the aligned flat stage partition, let K_b be the cells containing the two complete endpoint blocks. It consists of one cell or two face neighbors. Use the same K_b wherever b is read. Write s^{K_b} for the parameters with the switches of K_b set to one and put $\eta_b(s)=\prod_{\Delta\in K_b} s_\Delta$. An interpolation of the far coordinate is

$$a_b(s)=\frac{1}{ig_j}\log\Big(e^{ig_j a_{\mathrm{new}}(b)}e^{i\eta_b(s)h_b(s^{K_b},g_jB)}\Big).$$

Here h_b is the admitted response read in the ordinary frame, using the original row and parent traces. At the full evaluation this is the inverse coordinate. If a cell of K_b is inactive, the correction vanishes. When both endpoint cells are active, K_b lies in one wall-component, and the guarded response reads that component. Thus no correction uses a different component's parameters or collar increments. The coarse pivot for this crossing uses the same blocks. At fixed collar increment the interpolated group map is a right translation, so the same density quotient applies. The bound on the product of the at most two switches costs a fixed factor. The preceding argument for the far radius absorbs it in the common switch margin.

Every inherited weight uses these common far coordinates at the crossings it reads. To estimate the inherited weights, split the field argument into the original coordinate and its displacement. For an entry F with actively integrated far and near slots f,n, put $\varsigma_b=\lambda_{\mathfrak{w}}s(\square_b)$ on its active component and zero otherwise. On an unchanged far slot let $a_{\mathrm{new}}(b)$ be its original coordinate and set $\Delta_b=0$. On a moved far slot put $\Delta_b=a_b(s)-a_{\mathrm{new}}(b)$. Use the joint interpolation

$$F\big(P_s;(\varsigma_b a_{\mathrm{new}}(b)+\tau_{\mathfrak{w}}\Delta_b)_{\mathsf{f}},(\varsigma_b)_{\mathsf{n}},(a_b)_{\mathsf{n}},\mathfrak{q}\big).$$

Here a_b on a near slot is its real value in the original chart. A moved crossing has a far slot. When all parameters are one, the far argument is exactly its value in the original chart. On a binary cut the displacement uses its endpoint gate, so is zero when either endpoint cell is inactive. Its read includes $a_{\mathrm{new}}(b)$, even at $\lambda_{\mathfrak{w}}=0$, because this coordinate enters the product logarithm. Choose the owner cell $\square_b$ from K_b, so this read is also guarded by the endpoint switches. The direct argument uses the owner's switch. The argument $\mathfrak{q}$ contains all the spectators and their inherited switches, which keep their values and radii. At zero switch a near entry is independent of its Borel field. At zero field it is independent of that switch. Thus the empty cut gives the original zero-slot value, also for the near entries. Use the unmultiplied physical coordinates for the integrated arguments of the Gaussian reference and its coordinate change. For the analytic interaction formed from a difference of strip quadratics use the corresponding far variables and the switched near variables $\mu_b a_b$ on all

its spectator legs. In a rooted read the original domain contains an endpoint of every crossing it reads. The extra endpoint cells therefore attach as face neighbors to those root cells. This is the attachment estimate on the flat grain, with at most eight choices of extra cell at each root cell. The old history trace is kept at the reader's address. The stage profile below controls admission of the pair, and the switched chain and double-block estimates control the native operators with several crossing slots. A newly composed map that varies an old near-field argument must supply its own real coordinate and near switch. The old switch property applies to spectators in their original slots.

The displacement part of an inherited term can be present at $a_{\mathrm{new}} = 0$, since the transformed argument then contains the collar field. The value at $\tau = 0$ depends on a_{new} and is estimated with the ordinary strip amplitudes. Let $\varrho_{\mathrm{st}}\mathfrak{b}_b$ be the old far radius. Even on the smaller enlarged disc $|a_{\mathrm{new}}(b)| < c\varrho_{\mathrm{st}}\mathfrak{b}_b$, the bound $g_j\varrho_{\mathrm{st}}\mathfrak{b}_b = o(1)$ keeps the product logarithm on its fixed physical disc. Differentiating it in its second factor gives

$$|\Delta_b(s)| \le C_L|\eta_b(s)h_b(s^{K_b}, g_jB)|/g_j \le C'_L\mathfrak{b}_b.$$

Here the last inequality uses the collar field on its stage box and the bound on the boundary offset. For the finite difference estimate the physical free strip box has $|a_{\mathrm{new}}(b)| \le C_0\mathfrak{b}_b$. Reserve at most a fixed fraction of the old radius for each of $C_0e^{\varkappa}|\lambda_{\mathfrak{w}}|$ and $C'_L|\tau_{\mathfrak{w}}|$, in units of $\mathfrak{b}_b$. In particular the two amplitude discs are simultaneously available, after intersecting the first with the pair-admission disc. For an estimate with an enlarged a_{new}-disc, the unshifted term instead uses its bound $e^{\varkappa}|\lambda_{\mathfrak{w}}|\,|a_{\mathrm{new}}(b)|/\mathfrak{b}_b$ in this same radius budget. The large strip-field disc and the large direct amplitude cannot both be spent on the same slot. Spectator slots keep their own discs.

Suppose an inherited term is bounded on the old joint disc by b_X. For a set of k components take the mixed difference in their displacement multipliers between zero and one. The Taylor coefficients that survive have positive order in every one of these multipliers. Summing the Cauchy bounds in those variables bounds the mixed difference by

$$b_X(c'\varrho_{\mathrm{st}} - 1)^{-k}.$$

This uses one supremum of the whole term, including when it reads several bonds of a component. In a coefficient whose displacement adds an endpoint cell, that cell must be active because η_b contains its switch. It attaches to the old support at the original endpoint. A component sourced only by the fixed boundary offset uses the offset estimate.

In the switched estimate keep the unchanged strip arguments and their old real selectors fixed while expanding in the new switches. Use the pair amplitude and the displacement amplitude separately. Let G be the difference between the evaluations with displacements $(\tau_{\mathfrak{w}}\Delta_b)_{\mathfrak{f}}$ and with zero displacements. Both evaluations use the same switched pair, the same direct strip argument and the same near dials. The fixed joined pair is part of the base. Any zero-increment displacement from the join enters G with the same multiplier $\tau_{\mathfrak{w}}$ as the rest of Δ_b.

Keep the original rooted read N fixed. For new switch support K, use the finite difference

$$\sum_{J\subset K}(-1)^{|K|-|J|}G(1_{N\cup J}).$$

The amplitude of a wall component is inherited by the pieces obtained on cutting it, with the original anchors retained. The finite difference is the integral of a mixed first derivative in the switches of K, over their unit intervals. Estimate this derivative on the spatial switch discs while keeping the two families of amplitudes on their joint discs. If both amplitudes of a new wall component vanish, the binary cut can delete its new cells. The pair increment is zero there and so are the direct amplified arguments and the guarded displacements of that component. Pairing the subsets with and without a new cell of this component makes the finite difference zero. The fixed read is kept in every summand. The difference also vanishes when all the displacement amplitudes are zero. Consequently its Taylor series in the amplitudes has at least one positive degree per new

wall component and a positive displacement degree somewhere. The unchanged strip dependence is summed by the original strip block expansion.

Let $a = (R_{\mathrm{pair}} - 1)^{-1}$ and $u = (R_\tau - 1)^{-1}$, where the radii refer to the two amplitude discs. Let z be the ratio from Cauchy's estimate in the spatial switches, with the exponential margin of their original discs. For k wall components the sum of the absolute amplitude coefficients of the finite difference at physical amplitudes is bounded by

$$b_X z^{|K|}\, ku(1+a)[a + u(1+a)]^{k-1}.$$

For a component marked with a displacement the degree sum is $u(1+a)$. At every other component sum the degrees with at least one of the two amplitudes present. Mark one of the k displacement components for this bound. It has an original crossing anchor in X, since the old reader contains a crossing endpoint and its displacement vanishes unless the endpoint gate is active. An endpoint added by the gate is one face step from that anchor. The other components attach as arms. Their connected sets, weighted by the spatial switch factor, have a sum bounded by $Ce^{-\nu D(a_0, X)}$ at a source anchor a_0. Here $D(a_0, X)$ is the length of a shortest attaching cell chain. The attachment length is included in the decay weight of the new domain. The old packing bound on the sum over source anchors then gives a factor at most

$$\exp\left(CN^*(a+u) \left[1 + \frac{d^\sharp(X) + 1}{\mathsf{N}_i} \right] \right)$$

for the unmarked components. The amplified pair radius here uses the stage gas choice $q - \mathfrak{p}_0 - 5r > 9r$. Together with the old strip radius this makes $N^*(a+u)$ small. Charge the displayed factor and the distance estimate below by reserving a further fixed multiple of $1/\mathsf{N}_i$ in the stage rate. Over the full waiting window this is a fixed loss.

For a pin in the new domain, let C' be the component of the marked original anchor. The old anchored tree and its attached arms place the pin at distance at most $CM(\mathsf{N}_i + d^\sharp(X) + \sum_W |W|)$ from C', in stage units. The same bound holds for the distance from C' to a component C met by the new domain. Reserve c/N_i of the rate and part of the spatial switch margin to extract the corresponding exponential in the distance divided by $M\mathsf{N}_i$. At fixed C', sum the marked original anchors using $J^\Sigma_{\mathsf{A}}(C')$. Earlier stage terms give the additional $CN^*\mathsf{N}_i$ from their old pinned bound. Lower-level strip reads are counted at their original endpoints, where their long-domain estimate still applies. Summing the distance weight over C' by the packing of the treated components gives, for both the new pinned norm and the new sum over domains meeting C^+, the bound

$$Cu \sup_{C'} \big(J^\Sigma_{\mathsf{A}}(C') + CN^*\mathsf{N}_i \big).$$

This uses the old summed-anchor norm for the marked component even when the new pin lies in the original domain. Replacing that sum by a count of possible anchors in a domain would cost a further waiting-depth factor.

To enter the difference in the primary potentials, subtract its value at $B = 0$ in the actual collar integration variables, at fixed pair and unchanged strip arguments. Every surviving block difference then uses at least one new collar block, and the old collar ratio $\hat{q}$ applies. The factor $\hat{q}N^*$ in the component bound is small, so this insertion fits the old $\mathsf{N}_i u N^* \mathsf{N}_i$ bound after summing the stages. At zero free source the subtracted offset has the exponentially small bound from the joined comparison. If the independent free shift y moves the physical zero, its extra displacement on the free-source disc is at most $C|\mathsf{y}|/g_j$, by the same fixed physical chart estimate. This part uses the free-source closure bound, with the small ratio $|\mathsf{y}|/(g_j \mathfrak{b}_b)$.

Count hot blocks among the current integration variables. At stage $j+1$ these are the level-j strip and collar nonpivots. Assign each coordinate block to the level-$(j+1)$ M-cube of one of its endpoints in the stage collar. If both endpoints are available, use a fixed convention. In the direct graded rule take the new sharp product on the free exterior mask and keep the inherited crossings

in their original strip coordinates. For the broader re-centred rule use the product on the passing branch above, where the smaller crossing ball makes the transported old test redundant. The two disagreement sectors of a comparison of sharp masks keep their real indicators and are treated separately. An earlier stored spectator or a solved pivot adds no block. Each owner cube has at most $C(LM)^4$ slots. The quiet box at level $j+1$ contains at most $C\check{R}_{j+1}^4 \le CN^*$ owner cubes in its collar.

At fixed shift source the smooth Haar difference at a free collar bond reads just its own variable block. The centre term reads none. Thus the alternating block expansion of the difference has the usual single active-block factor $\hat{q}_v$ and at most e^{2a_1} from the hot-block charge. The shifts formed from fixed stage data add their rooted carriers to the localization and no current integration block. This potential reads the same shift source as the translated field. Add its envelope to the primary potentials while keeping the one closing index for that source and carrier. The bounded number of free slots of a cell then adds a bounded amount to the hot-block activity, using the smooth Haar bound above. In the stage tail estimate the weight of order $(\mathsf{N}^*)^{-1}$ at the sharp threshold gives the factor $\exp[-c(\log\theta_t)^{2\mathfrak{p}_1-4r}]$, which pays the existing activity of order $(\log\theta_t)^{4r}$ under the exponent choices of the step. A failed sharp branch uses the separate cutoff Jacobian in its real history kernel. On the quiet branch the product over at most $C\mathsf{N}^*$ transformed slots has log bounded by the sum of their shift bounds divided by δ_j'. The quiet collar decay pays this sum as well as the factor N^*. This costs only a bounded density multiplier. A space-time weight on that history uses the survival reserve.

Use this ownership for the gas and keep the graded tree for the term's carrier. In the flat last stage the two cell systems coincide. If a graded carrier cell meets new hot slots from a treated component, their number is at most the total CN^* for that component. The separation of the treated boxes puts the slots of at most one treated component at such a cell, including the fixed endpoint enlargement. Hence the new hot-block factor on the added cells is bounded by $\exp(Ca_1N^*\sum_W|W|)$. With $a_1=\hat{q}$ it fits the spatial switch margin, also in the earlier stages. The bound on the ratio of adjacent grades gives bounded degree for the graded cell chains. Its volume conversion $L^{4(\mu-j-1)}$ is used for an old coarse pin, where the path to the anchor pays for it. Count only the assigned integration blocks in the gas. The Gaussian cost below uses the same count, with the error from each guard weighted by the number of slots it protects.

There is a compatible grading for the switched walks of the stage response. On the part below the next layer use the level-$(j+1)$ M-cubes. Above it, on the prospective layer $\mu > j+1$, use the level-μ M-cubes. The stage regions are unions of these nested cells and consecutive faces are separated by a full cell of the larger level. Small relative enlargements of the cells meet at most adjacent grades. They have bounded overlap, by separation of nonadjacent layers and by the cube count within each grade.

For a walk use the union of the closed hulls of its constituent cells. Let G be a graded cell of side $M\xi_\mu$ that meets one such hull. The hull's diameter is at most $C_L\mathfrak{M}\xi_{n_*}$, with n_* its largest constituent level. If $n_* > \mu+1$, its level-n_* constituent would lie in the region at that level at distance at least $M\xi_{n_*}$ from G. For sufficiently large M this is impossible. Thus the tree that visits the hull meets a small relative enlargement of G. Unless that tree lies wholly in the enlargement with twice the width, it spends weighted length at least c_LM there: before exiting it uses spacings at most $\xi_{\mu+1}$. Sum over these enlargements by bounded overlap. The cells whose larger enlargements contain the whole tree are bounded in number by the same overlap. The initial hull, when it is counted separately from the visited hulls, meets only a bounded number of cells by its diameter and the same level comparison. Hence, for the walk length $|\Gamma|_{\mathbf{B}}$, the number of distinct graded switches is at most

$$C_L + C_L|\Gamma|_{\mathbf{B}}/M.$$

The switch loss therefore fits in the native walk decay after taking M large compared with the switch radius. Apply the weighted walk summation to the individual scalar monomials and their partial

sums. The cost $e^{C_L \varkappa}$ is fixed and the rate loss is $C_L \varkappa / M$. In particular, if the native absolute sum is bounded with weight $e^{\delta |\Gamma|_{\mathbf{B}}}$, the sum after switching at rate δ' is bounded by the same constant times $e^{C_L \varkappa}$ for $\delta' + C_L \varkappa / M \le \delta$. This follows termwise from the distinct-tag count. Replacing old tags by their parent set can only decrease the number of factors on this common polydisc. The prefactor $e^{C_L \varkappa}$ changes the fixed source and current ceilings in the contraction. Reduce these ceilings before choosing the small-coupling range.

Use an auxiliary standard partition at the top of the native tower to check the torus floors for the unswitched walk setting. On the actual graded grid attach to each native term the product over all closed graded cells meeting its padded hull. For a test of a native kernel, apply the graded count to each tree joining the two test sites and visiting the trail, including the initial hull as above. If the native test has rate ϑ, this gives

$$|s^{\omega}| e^{-\vartheta d_{\mathbf{B}}(\omega; y, y')} \le e^{C_L \varkappa} e^{-(\vartheta - C_L \varkappa / M) d_{\mathbf{B}}(y, y')}.$$

Here the distance in the exponent on the left is the infimum over the test trees. The native sum over terms starting in the test window gives the same estimate for every partial sum with the native window and mass constants. Use this for $\mathsf{H}_0, \tilde{\mathsf{G}}, \mathsf{H}, \hat{\mathsf{S}}$ and, when used for the potential read, the walk datum of $D(1 - \mathsf{R}) D^{\mathsf{T}}$. Take M large so that the rate loss fits inside the native spare decay in each test. The layer-ratio estimate and the weighted count of bonds over each site then give the same operator types for the four maps of the reduced system, including the transpose of H, with a larger constant. The contraction and its weighted source estimate use these operator types and the unchanged local structure. This gives the switched response on the smaller fixed source and current discs, with holomorphy by uniform convergence of the fixed-point iteration.

For a face of the switch polydisc, keep the switches in the allowed cells complex and put the others at zero. Define wall adjacency by a common face of positive three-dimensional measure, including a subface at a change of grade. At any point of the padded hull the closed cells containing that point form a wall-connected set. Indeed the small coordinate orthants at the point belong to these cells, and consecutive orthants across a coordinate plane give either the same cell or a common wall. The union of the cells containing the point contains a neighborhood of the point. Since the hull is connected, its full tag set is wall connected: different wall components of the tag set would partition the hull into disjoint closed sets, since all tags containing any given point belong to one component.

A term survives on the face only when all its tags lie in a single allowed wall component. The native margin puts the four-neighborhood of each kernel site inside the padded hull. Thus, if $\mathbb{Y}_{\mathfrak{k}}$ is the set of sites whose four-neighborhood cubes lie in the interior of the union of $\mathfrak{k}$, the surviving terms and their transposes are carried by $\mathbb{Y}_{\mathfrak{k}}$. The interiors for distinct components are disjoint. In particular the three-neighborhood of $\mathbb{Y}_{\mathfrak{k}}$ misses every other carrier set. Apply the splitting of the reduced system over separated carriers. The potential and the supported current bracket split. In the multiplier the diagonal term $-\mathsf{a} B'$ is kept separately, as in the splitting identity for the bracket. Use the ambient row types and true-boundary stencils throughout. In the native exterior collar the two parent blocks of a completed level-j row are in the old layer j, at distance $O(L \xi_j)$ from the row. Include both parent blocks and the pivot in the source read. A lifted row with an additional parent outside the raw margin uses the connected carrier of that parent stencil as well. Gate the corresponding source contribution by the tags of its complete stencil. The extra switches cost a fixed factor in the source bound, and at full switches the source is the original completed source. At full switches the native terms sum to the original four operators and the full response is identified by uniqueness.

To compare two placements of a cut on the same torus, use a common union R of the graded cells in native settings with the same scales and walk parameters. Take the layer traces $\Omega_n \cap R$ on the common finest native grid. Choose the graded cell widths on the nested grids of the native setting. Each graded cell, each layer member and each padded native hull is then a union on the

finest grid. Equality of the traces on R therefore gives equality on each padded hull contained there. For a surviving atom the identity on its hull is then a native shift. Locality in the sequence identifies its index and coefficient at matching pair data on that hull. Repeat the comparison from the other setting, so the sums have exactly the same indices. The common graded grid gives the same tags to the matched hulls. For a marked conditional walk include its conditioning set in the trace and use the same compression mask on the matched endpoints.

For the reduced equations the same comparison identifies the tops, levels, row types and outward endpoints throughout the padded read. A site or a row is assigned by the layer memberships of its sites, with both ends covered by the margin. Thus the same actual averaging blocks, pivot reads and retained plaquettes enter the local structure. Compare the pair and the independent current on these stencils, including the true first-member plaquette lists. The reduced source agrees when the plain source agrees on the full stencils of its naturalization and completion. These are the data needed to apply uniqueness to the component equations on R. The comparison is an identity with the switches in R still complex and those outside R set to zero.

In a preparatory integration the changed member at level $q = j + 1$ removes the released fine rows from the level-j determining set and adds the coarse target rows. A retained coarse row on the old face can change from outward to interior. Both versions of such a row may carry the same grade-q tag. The outward equation reads the seam factor of its full outer block, even at zero plain increment on that row. The interior equation uses its plain increment. At the changed seam form each response in its own native setting. In the old problem the new coarse value is the fixed target of the pivot equation, and the completed fine rows supply the old plain source. In the prospective problem use its actual new row set. In the ordinary centre construction the restriction to the fixed join uses the induced ordinary datum and its own action. It follows from the critical restriction on that join, together with the endpoint restoration above. The ordinary depth-q operators and the full-depth collar operators retain their own native settings.

Along a fixed sequence of stages the regions grow and the base level increases. An old graded cell lies in a current cell because the current grade there is at least its old grade and all grids are nested. For an inherited walk take the parent image of its actual tag set, using its original boundary ownership. On a binary cut the old tags are all active exactly when all their parents are active. The full-switch coefficient is unchanged. For a walk formed with a closed-hull tag rule the same image is the set of current cells meeting that hull, since each is the union of its old cells. Apply this identity with the original hull. Additional endpoint or response stencils are filed as new attachments. The new monomial uses each graded cell once. The per-slot switches of the carried fields keep their own arguments. For the ordinary join, which ends at level $j + 1$, this retagging starts from its admissible standard partition. The full-depth collar Hessian and its roots use their native walk terms on the same active cells.

For the shear $\mathsf{T} = I + \mathsf{S}$, $\mathsf{S}(a, B) = (\mathsf{L}B, 0)$, one has $\mathsf{S}^2 = 0$ and $\mathsf{T}^{-1} = I - \mathsf{S}$. On a full component preserved by this shear the Gaussian determinant is unchanged, and the covariance is the old covariance multiplied by $I-\mathsf{S}$ and its transpose. Weighted row and column bounds for L and the old covariance give the corresponding decay for this product by the triangle inequality for the distance. A compression to a set preserved by the shear is a congruence of the compressed precision. Use $\mathsf{T}z + d$ as the affine reference of the inverse map, with z the new coordinates. Here L is the derivative in B at zero and d is the value of the inverse at zero. Write $r(z)$ for the remaining part. It includes the term linear in the new strip coordinate from its product with the offset, bounded by $Cg_j|a_{\mathrm{new}}(b)||d_b|$. If the old quadratic is $Q(v) = \frac{1}{2}v^{\mathsf{T}}Dv - \ell^{\mathsf{T}}v + c$, then its new precision and linear coefficient are

$$D' = \mathsf{T}^{\mathsf{T}}D\mathsf{T}, \qquad \ell' = \mathsf{T}^{\mathsf{T}}(\ell - Dd).$$

The new constant is $c + \frac{1}{2}d^{\mathsf{T}}Dd - \ell^{\mathsf{T}}d$. The rest of the change in Q is

$$r(z)^{\mathsf{T}}[D(\mathsf{T}z + d) - \ell] + \tfrac{1}{2}r(z)^{\mathsf{T}}Dr(z).$$

Include the sum of the one-slot logarithmic Haar quotients and one inverse-pivot Jacobian per changed coarse row.

Suppose the derivative L has a walk expansion on the same grain as the old precision, with both endpoints in each term's carrier. In $D' = D + \mathsf{S}^{\mathsf{T}}D + D\mathsf{S} + \mathsf{S}^{\mathsf{T}}D\mathsf{S}$, join successive carriers at their common index. Their union is connected, its length is bounded by the sum of the lengths, and the weighted masses multiply. The same joining applies to the quadratic remainder. For $r^{\mathsf{T}}Dr$ the two remainder carriers attach at the two ends of the same old precision term. The weighted row sum therefore bounds the mass per crossing. Use the actual products of switches in both expressions. A shared cell can appear more than once in such a product.

For the derivative carrier expansion, fix the complete endpoint carrier of the crossing and expand $\mathsf{L}_b(s;c)$ in the other switches. To read a coefficient with support Y, set to zero every switch outside Y and the endpoint carrier. The face identity then makes the resulting function independent of any switch separated from the endpoint carrier. It is also independent of the source coordinate if its complete stencil is outside that component. This gives the required vanishing of the corresponding coefficients. On a uniform switch disc of radius R_s, a bound $Ce^{-\mu d(b,c)}$ on the derivative gives, by Cauchy, the absolute sum at $|s| \le r_s < R_s$ over monomials with support exactly Y bounded by

$$Ce^{-\mu d(b,c)} \left(\frac{r_s}{R_s - r_s}\right)^{|Y|}.$$

Indeed each cube of Y has a positive degree, and summing those degrees gives the displayed geometric factor. Choose the raw response disc larger than the disc for the expansion, and use its corresponding source radius. The degree of the graded wall graph is bounded in terms of L, since neighboring grades differ by at most one. A connected set attached to the endpoint carrier is visited by a walk around a spanning tree, of length at most twice its size plus a fixed endpoint term. The resulting exponential count is paid by the switch margin. Choose the margin before M. The same argument applies to r_b, since subtracting the affine reference preserves the cut dependence and the bound of order $g_j(T+d)^2$ on the larger section. For d_b the terms that remain connect the two-block read to the join boundary. Use this same grain for the wider guards.

For the restricted inverse on W, take an intermediate set W_1 of variables containing W with a buffer. Use a guard beyond W_1 on which the switches are one, and the old real reference pair. Set the exterior switches to zero for the reference operators. Write P_W, P_1 for the projections onto W, W_1. The old local-positivity bound supplies a floor on the compression $D_{1,0}$ to W_1. Its congruence by $I + P_1\mathsf{S}_0P_1$ has a uniform floor, since its off-diagonal part is square-zero. To compare its W-compression with $A_{W,0} = P_W\mathsf{T}_0^{\mathsf{T}}D_0\mathsf{T}_0P_W$ on W, use

$$\mathsf{T}_0P_W = P_1\mathsf{T}_0P_W + (I - P_1)\mathsf{S}_0P_W.$$

The difference of the two compressions contains the last term at least once. Its norm is exponentially small in the buffer by the weighted bounds. This gives the real floor on W for a sufficient buffer, also when W cuts across the shear.

At the same reference pair, a term in the complex cut perturbation must reach from W outside the guard. The joined carriers, including those of S, bound this perturbation by $Ce^{-\nu d_{\mathrm{cell}}(W,G^c)}$ in the weighted row and column norm, with G the guard. The full perturbation E_W adds the change from the admitted real pair to the actual pair on this guard. At fixed switches the change of $\mathsf{T}^{\mathsf{T}}D\mathsf{T}$ is bounded by $C(\|\Delta D\|_\nu + \|\Delta\mathsf{S}\|_\nu)$, where $\|\cdot\|_\nu$ denotes the maximum of the weighted row and column sums. Expand the difference in the three factors and use the uniform norms on each section. The real floor and the exponential kernel bound give the weighted inverse of $A_{W,0}$ at a reduced rate by the local-resolvent estimate. Use

$$(A_{W,0} + E_W)^{-1} = \sum_{q\ge 0}(-A_{W,0}^{-1}E_W)^q A_{W,0}^{-1}$$

when the weighted norm of the product is less than one.

Use the old real Gaussian reference, namely the pair $(U, 0)$ with the same real factor U. On the joined response carrier use the same true-boundary prescription there, so at an incomplete stencil its current is the restricted variation at U. Compare the shear on the section with coordinates $q = (A', \mathbf{J})$, with norm $\|q\|_*$ the supremum of the layer-scaled potential, its first covariant difference and the independent current. The gauges on the complete joined cubes depend only on U. Fix their ceiling and a fixed upper bound for the real curvature with room in the raw response class. On a small fixed ball $\|q\|_* < r_*$, the plaquette perturbation estimate bounds the change of scaled curvature by $C_L(r_* + r_*^2)$, using adjacent-layer units on the full stencils. The independent current and the restricted variation on the true boundary fit the raw current radius by the same choice of ceilings. Reduce r_* to leave room also for the source conversion and the endpoint logarithm on the fixed physical collar disc.

On this section, for $\|q\|_* < r_*/2$, apply Cauchy's estimate to the line $(U, zA', z\mathbf{J})$ at fixed switches. The uniform weighted bound for the shear coefficients on $|z| < r_*/\|q\|_*$ gives

$$|\mathsf{L}_{bc}(U, A', \mathbf{J}) - \mathsf{L}_{bc}(U, 0, 0)| \le C\,\frac{\|q\|_*}{r_*} e^{-\mu d(y_b, y_c)}.$$

Summing at a smaller weight gives the required $\Delta\mathsf{S}$ bound. The old Gaussian comparison supplies ΔD on its own domain. The running radii fit inside this fixed response ball at weak coupling. The targets along this line use the averages, completed rows and parent lifts above. At $z = 0$ these give real targets in the same fixed frame. The old spectator occurrences keep their values.

Transport the old admitted decoupled covariance factor $R_0(\hat{s})$ by $R_1(\hat{s}) = (I - \mathsf{S}(\hat{s}))R_0(\hat{s})$, using the same guarded switches as in the precision. For the compression to W write A_W for the transformed precision on W and B_W for its block from the complement into W. Take $C_W = A_W^{-1}$ and $\Gamma_W = B_W R_1$, extending B_W by zero on W. The product has the same carrier joining and guard comparison. At full evaluation $R_1 R_1^{\mathsf{T}} = (D')^{-1}$, and block inversion gives its marginal on W as

$$C_W + C_W \Gamma_W \Gamma_W^{\mathsf{T}} C_W.$$

The full normalizer uses $\det D' = \det D$.

For the cut identities choose the guard as a union of fixed guards G_b of individual active slots. The connected cell set G_b contains every cell meeting the closed owner cell enlarged by a fixed fraction of its side divided by L. Add the prescribed endpoint and parent cells. For two cells with touching closures the grades differ by at most one. Subdivision on the finer of those grids shows that only $O_L(1)$ cells meet this enlargement. With M larger than the fixed resolvent patch width, it contains the local buffers of every cutoff that is nonzero at b. All masks come from the ambient stage. For a set W of integrated slots put $G(W) = \bigcup_{b \in W} G_b$. If Z contains $G(W)$, every G_b lies in the wall-component of Z containing its owner. Thus, for each such component Z_α, with W_α the slots of W owned there,

$$G(W_\alpha) = G(W) \cap Z_\alpha.$$

Use the same ambient lattice partition and the original slot mask in each component. Every surviving precision and root atom retains its full parent and patch reads. Its indices therefore agree with the indices in the component restriction. In particular A_W splits into the blocks A_{W_α} at a binary cut, and its inverse is taken block by block. The same split for $B_W R_1$ uses independent noise slots in the distinct components.

With $F = \Gamma_W$, use the normalized joint Gaussian in the active variable x and standard auxiliary noise y with quadratic exponent

$$-\tfrac{1}{2}(x - m - C_W F y)^{\mathsf{T}} A_W (x - m - C_W F y) - \tfrac{1}{2} y^{\mathsf{T}} y.$$

With n_x, n_y the real dimensions of the two vectors, the density factor is

$$(2\pi)^{-(n_x+n_y)/2} \exp(\tfrac{1}{2} \operatorname{Tr} \log A_W).$$

Both factors multiply over the components. Unused noise integrates to one. Here $\log A_W$ is the matrix logarithm of the actual switched compression, taken on the branch fixed by its positive real reference. The guarded perturbation is smaller in norm than the real floor, so A_W stays strictly accretive on the cut polydisc. Its logarithm there is holomorphic and agrees with the blockwise logarithm on a binary cut. This normalization uses the inverse A_W^{-1} and its own determinant. The independently switched full root supplies $F = B_W R_1$. Away from full switches the definition only uses that factor and its carrier bounds. Integrate out y to obtain the normalized cut measure $\mathcal{J}(W; s)$. At full switches it is the actual Gaussian marginal, by the identity for R_1.

For a cell set $\mathcal{K}$ outside $G(W)$, take the alternating sum

$$\nu(W, \mathcal{K}) = \sum_{\sigma \subset \mathcal{K}} (-1)^{|\mathcal{K} \setminus \sigma|} \mathcal{J}(W; \mathbf{1}_{G(W) \cup \sigma}).$$

Summing over $\mathcal{K}$ gives the full marginal by inclusion and exclusion. For fixed $\mathcal{K}$, the preceding guard equality factors the sum over wall-components of $G(W) \cup \mathcal{K}$. These are the two cut identities used by the gas. The determinant in $\mathcal{J}$ is a conditional normalization. The direct normalizer of the full stage is filed separately. The root identity with the inverse precision is used at full switches.

For the Gaussian cost on a graded cell Δ use its physical side ℓ_Δ and put $q = j + 1$. The ordinary kept form and the centre response of the strip use towers through level q. The new collar form uses the full prospective stage sequence. Its walks start at active slots in Z_q, with a fixed endpoint enlargement. Inside a quiet component the old Ω_{q+1} is separated from Z_q by at least ca_q, where $a_q = M \check{R}_q L^q$. This member is unchanged by the present stage. For an earlier stage the active slots are also far inside X, clear of the top joining collar. At the last stage the top level itself is q. Thus, until a walk has traveled a distance ca_q from an active slot in an earlier stage, it cannot use a layer with spacing greater than L^q. If it reaches another treated box, use the same estimate up to the first exit from the inset of its own box.

Put the guard at one on the cells touching the cells of the active set and include the fixed carrier reach of the chosen switched root. Use the local collar root below on the full stage tower and form the kept-strip root on its ordinary level-q grid. Take the parent image of the strip's fixed guard in the common cells. Adjacent grades differ by at most one, so around each active cell this guard covers a physical neighborhood of width at least $c\ell_\Delta / L$. Reserve the fixed one-step carrier reach inside this neighborhood. For q below the last stage the next original member stays unchanged on X. The active slots are in the carried G_q, which has the quiet gap of at least $8a_{q+1}$ to that member. Since $a_{q+1} \geq a_q$, this gives the upper clearance through the compressed stages. At the last stage there is no higher member. On the lower side the prepared separation gives room ML^q for the local buffers. For a patch crossing the exterior of the treated box use the separation of the prospective member at level q from the complement of the member at level $q - 1$.

Use the padded hulls in the escape estimate. A native atom whose constituent cells are all of levels at most q stays within $C_L \mathfrak{M} L^q$ of the tree point that meets it. If it has a constituent of higher level, follow its connected cell family to the first such constituent. The bounded family of earlier cells puts the tree point within $C_L \mathfrak{M} L^q$ of the higher member. The initial cell is anchored to the active index and has the same carrier bound. After allowing these fixed reaches, an off-guard term must already have paid weighted length

$$d_\Delta = c_L L^{-q} \min\{\ell_\Delta, a_q\}.$$

Use the native weighted lengths for the absolute walk sums. The displayed bound extracts an exponential for a term which leaves the guard, with room left for the row and column estimates. The number n_Δ of actual active slots is at most $C_L L^{-4q} \min\{\ell_\Delta, a_q\}^4$: use the volume of the cell and, separately, the size of the level-q quiet box. In the native stage grid the active slots and their local guards are at base grade q. If a later stage retags the formed term, retain the estimate at

the time of its formation. For each cell with active slots, $u = L^{-q}\min\{\ell_\Delta, a_q\} \geq M$. Consequently $n_\Delta e^{-cd_\Delta} \leq C_L u^4 e^{-c'u}$ is uniformly small once M is large.

For the shear, compare the response at s with the response at s_G, obtained by setting the switches outside the guard to zero. Keep the same ambient pair and stencils. Fix an active anchor b in Δ and use the weight $w_b(y) = e^{-\eta d_{\mathbf{B}}(y_b,y)}$, with $0 < \eta \leq \theta_0$ in the contraction estimate and η small compared with the physical source-decay rate. In each difference of primitive operators, a surviving summand visits a tag outside the guard. Join the test tree for a summand read at y to a path from y_b to y. The first native cell meets the test window at y, so its padding is covered by the same initial allowance. The first-escape bound applies to the joined tree with its padded carrier. The weight pays for the path to y; a fixed part of the native rate pays for the rest of the escape. The remaining rate gives the ordinary site sums. Thus for each primitive map O and bounded input f, in the raw scaled norms,

$$\|(\mathsf{O}(s) - \mathsf{O}(s_G))f\|_{w_b} \leq Ce^{-cd_\Delta}\|f\|_\infty.$$

The source prepared before switching is the same in both equations. If a source contribution is gated, its change has the same weighted bound, since its complete stencil meets the exterior. The change in the initial multiplier $\lambda^0 = \mathsf{KJ}$ satisfies the operator difference bound as well.

Subtract the two reduced fixed-point equations in the coordinates $(T, \lambda - \lambda^0)$. The first difference, between two iterates of the same map, costs at most half their distance in the weighted norm. At the second solution the change of map costs Ce^{-cd_Δ}, by the preceding bound and the local weighted estimate for $\mathsf{C}_T'^{\mathsf{T}}\Delta\lambda^0$. This proves the bound for the solution difference in that norm. The local endpoint read at d can lose the factor $e^{\eta d_{\mathbf{B}}(y_b,y_d)}$. Use Cauchy on the smaller fixed physical source disc to bound the difference of its derivatives. For the shear the rescaling of the input by g_j cancels the division of the output by g_j. Independently, the weighted source estimate bounds either derivative by $Ce^{-\mu d_{\mathbf{B}}(y_d,y_c)}$ for an input at c. The geometric mean of the two bounds gives, before summing,

$$\left|\mathsf{L}_d(s;c) - \mathsf{L}_d(s_G;c)\right| \leq Ce^{-c_0 d_\Delta} w_b(y_d)^{-1/2} e^{-\frac{\mu}{2} d_{\mathbf{B}}(y_d,y_c)}.$$

For the transposed kernel use $w_b(y_d)^{-1/2} \leq w_b(y_c)^{-1/2} e^{\frac{\eta}{2} d_{\mathbf{B}}(y_d,y_c)}$. The estimate holds on the larger switch disc, so the same escape factor can be retained when taking Cauchy coefficients that use an exterior switch. For a product difference, telescope the factors. At the changed factor the preceding bound leaves the inverse weight at its entry site. The triangle inequality bounds this inverse weight by the product of $e^{\eta d_{\mathbf{B}}/2}$ along the preceding legs from the anchor. The unused decay on those legs pays this product, with room for the row and column sums. The inverse root uses the local-resolvent carriers below.

This also gives a comparison away from a changed seam. Use a common R with matching traces and complete source and endpoint stencils as above. In each setting restrict the switches to R; the restricted read at b is the same in the two settings. For each unrestricted read subtract its own restricted read by the weighted estimate. The error is the sum of the two escape bounds, each in its own weighted distance. The derivative comparison uses the same physical input coordinate and the same Cauchy disc on both sides. A carrier that reaches a changed layer, boundary action or completion stencil can instead contribute an unmatched term. In the conditional strip form use the native kept and rejected chains at each evaluation, including the crossing and coupling terms in the interaction. At the collar use the actual pivot and seam curvatures in the native Hessian below.

To see the normalization cost, set $A = C_W^{-1}$ and $F = \Gamma_W$. In the representation with auxiliary standard Gaussian noise the joint precision is

$$K = \begin{pmatrix} A & -F \\ -F^{\mathsf{T}} & I + F^{\mathsf{T}} C_W F \end{pmatrix}, \qquad \det K = \det A.$$

At the real reference it has a uniform floor by the floor of A, the bounded norms, and the triangular change of variables. Let e_b be the sum of the absolute row perturbations of A and F at active slot b. With bounded absolute row and column sums, $C_W - C_{W,0} = -C_W(A - A_0)C_{W,0}$ and the three-factor expansion of $F^{\mathsf{T}}C_W F - F_0^{\mathsf{T}}C_{W,0}F_0$ bound the entrywise sum of $K - K_0$ by $C\sum_b e_b$. This also bounds its trace norm. The uniform operator perturbation is small on the admitted section. Let P be the projection onto the x coordinates. After multiplying the absolute density by $e^{\gamma_2|x|^2}$, the real precision is $\operatorname{Re} K - 2\gamma_2 P$. In the centered case the logarithm of its total mass is

$$\tfrac{1}{2}\operatorname{Re}\operatorname{Tr}\log A - \tfrac{1}{2}\log\det(\operatorname{Re} K - 2\gamma_2 P).$$

At the reference the two determinants agree. For a positive reference H_0 of uniform floor and a small perturbation E, the series for $\operatorname{Tr}\log(I + H_0^{-1}E)$ is bounded in absolute value by $C\|E\|_1$, where $\|\cdot\|_1$ is the trace norm. Apply this to A and to the real precision. The projection has trace n_x, so the tilt cost is at most $C\gamma_2 n_x$. For complex m first translate the real x by $\operatorname{Re} m$. In the real exponent the imaginary mean then contributes a constant bounded by $C\|\operatorname{Im} m\|^2$ and a real linear term with norm bounded by $C\|\operatorname{Im} m\|$. The tilt contributes the constant $\gamma_2\|\operatorname{Re} m\|^2$ and a linear term of norm $2\gamma_2\|\operatorname{Re} m\|$. Completing the square using the uniform floor gives the additional cost $C\|\operatorname{Im} m\|^2 + C\gamma_2\|\operatorname{Re} m\|^2$. The offset on the physical section is exponentially small. A free source that moves the mean can be restricted to a disc on which $N^*\|m\|_\infty^2$ is small, leaving room for the physical shift.

The guard and pair comparisons give $e_b \le C(e^{-cd_\Delta} + \epsilon_{\mathrm{pair}})$ for b in Δ, with the switch loss included in the constant. The running pair radii give $N^*\epsilon_{\mathrm{pair}} = o(1)$ on the joint Gaussian section. Use the reference coupling of the current scale in this Gaussian. The difference from the position-dependent Wilson weight is in the interaction. In particular the separate disc for ratios in the incoming terms does not enter e_b. If the Gaussian itself is rescaled by a ratio τ, the same argument charges $Cn_\Delta|\tau - 1|$ in each occupied cell, so that option requires the corresponding occupancy bound on its radius. Take γ_2 a fixed small multiple of $1/N^*$. After integrating out y, the tilted total variation of the cut marginal is bounded by the tilted absolute mass of the joint density. Thus in any cut component the logarithm of this bound is at most

$$C\sum_\Delta n_\Delta\big(e^{-cd_\Delta} + \epsilon_{\mathrm{pair}} + \gamma_2 + \|\operatorname{Im} m\|_{\infty,\Delta}^2 + \gamma_2\|\operatorname{Re} m\|_{\infty,\Delta}^2\big),$$

where the sum is over its occupied cells. Each summand is bounded, and a hot coordinate at scale $(\log\theta_j)^{\mathfrak{p}_1}$ gains $\exp[-c(\log\theta_j)^{2\mathfrak{p}_1-4r}]$. This pays the stage bound $\exp(C(\log\theta_j)^{4r})$ because $2\mathfrak{p}_1 > 8r$. The determinant of the full active reference still uses the old stage normalizer. These bounds use the native response and local-resolvent families in the fixed ambient stage. For a change of ambient tower the corresponding completed rows and native carriers must agree on the component where the comparison is made.

In the complete stage integral the reference is the sum of the homogeneous retained strip quadratic and the homogeneous collar quadratic. The collar linear term in the constant-weight Wilson part vanishes by stationarity on the fixed averaging fibre. The remaining interactions, including cross-component strip reads and changes of the background or coupling, are in the potentials. Unintegrated near fields occur there with their original real values and switches. Thus $\ell = 0$ for this reference on the complete integration vector. The new mean is $-\mathsf{T}^{-1}d = -d$, since d has only strip components. On a guarded read take the continuation $-P_W d(\hat{s})$. It has the same carrier as the offset and fits the smaller sharp threshold on the crossing slots. At full switches it is the mean of the full Gaussian restricted to W. The covariance formula accounts for the complementary coordinates. The real sharp tests still act in the specified fixed integration charts. All Taylor terms of the potentials, including any linear terms, remain in the interaction.

On the admitted joint switched section write the exact active inverse as $\mathsf{T}z + d + r(z)$. With T bounding all arguments on their actual enlarged discs, the nonlinear Gaussian correction is

$$-r(z)^{\mathsf{T}} D(\mathsf{T}z + d) - \tfrac{1}{2} r(z)^{\mathsf{T}} D r(z).$$

The product-logarithm and fixed-radius source estimates give $\|r\|_\infty \le C g_j T^2$. With the same endpoint gates for the exact and affine coordinates, r_b vanishes if either endpoint cell is inactive, and a surviving cut coefficient reads only the wall component of those cells. Cauchy's bound on the switched disc sums these coefficients with an exponential weight on their attached cells. The weighted row sums of D and T then bound the displayed terms, filed at a changed strip slot, by $C(g_j T^3 + g_j^2 T^4)$ in the weighted sum. For the term with two remainders use the row bound at one of its slots and join the other slot's carrier along the same matrix chain. This requires only one sum over the changed anchors. The Haar and pivot terms have the rooted bounds just proved. For the norm pinned at any cell of a joined carrier, keep a portion of the native spatial switch and walk decay. The distance from that cell to the changed anchor is at most the number of cells in the connected carrier, with a fixed enlargement for the endpoint blocks. Use the reserved decay to sum over anchor cells, whose face graph has bounded degree. Multiplication by the slot count of an owner cube, or by the logarithmic slot count over the component, is harmless since $g_j T^3$ is smaller than any fixed inverse logarithmic power.

For a mixed strip term with a fixed exterior slot, substitute only its active argument and keep the original switch on any near exterior argument. Its affine change involves $\mathsf{S}z + d$, so estimate it using the old chain bound. In the physical stage the selected strip masks are whole kept components. The kept form therefore has no mixed block against the fixed exterior components. Rejected chains and the ratio term are still boundary interactions. Use their formation rule chain by chain. Under the original local keeping predicate, rejection costs a cell of travel. This gives $e^{-c\delta_\star W_t}$ on the enlarged strip box before the remaining carrier decay. The ratio term uses kept chains, possibly short ones, with a factor $|1 - \tau_k|$. Both estimates absorb the two enlarged field radii. A Gaussian cut inside a kept component uses the full marginal formula for the omitted variables.

The stage bounds allocate separate margins for the pointwise reads, the tower reads and the core. The independent current increment uses the pointwise margin. The tower current, formed by averaging and solving the auxiliary problem for the substituted configuration, has its own estimate. On the graded interior windows, Prop. 3.138 and Cor. 3.140 apply to settled elements and control the changes by the weighted potential and its first difference. For an address read to depth p, its nonempty level-$(p-1)$ localization cube forces at least $M/L \ge L^3 \rho \ge 6\rho$ sites per torus period at that depth. This supplies the period floor in the ambient estimate. The full current stencil and the complete row reads remain those of that fixed address.

Here is the budget on a fixed inherited address. Write $\mu(x)$ for the layer of the preceding response sequence and $\ell(x) \le \mu(x)$ for the layer of the earlier address, truncated at its reading depth when required. Put $q = j + 1$, and write $D_n(x \mid l) = |l - q|$ inside a treated component and $(t - q) + (t - l)$ outside the treated components of this stage of level t. The decrease in the coefficient of the radius at a fixed index l is

$$\frac{\mathsf{g}_t(l)}{2\mathsf{N}_t} + \beta_{\mathrm{R}} 2^{-|l-q|} \mathbf{1}_{\mathcal{Z}_n}(x) \;\ge\; \gamma_\star 2^{-D_n(x|l)}, \qquad \gamma_\star = \frac{\theta_{\mathrm{s}} \beta_{\mathrm{s}}}{2\mathsf{N}_t}.$$

For a fixed tower address its left-hand read and its lift are unchanged. Multiply this coefficient gap by $L^{i-r} L_\flat^{2e_{\sigma''}(x)} \alpha_{0,\ell(x)}^{\sigma'' | \sigma_n}$ for the slack in normalized tower units. Where the layer changes from j to q, the ratio of the two scale weights gives a fixed fractional margin, including the lift gained there. The stage transition uses the same unfinished top radius.

At an inherited core the restriction also keeps the left-hand read and its radius number. The coefficient in the restricted bound is the later coefficient at the core's index. The gap at that index supplies the core margin throughout the original domain, even outside the treated component. In

the room estimate let $\mathsf{v}(b)$ be the pointwise gap profile in the input length $\mathsf{L}(b)$. For a core of scale ξ_i the shift uses the profile $\xi_i \mathsf{v}(b)/\mathsf{L}(b)$. The layered profile comparison bounds it by a fixed multiple of the core margin, with the core's radius profile included. This is the core condition in the same room estimate that handles the pointwise and tower clauses. Thus the stage amplitude bound also gives admission to the inherited graded cores.

The weighted path from the changed zone to x must traverse the intervening layers. On leaving a treated component it first reaches the original top layer t, since the quiet exterior of level t is inset. Thus, with $d^-(x, \Sigma')$ the preceding weighted distance, $D_n(x \mid \mu(x))$ is at most a fixed constant plus $d^-(x, \Sigma')/\varrho_0$. Here ϱ_0 is the layer traversal floor. The pinned response, in its own normalized units, has profile bounded by

$$s_1(x) = C g_j p_0(g_j) |\lambda_{\mathfrak{w}}| |B|_{\mathfrak{w}} e^{-\delta_1 d^-(x,\Sigma')}.$$

The constant includes the turn and switch costs, and $\delta_1 \le \delta_{\mathbf{H}}/2$. At the earlier address the shift and its first difference are bounded by $L^{-(\mu-\ell)} s_1$ in that address's units. The pointwise plaquette and current comparisons have at least this scale gain.

The settled tower estimate convolves this last bound with the tower decay in the earlier ambient distance d^{a}. One has $d^{\mathrm{a}} \ge d^-$. The difference of the layer losses $\mu - \ell$ at two points is at most $2 + 2d^{\mathrm{a}}/\varrho_0$, by counting crossings in each sequence. It follows that this convolution, in the form of the weighted supremum in the tower estimate, is at most a constant times $L^{-(\mu(x)-\ell(x))} s_1(x)$ when $\delta_1 + 2 \log L/\varrho_0 \le \delta_{\mathrm{T}}$. The required joint tower-class admission uses the same small shift on the full localization as in the estimate below.

Divide by the gap at $\ell(x)$. The bound

$$D_n(x \mid \ell(x)) \le D_n(x \mid \mu(x)) + \mu(x) - \ell(x)$$

leaves the factor $(2/L)^{\mu(x)-\ell(x)}$. It pays the part of the adjacent-coupling comparison coming from lowering the index to $\ell(x)$. In the running radius $C_\iota \theta_l^{-1/2} (\log \theta_l)^{q_{\mathrm{rad}}}$ the function of θ_l decreases at weak coupling. For an earlier index the logarithmic factor in the radius is at least as large, and the bounded drift of θ_l costs at most the square root of one plus the level difference. For the remaining comparison the bounded running increments cost at most $C(1 + \sqrt{|j - \mu(x)|})$. The factor $e^{-\delta_1 d^-/2}$ pays this factor and the factor $2^{D_n(x|\mu(x))}$, since $\delta_1 \varrho_0 \ge 2$. This leaves the distance factor at rate $\delta_1/2$.

For an inherited domain X, write $\mathsf{d}_n(X)$ for its distance in cubes from the changed layer and $|B|_{\mathfrak{w}}$ for the supremum on component $\mathfrak{w}$ divided by the box radius. The stage profile budgets the increment by

$$\mathsf{a}_n^\delta |\lambda_{\mathfrak{w}}| |B|_{\mathfrak{w}} < e^{\delta_\star \mathsf{d}_n(X)}, \qquad \mathsf{a}_n^\delta = O\big((\log \theta_j)^{-(q_{\mathrm{rad}} - \mathfrak{p}_0 - r)}\big).$$

Here q_{rad} is the exponent of the running radii. The power comes from $\gamma_\star^{-1} = O(\mathsf{N}_t)$, $\mathsf{N}_t = O((\log \theta_j)^r)$, and the ratio $g_j p_0(g_j)/\alpha_{0,j}$. The physical values $\lambda_{\mathfrak{w}} = 1$ satisfy this inequality for small coupling. For the common substitution take the intersection of these discs over the actual readers. The uniform disc obtained at $\mathsf{d}_n = 0$ is sufficient for joint admission. On the readerwise larger discs the same common formula is restricted to that reader. The fixed analytic disc of the ordinary joined centre is used for its own unamplified source. The stage discs are also limited by $|\lambda_{\mathfrak{w}}| e^{\varkappa} < c_{L,\varkappa} \varrho_{\mathrm{st}}$, where $|s| < e^{\varkappa}$ and ϱ_{st} is the strip radius in units of its field threshold. The fixed factor $c_{L,\varkappa}$ leaves the margin for the inverse strip arguments. The physical value remains interior for small coupling.

The real layer allowance $e_l = \check{R}_l^2 \varepsilon_l$ is used in admitting the base pair. The largest compressed conversion for current or local gauges costs $O(\check{R}_l^3)$. Thus it requires the $\mathfrak{p}_0 + 5r$ logarithmic power of the real endpoint estimate. The stage floor $q_{\mathrm{rad}} \ge \mathfrak{p}_0 + 7r + 1$ leaves room also for a sum over the N_i stages. The response amplitude in the displayed profile inequality is determined by the free collar box and the running radius. It uses the actual collar increment, rather than the bound for the base pair.

4.17.1.33. Domains of the earlier entries. Use the graded formation rule from the bare density onward. A tower address consists of an earlier structure σ'', a localization Z of level i, and a depth $1 \le \mathsf{p} \le i$. At level zero the direct bare reads use the pointwise clause. The tower of an earlier address is the meet of the localization tower with the sequence of σ'', through depth p. For $\mathsf{p} \le r \le i$ remove two layers of level-$(r-1)$ M-cubes from Z to form $Z^{\wr r}$. Read a plaquette or a current stencil when all its corners lie in this window. Its base point then lies in the layer of the tower of index $\min\{\mathsf{p}, \ell\}$, where $\ell = \min\{m_{\sigma''}(x), i\}$ is the nominal layer. Indeed $Z^{\wr r} \subset Z^{\wr \mathsf{p}}$. The two-layer localization comparison for $M \ge L^3 M_1$ gives agreement of the tower and earlier region memberships through p on that window, where M_1 is the cube size used in the localization. In bare units the curvature and current bounds use the respective factors $L^{-2\ell}$ and $L^{-2\ell-\min\{\mathsf{p},\ell\}}$. Both are multiplied by the layer radius with its lift and ambient coefficient, and by L^{i-r}. The tower itself and the ambient coefficient thus play different roles under restriction.

4.17.1.34. The allowance and the stage gap. The profile hypothesis in Prop. 3.143 follows from the actual radius clauses at an inherited stage address. We give the comparison, including its dependence on the stage. Fix that address, its ambient structure σ'', its level i and its window index r. Put $m(z) = \min\{m_{\sigma''}(z), i\}$. This is the nominal ambient layer, denoted by ℓ above; the native settled tower index is $\min\{\mathsf{p}, m(z)\}$. The clause radius and its stage gap are indexed by the nominal layer. Abbreviate by α_m the radius $\alpha_{0,m}^{\sigma''|\sigma_n}$ selected by the bare-level, unfinished-top and adjacent-index conventions. Let $e(z) = e_{\sigma''}(z)$. Choose a fixed $C_\alpha \ge 1$ large enough to include the ratio of the potential radius to the curvature radius, the adjacent-index comparisons and the change of base point within a complete stencil. Here we use the actual running radius system of the stage formation, whose components have the same logarithmic power, or a fixed absolute system. The ratio of its two components is fixed in either case; taking the minimum of neighboring running radii preserves that ratio. Thus C_α is independent of the stage, coupling and depth. Define

$$B(z) = (1 + \beta_{\mathrm{s}}) C_\alpha L_\flat^{2e(z)} \alpha_{m(z)}. \tag{4.cdxlvi}$$

The pointwise clauses on this inherited address give $A(z) \le B(z)$, with A as in eq. 3.mcxxxi. The independent current does not enter A. At a real stage endpoint the stronger tested allowance $\check{R}_l^2 \varepsilon_l$, including its compressed-scale conversion, also fits this bound by the endpoint calculation.

Fix $0 < \kappa < \delta/4$, where δ is a common rate in Lem. 3.142 and Prop. 3.143. Decrease the common stage rate δ_0 if necessary so that $0 < \delta_0 \le \delta$. Set

$$R_\kappa(x) = \max_z e^{-\kappa d^\flat(x,z)} B(z). \tag{4.cdxlvii}$$

This is a deterministic function of the structure and its radii. The triangle inequality gives $R_\kappa(z) \le e^{\kappa d^\flat(x,z)} R_\kappa(x)$, and $A \le B \le R_\kappa$. Thus eq. 3.mcxxxv holds with $C_0 = C_1 = 1$ and $\mathcal{R} = R_\kappa$, without an additional profile assumption.

For the stage profiles one also has

$$R_\kappa(x) \le C_B B(x), \tag{4.cdxlviii}$$

where C_B is fixed before the coupling ceiling. Here is the layer comparison that proves this assertion. Let $d = d^\flat(x,z)$ and let ϱ_0 be the common traversal floor of the inherited determining sequence and its original regularity ancestor. The latter sequence is coarser; truncating the inherited sequence at i only increases its metric. Counting the intervening separated layers in each sequence gives

$$|m(z) - m(x)| \le 2 + 2d/\varrho_0, \qquad |e(z) - e(x)| \le 4 + 4d/\varrho_0.$$

Indeed a path between layers differing by h crosses at least $h-2$ complete intervening collars. Apply this to the two layer functions whose difference is e. The endpoint conventions for the radius move its selected index by at most one at either end.

For the running function $\theta^{-1/2}(\log\theta)^{q_{\mathrm{rad}}}$, choose the coupling ceiling so that $\log\theta > 2q_{\mathrm{rad}}$. This function decreases with θ. The frame bounds eq. 2.xx then give, for radius indices a, b, $\alpha_a/\alpha_b \le$

$C(1+\sqrt{|a-b|})$. To check this in the direction in which the radius grows, use $\theta_b \le \theta_a + \bar{B}|a-b| + c_5$; the square-root factor bounds the power of θ, while the logarithmic factor decreases. The opposite direction costs only the fixed correction c_5 at the weak-coupling ceiling. The minimum of neighboring radii obeys the same estimate. Consequently

$$\frac{B(z)}{B(x)} \le CL_\flat^8(1+\sqrt{4+2d/\varrho_0})e^{8(\log L_\flat)d/\varrho_0} \le C_B e^{(8\log L_\flat+1)d/\varrho_0}.$$

Choose the fixed geometric floor so that $(8\log L_\flat+1)/\varrho_0 \le \kappa/2$. Multiplication by $e^{-\kappa d}$ and maximization over z prove eq. 4.cdxlviii. This choice enlarges only the fixed geometric constants.

Write $\mathsf{gp}_n(x,m)$ for the deterministic margin between the two stage bounds at the read. The coefficient decrease computed above gives, at a fixed inherited index,

$$\mathsf{gp}_n(x,m) \ge \gamma_\star 2^{-D_n(x|m)} L^{i-r} L_\flat^{2e(x)} \alpha_m, \qquad \gamma_\star = \frac{\theta_{\mathrm{s}}\beta_{\mathrm{s}}}{2\mathsf{N}_t}. \tag{4.cdxlix}$$

Define the number used in the cut estimate by

$$a_{\star,n,x} = \min\left\{1, \frac{\gamma_\star 2^{-D_n(x|m)}}{C_B(1+\beta_{\mathrm{s}})C_\alpha}\right\}. \tag{4.cdl}$$

It is positive and depends only on the address, the stage and the read. Combining eq. 4.cdxlvi, eq. 4.cdxlviii and eq. 4.cdxlix gives

$$R_\kappa(x) \le a_{\star,n,x}^{-1}\mathsf{gp}_n(x,m).$$

The radius and lift cancel, and $L^{i-r} \ge 1$ improves the bound. No lower bound for $a_{\star,n,x}$ independent of the stage and the read is asserted. By Prop. 3.143, a cut satisfying its complete-carrier separation changes either settled read by at most

$$K_{\mathrm{D}} a_{\star,n,x}^{-1} e^{-c\delta_0 D}\mathsf{gp}_n(x,m). \tag{4.cdli}$$

In particular, to spend at most a fraction $\vartheta \in (0,1)$ of that margin it suffices to impose

$$D \ge \max\left\{K_{\mathrm{cl}}M, \frac{1}{c\delta_0}\log\frac{2K_{\mathrm{D}}}{\vartheta a_{\star,n,x}}\right\}. \tag{4.cdlii}$$

The same criterion applies simultaneously to finitely many reads by taking the largest required distance. In particular the dyadic coefficient loss is paid by the displayed distance when such simultaneous margin preservation is required.

4.17.1.35. A geometric cut of a settled tower clause. In the units of the earlier address, cut Z by a union R of level-t cubes and keep the component Z_R of $Z \cap R$ containing the base x of the read. Components here join also at corners. Suppose that x is at distance at least $\mathsf{D}+3M_1$ from $Z \setminus R$, with $\mathsf{D} \ge K_{\mathrm{cl}}M$ as in the localization bound. The cut tower is finer by monotonicity of the layer construction under enlargement of the complement. The complete-carrier argument following Prop. 3.143 locates every changed datum read within $C_{\mathrm{cut}}M_1$ of the actual cut $Z \setminus R$, including the old parent pillars and outward endpoint blocks. It also treats discarded components by first exit through the actual cut; it requires no extra spacing assumption between such components. Increase K_{cl}, once, so that $(C_{\mathrm{cut}}-3)_+M_1 \le \mathsf{D}/2$. Every changed complete carrier is then at distance at least $\mathsf{D}/2$ from the read. The retained r-window, complete stencil, free pillars, nominal layer m and native tower index $\min\{\mathsf{p}, m\}$ are unchanged there.

For the same admitted pair, Prop. 3.143 and eq. 4.cdli bound the change in the magnitude of either settled read by

$$K_{\mathrm{D}} a_{\star,n,x}^{-1} e^{-c\delta_0 \mathsf{D}}\mathsf{gp}_n(x,m).$$

The positive factor $a_{\star,n,x}$ is the explicit number in eq. 4.cdl; it depends on the stage and the read. The bound of the clause depends on the location, indices and structures, so it has the same right-hand side before and after this cut. An available margin larger than the displayed error survives

the restriction. In particular eq. 4.cdlii is sufficient for preserving a prescribed fraction of the stage gap. This proves the row and domain comparison with its stated margin and distance condition. A composed reader uses the stencils and switches of its actual presentation.

4.17.1.36. Shifting the field in a fixed tower. On these windows the tower comparison estimates the recomputed current itself. Write $\mathbf{U} = e^{i\eta A'}U$ and $W^u = e^{i\eta(A'\boxplus\mathbf{A}^\circ)}U$ using one real factor U and the local logarithm of the shifted pair. When both potentials lie in the admitted tower class, Prop. 3.138 and Cor. 3.140 give the normalized current increment

$$L^{2\ell+\min\{\mathsf{p},\ell\}}|J^0_{\mathsf{p},Z}(W^u)(b) - J^0_{\mathsf{p},Z}(\mathbf{U})(b)| \le C\max_{c\in\mathsf{Z}^+} e^{-\delta_{\mathrm{T}}d^\flat(y_b,y_c)}\max\{l(c)|v(c)|, l(c)^2|\nabla_U v|_{\mathsf{Z}}(c)\},$$
$$v = A'\boxplus\mathbf{A}^\circ - A'.$$

Here J^0 is in bare units, and Z^+ consists of the positively oriented inner bare bonds of the localized first member. Each y_c is the earlier ambient pillar top of the base point of c. Use that sequence's distance $d^\flat$ and local length l. The comparison allows the base point of the full stencil within $2\xi_{\mathsf{p}}$ of Z^{lp} when the whole stencil is in the localization's bond set. The agreement of the region memberships on that halo covers stencils that straddle an ambient layer boundary. The same estimate holds for the plaquette increment with weight $L^{2\ell}$.

Use the real factor U of the input on the whole localized first member. The pinning estimate bounds the relative logarithm of $W^u\mathbf{U}^{-1}$ and its covariant first differences with this same real factor. Use the resulting $\mathbf{A}^\circ$ in the product $A'\boxplus\mathbf{A}^\circ$. The small product chart gives a single holomorphic choice on each fixed-real-factor section. In particular the real factor of the recomputed tower stays U.

The ambient lengths of the earlier address are at most the lengths at the input, including at the base points of the full stencils. The pointwise input radii therefore bound $\mathsf{n}_c(A')$ and the normalized curvature of U on the entire first member. This uses the full localization for the radius test, while its inset windows specify the output stencils. Let $\mathsf{u}(c)$ be the maximum of the earlier weighted value and first-difference bounds for the relative shift, and let $\mathsf{u}^+(c)$ include the neighboring bonds of the product estimate. Apply the common radius budget on these complete carriers. The turn cost is fixed in terms of L, M, and the bound on u there is $CL^{-(\mu-\ell)}s_1$. The same bound, with the neighboring maximum, is small uniformly as the coupling ceiling decreases. Thus the base norms can be put below $a_{\mathrm{T}}/2$ and the shift satisfies

$$\mathsf{u}(c) \le (256L^2)^{-1}, \qquad \mathsf{n}_c(A') + 2\mathsf{u}^+(c) < a_{\mathrm{T}}$$

throughout the section. The geometric floor of the tower theorem is the separation floor for its fixed localization, chosen before the coupling ceiling. The shift estimate now gives the recomputed tower on this same mask. Fit the resulting normalized increment in the available window margin, with L^{i-r} at window r, by the preceding budget.

Give each boundary term, potential away from the strip, stage correction and interaction term the structure of its formation. Carriage retains its level, localization domain, function and space. When a stored coordinate is integrated, its occurrence in the prospective evaluation is set to zero and its switch is discarded. Before the first stage the sum of earlier stage corrections is zero. At each subsequent stage keep the original domain and stored attachment of each correction already formed. The old evaluation of the sum uses the levelled triple restricted to each of those domains. The prospective evaluation uses its own triple and sets the strip field being integrated to zero. The difference of the two evaluations enters the new collar integral. Lifting a lower boundary term to a larger support for the expansion leaves its original argument domain in place.

On the common stage profile bound, the levelled substitution sends the stage-$(n+1)$ space into every earlier graded space. The prospective evaluation uses restriction from the output structure. At each slot the formation structure precedes its own level's output structure, which in turn precedes the current output. For a carried slot take the standard reduction of the outgoing history on its

original domain. This reduction has the completed trace of the healed label on the domain's windows, treats no component on its enlarged read, and keeps the recorded drop-outs there. If the enlarged read misses the treated components, one may use the history itself. The traces on the smaller windows agree for all these choices. Restrict the reduction to the old level before taking the term and its space. The first members of its tower clauses are contained in the original domain. Intersecting the same read of the old sequence with the same localization tower gives the same clause on each such first member. Identify the original first member, the determining rows including the one-step completions, and the pairs of tower and window indices before comparing radii. The order of layers and the distance comparison in the profile estimate are comparisons within that common labelled sequence. For a stored region transported to the new label they apply after the address has been matched: on its full read the sequences agree, and the tower, window, lifts and address radii persist. Pointwise descent between two output labels by itself gives only the pointwise part of this comparison. A term whose old hull has been absorbed uses the new filed term, with its own formation domain.

For example, a kept-chain summand of the ordinary ratio correction that reads a far strip bond has the form

$$-\tfrac{1}{2}(\tau_l - 1)\sum_{b,b'} a_b^{\mathsf{T}} D_\omega(P)_{bb'} a_{b'}.$$

Here l is its original fluctuation level and D_ω is the kept chain in the ordinary conditional form. On its full carrier in the original two-cell strip trace, the regular-pair comparison applies to the pinned pair with the original free rows. It uses pointwise potential and current estimates. Its far arguments are the joint strip coordinates bounded above, and its near arguments use the old multipliers. The row estimate on the enlarged field disc is $C|\tau_l - 1|(\varrho_{\mathrm{st}}\mathfrak{b})^2$ times the old carrier decay, within the tube bound. A rejected long chain uses its own pair domain on its complete carrier.

For an inherited cluster or strip-transfer entry that uses an earlier activity, keep the two blocks and parent transports of the strip at its original step, as well as every tower address $(\sigma'', i, Z; \mathfrak{p}, r)$ of its formed argument. For instance, in a boundary cluster $E^\sharp(X)$ a vertex made from an incoming boundary term uses its ordinary potential on Y, with $Y^\sharp \subset X$. Recover the ordinary trace on the one-layer windows of X at each level. It specifies the old cuts, tiers and which input potential has this support. The ordinary fluctuation substitution in that potential uses the determining rows and gauge cubes of $Y^\sharp$. Its fluctuation variables are those of the ordinary formation, distinct from the free variables of the later collar.

At the original step k, a vertex of species V^B is made from localized differences $f(P_{\mathrm{o}}; \mathfrak{q}) - f(P; \mathfrak{q})$ of an incoming boundary term on its original domain, say D. In both evaluations the stored arguments $\mathfrak{q}$ are the same. The ordinary substitution in P_{o} uses the corrected ordinary fluctuation at $\mathcal{M}^k\mathbf{U}$. With the real factor U fixed, the substituted link and the independent current are

$$e^{i\eta A''(b)} U(b) = u(b_-)\, e^{i\eta\lambda_{\mathrm{o}} H(b)} \mathbf{U}(b)\, u(b_+)^{-1},$$
$$\mathbf{J}'' = \mathrm{Ad}(u)(\mathbf{J} + \lambda_{\mathrm{o}}\mathsf{j}).$$

Here u is the ordinary pinned levelling map and j the reduced current increment of this response. The identity of the second line with the physical current holds at the full real arrival. The complex tower clauses use the recomputed tower current of the shifted potential on their own windows.

For admission at this inner substitution, the ordinary step supplies the coefficient gap $c_0\, 2^{-(k+1-n)}$ at the index n of each earlier clause, including when the reference radius is the smaller of two adjacent radii. Use that gap times the clause's radius as the margin in the weighted potential estimate. For a tower clause the comparison of profiles includes the length ratio between the tower and the input sequence, and the exponential in their distance from the stencil. The separation of successive layers pays the geometric gap ratio and the square-root ratio of the running radii. This gives the pointwise, tower and core room for the ordinary response. Write r_D for this room after

the reduction for the pinned map. For an ordinary field box bounded by $\mathsf{C}_{\mathcal{A}}\delta_k$, use the separate amplitude radius given by

$$R_{\mathrm{o},D}^{-1} = \frac{C}{r_D}\,\mathsf{C}_{\mathcal{A}}\frac{\delta_k}{\alpha_*}e^{C\varkappa-\delta_*\mathsf{d}_k(D)}.$$

The bound applies to the whole original graded section, with $R_{\mathrm{o},D} > 2$ on the enlarged ordinary formation box at small coupling. Here one uses its enlarged $\mathsf{C}_{\mathcal{A}}$ in the radius formula. The far stored fields in the vertex retain their original radii.

In the closed cluster the integration over the original ordinary B_I still uses its fixed real cutoff balls and its original conditional Gaussian, with the mean determined by B_E. At a moved crossing it is only the external far slot of B_E that takes the reconstructed coordinate. When the outer substitution lies in the original graded formation section and these external slots lie in its field box, the original absolute majorant of the cluster applies on the whole integration section. The outer stage margin is used for these membership tests. The subsequent ordinary substitution uses the gap and amplitude of its original step, uniformly over the section just reached.

For the first earlier-stage correction that reads this strip, carry the closed first-stage function, including the carriers of its original source closing. The second stage uses the common stage triple on that full formation domain, including its inherited cores. The old evaluation uses the reconstructed far field, and the prospective evaluation sets that integrated field to zero. The original source closing is already part of the carried function. In this correction the far slot is a stored-field argument. Its parent targets are read through the pair.

For a tower-current read use the common real factor and the earlier weighted potential bounds on all of Z for both the base and the pinned input. The six incident plaquettes and the halo of the stencil must be in the graded read of the same address. The new filing hull carries the resulting term while these evaluations use their original tower. In a newly composed operator we must also check the joint read of the retained datum if it enters the strip inverse in a separate role. The one-step forms and elimination factors use their separate pair domains.

4.17.1.37. Carrying the formation reads through a cut. A formed summand has a fixed base read. Keep the part of its original structure, row masks and stored attachments used there. An earlier normalizer or closed cluster term enters once with its formed function. The closed carrier includes the attachments of the earlier source closing. The current substitution acts on this closed function. It changes the pair and the currently integrated variables, on the rooted arms of the current bracket. In particular the zero-increment value at the fixed base has no new spatial switch. A bracket using the old summand keeps its complete base, and its response differences are formed on that base with the new source arms.

An old quadratic or pivot factor instead uses its one-step trace. For the strip Schur form keep the original chain classification into kept and rejected terms. The rejected chains and the coupling correction retain their original filing in the exponent. At each full evaluation their sum with the kept form is the original conditional quadratic. Retag a kept chain by the parent image of its actual old tags, as in the grading argument. Its binary-cut criterion is inherited through that image. A solved row uses the original target and its complete double block, including the prescribed group links. Keep its determinant with that row.

At a stored spectator the base includes its original site, top, and full pillar. In an actual stage structure a stored endpoint at level l is a top or has its parent at level $l+1$. The complete level-$(l+1)$ block is separated from level $l+2$. Its membership at level $l+1$, and hence its pillar and transport, persist while this field remains stored. In a genuinely finer geometric localization the same site may become a top. The transport in that new localization cannot be used for the earlier occurrence just from the depth bound.

Use the fixed stage geometry in the binary cuts of the response. For each original top y keep the complete dependence set of the pin, including the averaged contour, the level-one neighbor margin, and the stencils of its turning cells. Use the padded hull of each response walk, which

contains the blocks of the output tops and of their four successive neighbors. The node factor and contour use internal links of the original block. The turn uses its child blocks. Include the actual two-bare-step stencil at the exceptional level-one pins. There the fixed ambient eligibility condition puts the nearby pillars at levels at most one. For an actual stored field of level zero the full parent block is separated from layer two by the storage margin. The complete pin and turn stencils are over the two-neighborhood of the original top. If a response at an output top z meets this read, the symmetry of the neighborhood puts the whole read in the four-neighborhood of z. This is the neighborhood in the padded hull.

Tag every closed graded cell meeting the padded hull. At each point of a surviving hull the cells that contain that point contain a neighborhood in their union. Their star is connected through positive-area faces by nested grid refinement. The connected hull is therefore inside one active wall component, also at faces between grades. For inherited walks use the parent image of their actual old tags. Pulling back binary switches along the parent map gives exactly the old binary test, even when the deduplicated complex monomial uses fewer factors. Keep the old closed functions as filed. For a new operator without an admitted native walk presentation we must still verify this padded-hull condition on the actual pin and output stencils.

On a binary cut a nonzero increment on a pin carrier then has that whole carrier in one active wall component. Otherwise the increment on the carrier is zero. On the original pillar form

$$p_y(a) = \tau[\mathbf{U}](a)^{-1} v[P;\mathbf{A}](y)^{-1} \tau[e^{i\eta\mathbf{A}}\mathbf{U}](a).$$

If the response is zero there, $p_y(a) = 1$. Otherwise the formula uses only the unchanged pair on the fixed carrier and the increment of the one wall component. On the child turning cell use $u = e^{-i\mu}$ with

$$\mu(x) = \mathrm{bp}_a(x) T_a[U](x) \tfrac{1}{i} \log\bigl(p_y(a)^{-1}\bigr),$$

using the original bump and real-factor transport. The turn is supported in the inner third of that cell. The pinned response therefore splits into the responses of the wall components, with disjoint nontrivial gauge factors. The cut restriction agrees on each active pin because its carrier, data and response traces agree.

Choose the pinned tops in the ambient geometry once. Work on sections where all needed tops are levelled on the whole polydisc. The local pin estimate is $|p_y^{\pm 1} - 1| \le c_{\mathrm{m}}(L)\varepsilon_y(\mathbf{A})$. The turned pair costs at most $\mathsf{C}_{\mathrm{m}}\|(\mathbf{A},\mathbf{K})\|_y^+$, where the norm includes the neighboring level-one pillars. Check this bound against the room of every earlier reader on the complete turn polydisc. On that polydisc gauge invariance at real turns and holomorphy give independence from the auxiliary bump or real-factor representation when the values at the stored sites agree. On a fixed real-factor section the transport equality extends from its open real slice to the admitted complex branch because both contour means there are holomorphic. Equality of pairs gives the same point pins. To identify the full turned triples compare their real frames on the turning cells as well, or use the invariance of the term on the admitted turn polydisc. Throughout this argument the stored values are fixed. In particular a Borel near value stays in its original slot and an inherited scalar switch keeps its old radius. Only an actively integrated far field is multiplied by $\lambda_{\mathfrak{w}} s$; for an actively integrated near field this multiplier is its scalar switch and the value itself is fixed. The recentered crossings use the far arguments already checked on their two blocks. A new reader which uses a different near argument must supply the corresponding real coordinate and switch rule.

For an island factor keep its standing history, integration measure and whole exempt hull. At fixed internal real data take the old and new pair evaluations of its analytic exponent. The internal real weight is the same in those evaluations. The island hull is one fixed read, with new response arms at its attachment. The cut factorization is applied at fixed island data, and the original island integral is taken once on its carrier. This uses the old bounds for the analytic exponent and the mass on that carrier.

Once the Gaussian and potential estimates on the common discs are available, the localized logarithm defines the new correction in its own formation space. On a fixed support, the accumulated correction is read from the last contributing stage by restriction to the spaces of its summands. The construction of the incoming terms begins with the bare density as described below.

The ordinary boundary terms, the lower boundary terms other than pointed sums and the earlier stage terms use only their declared strip slots. Such a slot is read from a domain containing one of its endpoints. A term formed at level l reads stored fields of levels strictly below l. Contact with an endpoint at the integration level can therefore create an attachment through the pair response while leaving the stored arguments as they were.

For the direct exterior-only mask consider the complete blocks of a new collar pivot. Both endpoint blocks lie outside the old Ω_q, whereas an old strip fluctuation slot at the integrated level has an endpoint in Ω_q. An inherited pivot that reads the changed collar uses its original ordinary strip component, whose affected blocks are in the old-wall comparison. The kept strip reference is integrated by whole components, and its mixed blocks across distinct components vanish. Keep separate strip factors and long-chain corrections on their original carriers. A determining value has its own row coordinate, even when it forms a reference on a block with a stored fluctuation.

The successful completed strip tests are products of bond tests. Split each product between its active and retained coordinates. On an active bond use the smallest of its passing thresholds. On the retained bonds keep the real indicators in the carried kernel. A failed rim product belongs to the component of its failure, so it is carried in the frozen part or the separate stopped branch. These splits give the real cutoffs of the passing conditional integral.

In the analytic difference of strip quadratics, write each chain on its carrier as

$$-\tfrac{1}{2}\sum_{b,b'}\eta_b^{\mathsf{T}}(D_Y^- - D_Y^+)_{bb'}\eta_{b'}, \qquad \eta_b = \begin{cases} a_b, & b \text{ far}, \\ \mu_b a_b, & b \text{ near}. \end{cases}$$

The multiplier belongs to the original slot in each occurrence, including both occurrences on the diagonal. This preserves the carrier and its cut rule. Inherited analytic functions keep the switches of their own slots. At $\mu_b = 0$ these functions and the new interaction forget a_b. At $a_b = 0$ they forget μ_b. The Gaussian reference and its determinant use the integrated coordinates themselves. The retained real kernel carries its own selectors. The surviving far fields keep their full original discs, since their occurrences in analytic functions and in the new polynomial are separate from the determining rows that form the response. The switch identities pass through the connected expansion once its old analytic readers are admitted on their formation domains.

4.17.1.38. The first stage and the physical density. At level zero the array contains only the bare inverse coupling, and the density is $e^{-\beta A(U)}dU$. There are no carried analytic entries at this level. At a step of level t, form the boundary terms of $\mathbf{T}$ as the sum of the localized normalizer, the cluster terms assigned to the boundary, the covariance and weight corrections, and the localized strip shift. Inside the small-field region their triple argument lies in the enlarged level-t core with radii $(1+\beta_{\mathrm{s}})\alpha_{\iota,t-1}$. On the other supports it lies in the graded space of the completed label just after $\mathbf{T}$. This structure precedes the structure at stage zero and has the same radius numbers there. The boundary construction gives holomorphy in the triple, the far fields and the switches on those spaces. On the cutoff zone it uses the real stored field; its Jacobian difference there is the difference from the zero-field value multiplied by the switch.

For a newly external plain far bond let $R_{\mathrm{out}}(b)$ be its declared carried radius. Choose the ordinary formation box on these bonds to contain the discs of radii $R_{\mathrm{in}}(b) = 2R_{\mathrm{out}}(b)$. This is a choice of the fixed prefactor C_1^{fl} of the current far-field box, made before the weak-coupling ceiling. Keep the real collar and rim bounds and all inherited stored-field discs at their prescribed sizes.

Indeed, in the guarded conditional Gaussian, the external-to-mean operator is a sum of kernels with a uniform exponential row bound. Newly external far bonds are at distance at least $cW_t - O(1)$

from the integrated bonds, where $W_t = LM\check{R}_t$. Their contribution to the absolute row sum, divided by the integrated threshold, is bounded by

$$C\theta_{\mathrm{c}}^{-1} \sup_{b \text{ far}} \frac{R_{\mathrm{in}}(b)}{\mathfrak{b}_k} e^{-c' W_t}.$$

It tends to zero even on the larger discs. Thus the far part of the mean leaves the margin supplied by the real collar and rim. The enlarged-box potential bounds apply with the chosen fixed prefactor. In particular the ordinary fluctuation bounds include the cubic error on the enlarged box and the ratio error bounded by a constant times $|1-\tau_k| \sup_b R_{\mathrm{in}}(b)^2$. The same tube bound and the same choice of logarithmic powers make these errors small for the cluster sum. Apply the uniform activity majorant on this formation box before making the strip substitution.

In the plain zone write $H(b;W)$ for a piece of the strip shift with carrier W. It includes both endpoint blocks and reaches the join boundary. On the pair sections of its formation,

$$\sum_{W} \sup |H(b;W)| \le C(\alpha_{0,k} + \alpha_{1,k}) e^{-c\check{R}_t}.$$

The same bound with a reduced $c > 0$ holds with a fixed prescribed carrier weight in the sum, by choosing M large at that rate. For a simultaneous transfer put

$$a_{\mathrm{pre}}(b;\mathbf{z}) = \frac{1}{ig_k} \log \left(e^{ig_k a_{\mathrm{post}}(b)} e^{-i\sum_W z_W H(b;W)} \right).$$

The physical map is recovered at $z_W = 1$. On fixed amplitude discs $|z_W| < R$, $R > 1$, the product logarithm gives a uniform displacement bound $CRg_k^{-1} \sum_W \sup |H(b;W)|$. The exponential in $\check{R}_t$ makes this smaller than $R_{\mathrm{in}}(b) - R_{\mathrm{out}}(b)$. This holds on all plain far slots together. Thus the transferred cluster can be evaluated on the full output discs and the transfer differences can be estimated on the z_W discs. On the cutoff zone use the separate real-field switch, with the smooth cutoff evaluated at the real field of that zone.

At full switches the strip correction is the change of the localized exponent under the strip substitution, together with the logarithm of its Jacobian. To see this, let $F_X[S]$ denote the combined term on X with the strip substitution turned on at the bonds of S. Include in F_X the retained quadratic term, the cluster and covariance terms that read the shifted coordinates, and the negative of the localized Haar log term in the strip formula. If W is the set of eligible switches, the sum of the differences with nonempty index set is

$$\sum_{\emptyset \ne S \subset W} \sum_{T \subset S} (-1)^{|S|-|T|} F_X[T] = F_X[W] - F_X[\emptyset].$$

File a difference on the union of the old domain and the shift carriers. This changes the index of the term in the sum and leaves its value there unchanged. In real coordinates $a \mapsto a'$ the pullback of the incoming Haar density is the Haar density at a' times the strip Jacobian. Keep the Haar density at a' in the reference factors and sum the log strip Jacobian separately on its carriers. At the zero stored field the cutoff is constant near zero, so the strip map is the identity there and its log Jacobian is zero.

At a physical argument U the ordinary step $t = k+1$ gives the exponent for the completed label $\mathcal{S}^+$.

$$\begin{aligned} \mathsf{A}^+(U) = A_{k,\mathcal{S}}(U) + \mathsf{n}_k + \sum_{z \in \Lambda^0} \sum_{z \in X \subset \Lambda} E^{(k+1)}(X,U,z) \\ + \sum_{X \subset \Lambda^{\sim -1}} R''^{(k+1)}(X,U) + \sum_X \left[E^{\partial}(X,U) + B_{\mathbf{T}}^{(k+1)}(X;U,\underline{\mathfrak{f}}) \right]. \end{aligned}$$

Indeed on $X \subset \Lambda$ the bond pointing weights sum to one. Points outside Λ^0 give E^{∂}, and remainder terms outside $\Lambda^{\sim -1}$ go to the boundary cluster family. Outside Λ the normalizer and cluster terms enter the boundary family directly. The form corrections and the strip differences just described are

added once. Use the reference convention with covariance $\tau_k^{-1} A_{\mathrm{II}}^{-1}$ on the integrated bonds. The change in the gauge quadratic relative to this convention belongs to the interaction. The scalar in this identity is

$$\mathsf{n}_k = n'(\theta_k)\#(\mathfrak{X}_{\mathrm{I}} \sqcup \mathfrak{X}_{\mathrm{E}}) + n''(\theta_k)\#(\Omega \cap \mathbb{T}^{(k+1)}) + \big(n''' - \tfrac{3}{2}\log \tau_k\big)\#\mathfrak{X}_{\mathrm{I}}.$$

The three counts refer to fluctuation bonds, gauge blocks and integrated bonds, respectively. They give the Haar value and field rescaling, the gauge normalization, and the Gaussian constant including the ratio correction. These counts depend on the label. The localized normalizer accounts for $-\frac{1}{2}\log\det A_{\mathrm{II}}$ and the log inverse determinants of the interior eliminated rows. The exterior row factors belong to the retained operation. If the local normalizer is centered at the trivial field, put the removed constant in the scalar part before recentering the vacuum energy. Rewriting the coupling and vacuum energy repartitions A^+. The tests of the completed label and the reference measures of its operations multiply this exponent in the real measure.

For the ordinary output, evaluate a stored factor in an adapted representative of the native determining set. The geometry of an ordinary stored bond of level ι puts its endpoints at tops or at sites in a pillar with top of level $\iota + 1$. Its parent block is separated from the next higher layer. Use the endpoint at which the stored factor is represented. If it is a top, the residual gauge group fixes it. Otherwise let a be the site, $y(a)$ its native pillar top, and $\tau[U](a)$ its contour transport. A gauge that is $\tau[U](a)$ at each such stored site and the identity elsewhere sets those transports to one and fixes the nodes. This uses the original pillars at all the stored reads. If U and U^w are two such representatives,

$$1 = \tau[U^w](a) = w(y(a))\,\tau[U](a)\,w(a)^{-1} \quad \Longrightarrow \quad w(a) = 1.$$

The background and its physical current transform together. Covariance of the factor therefore gives the same value on both representatives with its stored arguments held fixed. For a kept operation that reads a root, the same conclusion uses the determining-node condition on that root. When a cut or a test tower changes a pillar, use the native evaluation for the stored factor.

For an earlier island (I, i) the root is a level-i site in $I^{\sim} \subset \Lambda_i^+ \subset \Omega_i$, which is disjoint from Ω_{i+1}. For $i = k$ this uses the separation of the newly appended Ω_{k+1} from the standing island. Thus the root lies in layer i of the ordinary output. If preparation acts on the component containing I, quarantine gives $i < h_t$ and the prepared sequence agrees with the original up through h_t. This leaves both layer membership tests at i and $i + 1$ unchanged. Outside the acted components the sequence was left fixed. In the healed comparison the surviving spectator roots are outside the added region Z, where their layers are unchanged. A level-i site in layer i is a determining node. For a current main operation, the entrance bond has its outer endpoint in the component and outside the prepared core, by the clearance of the main box. That endpoint is a node at the current top level. These checks fix the roots in the corresponding residual gauge groups. A crossing fluctuation whose initial point is outside its box transforms at that point. The exterior starts in an earlier operation lie on the same single-layer shell inside $I^{\sim}$. In the current operation they lie on the outer level-t shell outside Z_t''. They are fixed nodes by the same layer argument. The residual action fixes the group-valued drop-out frame variables directly.

Lower boundary terms formed in the same manner keep their original graded spaces. The stage-origin terms have the graded spaces of their respective stages. The terms from exponentiating an earlier large-field operation use its output space. They are the interaction with no chosen component together with the additional localized remainder. The boundary parts of the pointed regular sums are formed on their single-scale cores. In the next ordinary step take the boundary and stored-operation potentials by subtracting the two evaluations at a common pinned substitution, with the stored arguments fixed. This subtraction is analytic on the graded step domain and preserves the far-field and switch radii of the entering terms. The regular, remainder and Wilson potentials use the plain substitution on their respective domains, since their arguments carry no stored fields.

These are the argument spaces of the formation rules. When using a reduced history as a donor, take its member with the space in which that member was formed.

For real evaluation, fix the outgoing and retained data on an admitted labelled fibre of a stage. Write a for the active old strip fields and B for the free collar variables. Let $F_-(a,B)$ denote the old evaluation of the entries being transferred, and let $F_+(a)$ denote their prospective evaluation at the same strip values. In both evaluations the switch of each integrated strip field is one and the spectator fields and switches are preserved. Each earlier correction has already closed its own response source against its stage shift. The fixed exterior exponent is $F_+(0)$, with zero in each integrated strip slot in the original coordinates and its switch removed. The zero of a translated integration coordinate can give a different stored value. For the remaining measure $d\Gamma$, containing the tests, chart Jacobians and Gaussian factors, the exact identity is

$$e^{F_+(0)} \int \exp\{[F_-(a,B) - F_+(a)] + [F_+(a) - F_+(0)]\}\, d\Gamma = \int e^{F_-(a,B)}\, d\Gamma.$$

The first bracket uses the same-strip response potentials. The second is the active strip dependence already present at the prospective background. It stays inside the integral. Use the estimates for the prospective strip entries at fixed background and include them once. In the joint strip substitution above, the empty cut gives $F_+(0)$ and the full cut gives $F_-(a,B)$. Its difference therefore includes both brackets. The kept strip quadratic has its separate Gaussian decomposition below. At this stage put $q = j+1$. The active variables of $d\Gamma$ are the level-j stored fluctuation on the selected old strip and the free nonpivots of the newly opened collar. The old slots meet Ω_q, have no endpoint in Λ_q, and exclude the original pivots. Take the whole stored mask of each selected component of $\Omega_q \cap Z_q$ contained in the treated X. Other stored variables are fixed, including deep core variables whose factors can still read the moving background. On the active strip keep the ordinary completion, collar and rim indicators on their original masks. Where several apply to the same slot their conjunction tests at the least of their thresholds. The free sharp collar ball acts on the new nonpivots. An additional sharp test in the inherited strip uses its own transported chart as above. The prospective regularity guard depends on the fixed datum and remains outside the collar logarithm. This includes the prospective crossing tests wherever they are used. The tests inside the integral are in their original real slots, with their thresholds set by the frozen frame. Completing a Gaussian square changes the reference exponent and its normalization. The domain of a hard cutoff stays in its original coordinate.

On a common parameter section, write the integral as $\int 1_E(a,B)\, F(P,\mathsf{y};a,B)\, d\mu(a,B)$, where E contains the fixed real cutoffs and F contains the chart and exponent factors. At each point of E, holomorphy of those factors gives holomorphy of F in the section parameters. A common integrable absolute majorant on smaller parameter discs then lets the Cauchy formula pass through the integral. This gives the analytic integral on that section, evaluated on the real data selected by the external guard. Its nonvanishing and localized logarithm use the connected expansion and its separate estimates below.

To identify $d\Gamma$ in the two representations, use the same reference scale θ_j for the Gaussian, the gauge draw, the thresholds and the fluctuation units. Put the difference from the running action weight in the interaction.

For the collar form put $q = j+1$ and use the full preceding determining sequence with its closed no-inward row set. The exterior collar is $K_q = (\Omega_q^c \setminus Z_q'') \cap X$. The direct graded rule releases level-j rows with an endpoint in K_q and neither endpoint in the old Ω_q. The added level-q coarse rows have the same endpoint rule on their own grid. Alignment by complete level-q blocks puts both blocks of any such row outside the old Ω_q. They lie inside the preceding member of level j. In fact for $q \le k_0$ the collar extends at most five coarse cells into the old exterior and for $q = k_0+1$ it extends seven. The eight-cell quiet gap keeps the blocks away from the old G_j, also at the first stage. For $q > k_0+1$ the separation between successive prepared faces is at least one M-cell of level

q. This gives the same conclusion for the remade preceding member. The parent and double-block reaches are $O(L^q)$ and fit these margins. Thus the nonlinear source is tight in the preceding metric.

In a double block meeting the prepared face, the internal fine links on the prepared side are held, and the links in the active block and those crossing that face are released. The regular inverse solves the new coarse row for its unique middle pivot. A row with no endpoint in K_q cannot read any released link in its full double block. A crossing into the old Ω_q belongs instead to the ordinary strip. Any change of its old pivot through the exterior block is handled in the inherited double-block chart with the old coarse target and the old coarea factor. At the overlapping stages use the actual preceding determining datum. In particular the level-j rows completed by the last stage already have its averaged values. Among the exterior coarse deltas, use exactly the newly added rows at this stage. The exterior stock has neither endpoint in the old Ω_q, since the ordinary step already eliminated rows meeting that member. This leaves the old-wall coarse row with one elimination factor and no additional exterior delta.

The base of the collar form is the prospective real background at the induced datum. This background is critical on the preceding fibre since that fibre at the induced datum is contained in the prospective fibre. Write z for the physical level-j nonpivot perturbation, $b(z)$ for the plain row increment in that sequence, and $\beta(z) = b(z)_\natural$ for its reduced logarithm. The retained plain rows have increment zero. On the free rows and pivots use the exact one-step graph

$$\mathsf{C}_V z - \mathsf{h}_V \widetilde{\mathsf{D}}_V(\mathsf{C}_V z).$$

The pivot contribution to the second derivative of this graph is $-2\mathsf{h}_V C_V^{(2)}(\mathsf{C}_V\cdot, \mathsf{C}_V\cdot)$. The moving level-$j$ rows of the old set are interior there. The naturalizer can also change an old outward row c of level q whose outer block reads the moving fine rows, even though $b(c) = 0$. For its outer end x write $\ell_x = (1/i)\log\theta_x(b)$ for the seam factor on the complete internal links of that block. Then $\beta(c)$ is $\mathrm{Ad}(V(c))\ell_x$ if $x = c_+$, and $-\ell_x$ if $x = c_-$. No internal link in that block is a coarse pivot, since each pivot is between two blocks. Reuse the same factor at an outer end shared by several rows, with the orientation of each row. Thus the pivot curvature belongs to the released level-j pivot rows and the seam curvature to the old level-q rows that read the moving block. A newly added coarse row is used in the fixed-target pivot equation and has no coordinate in β. The naturalizer reads plain increments once. It does not propagate a reduced increment into a further level.

Write $F(A)$ for the Wilson action at $e^{i\xi A}U_0$ in the reference normalization, and $\mathcal{Q}(A)$ for the straightened row logarithm. Let $A(z) = \mathbf{H}(\mathbf{1}; \beta(z))$ be the real response of the preceding problem. Its node gauge restores exactly the plain datum and preserves F. Put $K = \mathcal{Q}'(0)$. On the real critical pair $F'(0) = K^{\mathsf{T}}\lambda_0$. For $P_B = A'(0)[B]$, differentiate $\mathcal{Q}(A(z)) = \beta(z)$ twice to obtain

$$(F\circ A)''(0)[B,C] = (P_B, F''(0)P_C)_\xi - \big(\lambda_0, \mathcal{Q}''(0)[P_B, P_C]\big)_{\mathrm{rows}} + \big(\lambda_0, \beta''(0)[B,C]\big)_{\mathrm{rows}}.$$

Here the reduced row pairing is the counting pairing, and the two terms with λ_0 are distinct. The inner constraint curvature has the minus sign from eliminating A''. The outer derivative uses the signed pivot and seam terms of β''. These terms remain even though the first variation on the fixed-target collar fibre vanishes.

Put $\nu(z)(c) = \xi_c^{-1}\beta(z)(c)$ and write $(\cdot,\cdot)_{\mathbf{B}}$ for the pairing with row weights ξ_c^4. On the real response slice the first two terms are the constrained form with $\mathsf{G}_1^{-1} - Q^{\mathsf{T}}\mathsf{a}Q$. Indeed the gauge projection term vanishes on the slice and the current correction of G_1^{-1} is the quadratic constraint term there. The linearized response in these units is $P_B = \mathsf{H}_1\nu'(0)[B]$: it solves the linear constrained variation at the prescribed row $\nu'(0)[B]$, with the same slice condition. Using $Q\mathsf{H}_1 = I$ and $\mathsf{G}_1^{-1}\mathsf{H}_1 = Q^{\mathsf{T}}\mathsf{S}_1$, where $\mathsf{S}_1 = (Q\mathsf{G}_1Q^{\mathsf{T}})^{-1}$, gives the Wilson form

$$\big(\nu'(0)[B], (\mathsf{S}_1 - \mathsf{a})\nu'(0)[C]\big)_{\mathbf{B}} + \big(\lambda_0, \beta''(0)[B,C]\big)_{\mathrm{rows}}.$$

Multiply by θ_j and insert g_jB, g_jC for the two physical perturbations. The scalar factor is $\theta_j g_j^2 = 1$.

On the complex section with independent current use this operator formula for the continuation. For the outer term take $\lambda_0(c) = \xi_c^3(\mathsf{H}^{\mathsf{T}}\mathbf{J})(c)$, using the same linear right inverse H as in the inner current correction. On the real critical slice $J = \hat{Q}^{\mathsf{T}}\lambda_0$ and $\hat{Q} = \mathrm{diag}(\xi_c)Q$. In the row pairing with weights ξ_c^4, this gives $\mathsf{H}^{\mathsf{T}}J = \xi_c^{-3}\lambda_0$, and $\mathsf{H}_1^{\mathsf{T}}J$ gives the same value there. The uncorrected and corrected right inverses can give different current contractions off the critical slice. The two attachments of $\nu'(0)$ to the native walk family of S_1 use bounded local stencils at levels $j, j+1$. The subtraction a is a local row term. In the last summand attach the native multiplier walk $\mathsf{H}^{\mathsf{T}}\mathbf{J}$ at the row of β''. In each case the walk and the complete local stencils meet at a common row. The bounds are absolute in the weighted walk norm and apply to the actual full-depth form.

The switched fixed-source derivative used for a centre response is obtained from the reduced equations. At zero source the multiplier is $\lambda_s^0 = \mathsf{H}(s)^{\mathsf{T}}\mathbf{J}$, in the counting coordinates of that system. Writing $\mathsf{m}(c) = \xi_c$, the counting right inverse is the weighted right inverse times m^{-1}. The Schur operator in the multiplier equation is $\mathsf{m}^3\mathsf{S}\mathsf{m}^{-1}$ in place of the weighted S. The diagonal conversions keep each native walk carrier. With $T_\lambda v = (\mathsf{C}''(0)[v,\cdot])^{\mathsf{T}}\lambda$, the derivative of the potential there is

$$\partial_{B'}\mathbf{H}(s;0) = \big(I - \widetilde{\mathsf{G}}(s)T_{\lambda_s^0}\big)^{-1}\mathsf{H}_0(s).$$

Expand the inverse by the small-current bound of the contraction. Each T_λ uses the complete local row stencils and the walk for the multiplier attached at that row. At a nonzero admitted source, differentiate the whole contraction and use its Neumann inverse on the potential and multiplier increments. The carrier is formed by joining the surviving walks and local row stencils at shared entries. At full switches on a real critical datum the linearized response on the constraint slice is $B' \mapsto \mathsf{H}_1\mathsf{m}^{-1}B'$, the response used above in weighted units. This identification does not replace the derivative on the switched section.

On the prospective axial blocks the soft density adds the Gram of the linearized mean contours. The carried gauge factors cover the old band. The gauge draws beyond that band cover the remaining active blocks. Their reference weight θ_j cancels the g_j^2 of the two scaled derivatives. Write its derivative in a changed gauge as the derivative of the relative contour $T(z)T(0)^{-1}$. A fixed real gauge conjugates this relative contour at the block centre and hence preserves the Gram. In the no-inward sequence a noncentral site of a complete active prospective block is free: the level-j rows from the preceding layer into that block are the omitted inward rows. If a density factor also reads a contour at a retained node in another mask, keep its exact factor in the interaction unless its variation on the collar graph is established. Constancy on a fixed critical orbit alone does not give its constancy along the varying datum.

The flat floor uses the actual plain tangent v_j of $\mathcal{M}^j U^-$, after the row and node conversion. Its value at an active nonpivot is $g_j B$, and its linear coarse row increment is zero on the fixed targets. At the flat pair the multiplier term and the inner constraint correction vanish. The Wilson Hessian controls the level-j curl of v_j. Indeed the linear one-step flux map on full carriers has row and column sums L^2, L^{-2}. Its ℓ^2 bound is one in dimension four, so one may iterate on the full backward union without a depth loss.

On a complete double block, zero circulations make a fine one-form a site difference. Zero mean contours make its site function constant on each block. A zero coarse row makes the constants equal. The resulting finite-dimensional bound controls the fine norm by the squares of the circulations, mean contours and coarse row. For a collar slot internal to one block use the single-block part. For a collar crossing use both endpoint blocks. At the prepared inner face the other block lies in the preceding layer j and its internal rows are held, so their tangent is zero. The coarse row across that face remains fixed. The crossing into the old Ω_{j+1} belongs to the inherited strip. Thus all the active collar slots have their full curl carriers and the required contour terms. Sum the block bound with bounded overlap and use $\theta_j g_j^2 = 1$. This gives the flat floor uniformly in the full depth, and coordinate compressions inherit it by extending the test vector by zero.

For the real comparison use the full form on the fixed collar geometry. Partition the active slots by real multipliers χ_ν with $\sum_\nu \chi_\nu^2 = 1$, supported in cubes of side $O(RL^{j+1})$ with bounded overlap, for a large fixed R. For a kernel $D(b,c)$ the partition error has matrix entries proportional to

$$D(b,c)\sum_\nu(\chi_\nu(b)-\chi_\nu(c))^2.$$

The row and column bounds give an error $C(R^{-2}+e^{-cR})$. To see this, use the first differences of the cutoffs for distances at most RL^{j+1}, and use the first escape length in the native metric at larger distances. Near an active slot the quiet collar and the preceding prepared separation leave a cell of clearance for the full buffered patch in layers $j, j+1$. Fix the native walk grain $\mathfrak{M}$, take R large at that grain, then take M large enough to put the buffer and its full stencils inside the clearance. Use one real gauge on the complete comparison cube, which meets the preceding layer j. For $j \geq 1$ the quantitative gauge clause gives, for $U^u = e^{i\mathsf{v}}$,

$$L^j|\mathsf{v}| + L^{2j}|\delta\mathsf{v}| \leq CML_\flat^{2e}\alpha_{0,j}.$$

The radius tends to zero after the fixed geometric choices, also with the allowed overlap factor. At $j=0$ the patch has fixed size in bare lattice units. A tree gauge on this box bounds the links and their first differences by a fixed constant times the bare plaquette bound, by filling its fundamental cycles inside the box.

Conjugate the whole compressed patch by the same real gauge, acting orthogonally on the active bond variables. Compare short terms with their values at the trivial pair by interpolating its link logarithms and its independent current from zero. Evaluate each short term on its full carrier, using the fixed local admission radii and Cauchy's estimate. Sum with the native weighted walk majorant. The multiplier term vanishes at the trivial pair and has the same small bound. A term leaving the buffer pays the first-escape cost even if its matrix indices coincide. Until escape it takes at least $cR/\mathfrak{M}$ native cell steps, which gives the exponential tail from the walk majorant. The floor follows by perturbing the flat form on each patch and applying the partition bound to the active nonpivot vectors. In applying the flat estimate to a localized vector, lift that vector through the collar graph at the fixed targets. Cutting off the previously lifted tangent need not preserve those constraints. This comparison also gives a real floor for the analytic operator at the admitted small real pairs with independent current, including the zero-current reference.

A carrier-restricted comparison uses the complete double blocks of its active slots and the same gauge and coarse target rows. If the guard includes the full local stencils and the surrounding buffer, the terms it deletes have the exponential first-escape bound. Their operator norm is below a fixed fraction of the real floor by the Schur estimate. This supplies local positivity for the guarded precision on these carriers.

Use the local resolvent construction for the inverse root. Take the partition above by translates on the level-j grid, with supports of side $O(RL^{j+1})$, normalized by the sum of the squares of the translated bump. Its normalizing sum is fixed by the grid and independent of the active mask. Around each nonempty support take an enlarged active patch and a further buffer, both of width of order RL^{j+1}. Write D_ν for the compression to the active slots of that patch of the sum of the unswitched precision terms with complete carriers in its buffer. Use the same rule after any prescribed compression of the strip. The real floor and the small complex pair perturbation give the local resolvent $G_\nu(x) = (D_\nu + x)^{-1}$ for $x \geq 0$. The weighted conjugation estimate bounds its rows and columns by $C/(x+\gamma)$ at a reduced rate, with $\gamma > 0$ fixed. For two active indices in a patch the distance is at least a fixed multiple of their physical separation in level-$(j+1)$ units. A path staying in the two-layer neighborhood uses at most that spacing, while a path leaving it first pays a length larger than the diameter of the patch in those units. Summing the entrywise resolvent bound over the level-j slots gives uniform row and column bounds, including on the compressed patches.

Set

$$G_{\mathrm{p}}(x) = \sum_{\nu} \chi_\nu G_\nu(x) \chi_\nu, \qquad (D + x) G_{\mathrm{p}}(x) = I + E(x).$$

With local matrices extended by zero the error has the two families

$$[D, \chi_\nu] G_\nu(x) \chi_\nu, \qquad \chi_\nu (D - D_\nu) G_\nu(x) \chi_\nu.$$

In the first use the absolute walk sum of D, placing the cutoff difference on each term. The square-sum of the cutoffs and the ℓ^2_ν bound on their translated differences give C/R after the weighted row sum. More explicitly, $\sum_\nu |\chi_\nu(d)||\chi_\nu(b) - \chi_\nu(c)|$ is at most $C \min\{1, |b - c|/(RL^{j+1})\}$ by Cauchy–Schwarz on the translates. Use the common entrywise resolvent bound before this sum. In the second, a discarded term with both endpoints in the local matrix must leave the buffer, which costs Ce^{-cR}. These estimates use the same complete carriers for D and its local inverse. The local inverse itself has the buffered patch as its carrier. All patches with active slots fit inside the base-layer neighborhood of the collar. Choose M larger than their fixed size in one-step units. Then a patch meets only a bounded number of the aligned base cells, so its switches cost $e^{C\varkappa}$. A small exponential weight on the physical patch diameter also costs a fixed factor, by choosing its rate of order $1/R$. With the remaining native walk decay for D, the absolute majorant of $E(x)$ is bounded by

$$\frac{Ce^{C\varkappa}}{x + \gamma} (R^{-1} + e^{-cR}).$$

Use R sufficiently large for this bound to be less than $1/2$ uniformly in x, then use the indicated floor on M.

Expand $G_{\mathrm{p}}(x)(I + E(x))^{-1}$ in these terms. The products join their carriers at common indices. Tag each resulting term by the distinct graded cells meeting the joined carrier. At binary cuts the surviving terms use only their active components. At full switches the sum is the resolvent of the physical precision. The integral with weight $x^{-1/2}/\pi$ gives the inverse-root family, since $(x + \gamma)^{-1}$ is integrable against this weight. The pair comparison uses

$$G_\nu(p; x) - G_\nu(p_{\mathrm{r}}; x) = -G_\nu(p; x)(D_\nu(p) - D_\nu(p_{\mathrm{r}}))G_\nu(p_{\mathrm{r}}; x).$$

It bounds the difference by $C\epsilon_{\mathrm{pair}}/(x + \gamma)^2$ on the same buffered mask. Telescope each resolvent product in one factor at a time. The remaining geometric sum is bounded by $\sum_{n \geq 1} n\, 2^{-(n-1)}$. Integration gives the pair bound $C\epsilon_{\mathrm{pair}}$ for the switched root on the same carriers. The guard error uses the separate first-escape bound on its deleted carriers.

For the log use the resolvent representation with kernel $(1 + x)^{-1}(D - I)(D + x)^{-1}$; this keeps the cancellation at large x before integrating. Each inverse or log uses the same locally formed precision and actual retained masks. The trace for the direct stage term is taken on the full compressed precision before the shear, since its determinant is preserved by that shear. Attach each diagonal of a log term at its actual active slot, with the whole carrier of the term. Subtract its value at the trivial pair using the same mask and buffer, and use the pair comparison of the resolvent products for the subtracted term. This trace supplies the direct stage normalizer. The normalized cut measure uses the separate determinant of A_W. This defines a switched root by its carrier terms. The full-switch identity is the one used in the Gaussian marginal formula.

On the stage carriers that admit a common-scale box cover, the subtracted trace can be summed over stages. Write $\ell = \log \theta_i$ at the top of the waiting window and choose $H = A \log \ell$. Split the trace expansion by carrier length in its native units. The terms of length greater than H spend part of the rooted decay to gain e^{-cH}. In the native local-gauge walk use the sum of its itinerary length and its number of factors for this split. The itinerary exponential pays for the first quantity and the spare walk-factor decay pays for the second. Use the actual stage anchors in the split.

For a short term, suppose the complete carrier is in a filled nonwrapping box of side at most CH in the stage units, with an admissible cover by overlapping gauge boxes of that scale. The

local potential, first difference and current have size bounded by $\mathfrak{a} = C\theta_i^{-1/2}\ell^C$ there, using the running radii in the waiting window. At small coupling $H\mathfrak{a}$ is within the gluing radius. Gluing the real gauges across the cover costs the side ratio in the potential and its first difference. Rotate the independent complex perturbation and current in the same gauges. This gives one gauge on the whole carrier, with the complete pair bounded by $CH^C\mathfrak{a}$ in its local coefficient norms. The trace is unchanged by this change of gauge.

Compare with the trivial pair on the same buffer and masks. The local resolvent comparison, or the telescoping estimate on the factors of the log walk, bounds the subtracted diagonal by its summable majorant times $CH^C\mathfrak{a}$. In the walk formula the closing loop stays in the filled box. Its transport is also within $CH^C\mathfrak{a}$ of the identity, by multiplying its links in that gauge. A fixed power of the walk length is paid for by the rate reserve. The same bound holds when a short term fits in just one of the original gauge boxes.

The uncompressed stages supply such a region for their interior roots on the real support. At stage level $q \le k_0$, the old component of level $q-1$ lies inside the hull whose eight-cell enlargement is Ω_q^c in the class box. The prepared Z_q'' removes five of those layers. The roots of the collar outside Z_q'' therefore have at least three level-q cells to the older core, before the fixed carrier padding. The lower re-made regions lie in that core. In the other direction use the quiet gap to the unchanged upper member. If the padded root neighborhood stays in the class box, a box of side ca_q around it, with fixed additional padding, uses only the two neighboring units. The ordinary current and curvature bounds on that box give the small real gauge by the large-box gauge estimate, with loss bounded by a fixed power of $\check{R}_q$. The two units cost a fixed factor of L. A carrier leaving this neighborhood pays $e^{-c\check{R}_q}$ in the first-escape bound. Thus these uncompressed roots can be summed on the physical real sections. On a complex section the same gluing applies when its real factor has the native small gauge clauses on the padded cover. The independent current is then estimated in its own coefficient norm.

In the local-gauge walk expansion, join consecutive transition sites by a path γ_a inside the padded localization $X_a^{\sim}$ of the factor. Close the path inside X_0. The localizations used here are connected unions of a bounded number of boxes, so each segment uses a bounded number of coordinate-monotone paths. The comparison of the two gauges at an overlap uses a path in the retained overlap. This must be checked for any overlap clipped by the stage mask. The complete closing loop γ lies in $X_0 \cup \bigcup_{a\ge 1} X_a^{\sim}$.

Let u_a be the gauge of the a-th factor. After conjugating the transition product by the root gauge, its factors have the form $u_a(x_a)^{-1}u_a(x_{a+1})$. Write this as $W_aU(\gamma_a)$, where W_a is a conjugate of $U^{u_a}(\gamma_a)^{-1}$. If the clause bound holds along the path, and $s(b)$ is the local scale of the link, then

$$\|W_a - I\| \le C\mathfrak{a}\sum_{b\in\gamma_a}\frac{\eta}{s(b)}.$$

Include the closing factor in this estimate. Telescoping the products of unitaries bounds the difference from $U(\gamma)$ by the sum of these errors. The adjoint closing factor differs from the identity by at most twice this sum plus $2\,\mathrm{dist}(U(\gamma), Z(G))$. The box diameter bounds the physical path length. For the weighted sum use the smallest scale met by the path. On a complete connected cover of $O(H)$ graded cells with adjacent grades differing by at most one, the ratio of the largest and smallest scales is at most L^{CH}. The errors of the local gauges then cost only a fixed power of ℓ times $\mathfrak{a}$.

For the walk comparison one can also use a chain of clause boxes in which only consecutive boxes intersect. Use this when the complete closing path runs through such a chain and the successive grades differ by at most one. Adjust the constant gauges in order along the chain so that the two gauges match at one site of each overlap. On an overlap the change of the relative gauge along a path is bounded by the sum of the link deviations in the two local gauges. The coordinate paths in a clause box have physical length at most a fixed multiple of its side. If $\xi_{\min}$ and $\xi_{\max}$ are

the smallest and largest units of the chain, moving the transition to the point of the closing path costs at most $C\mathfrak{a}\,\xi_{\max}/\xi_{\min}$. The paths within the boxes obey the same bound for their transports. Multiplying these factors bounds the closing loop by a fixed power of H times $\mathfrak{a}\,\xi_{\max}/\xi_{\min}$. For a short term through $O(H)$ boxes, this size ratio is at most L^{CH}. The remaining log-walk factors use their original local gauge estimates. This proves the short-term bound also for these chains, with an extra factor at most ℓ^{C_A}.

There is a second closing-loop estimate for the compressed region. Suppose its complete closing loop is carried between the class box and the strictly inset old box of level k_0. On that full shell the prepared grades are at least k_0. With the real curvature bound on the shell, each bare plaquette defect is at most $C\mathfrak{a}\eta^2/\xi_{k_0}^2$. Choose each coordinate path in a box by moving in one coordinate at a time. A walk with p nonroot factors then has at most $C(p+1)$ straight pieces. The local path errors also obey the weighted estimate above with $s(b) \geq \xi_{k_0}$. A padded box of diameter $C_L\mathfrak{M}\xi_i$ therefore costs at most $C\mathfrak{a}\mathfrak{M}\xi_i/\xi_{k_0}$ per factor. The rectangular shell loop estimate bounds the holonomy defect by the number of straight pieces times the square of the outer side in bare units times this plaquette bound. The two bare mesh factors cancel. The remaining scale cost is bounded by

$$C(M\check{R}_i)^2(\xi_i/\xi_{k_0})^2 \leq C(M\check{R}_i)^2(L\check{R}_{k_0+1})^2.$$

Here $\mathsf{s}_{k_0+1} = M$ gives the last ratio. The result is a fixed power of ℓ times $\mathfrak{a}$, with the walk-length factors paid as above. Thus a short loop on this full shell is also covered by the subtracted trace estimate, even when it has no thin-chain cover. This use of the shell requires the plaquette bound between the two boxes, including its filling plaquettes. It applies on the real support and to restrictions of stage pairs on the whole class domain with this bound on their real factor. For a supremum on a locally defined pair space, one must show that the admitted pair has such an extension or bound its closing transport on the filed domain itself. The local gauge clauses can hold on an annular carrier for a flat connection with noncentral holonomy.

In the native weighted distance there is a lower escape bound for these compressed collars. At $q = k_0 + 1$, the prepared box removes seven of the eight outer cells from the old hull enlargement. To reach the old core from the active collar costs at least one of these cells. At $q \geq k_0 + 2$, a connection from outside Z_q'' to the old core crosses the band between Z_{k_0+2}'' and Z_{k_0+1}''. Its width is $2M - \mathsf{w}_{k_0+2}$ in top units, at least cM. That band has grade $k_0 + 1$. By the definition of weighted length, crossing it costs at least $cM\xi_i/\xi_{k_0+1} = cM\check{R}_{k_0+1}$. Fixed root padding can be reserved inside this width. This proves confinement away from the old core for short connections charged their native weighted length. For a native walk whose padded factors are unions of a bounded number of proper-scale localization boxes, the same escape also controls the closing paths. These are the native localizations of [B85c, Section 3C and Theorem 3.10]. Indeed, with the native grain $\mathfrak{M}$ fixed, the physical diameter of any one padded factor is at most $C_L\mathfrak{M}\xi_i$. Choose the stage M large enough that this is less than a fixed fraction of the width of the protecting band. If a padded factor meets the old core, every itinerary through that factor must penetrate to the inner part of the band or cross it. The cost is again at least $cM\check{R}_{k_0+1}$, including the first compressed stage where the protecting width is one cell. In the native walk distance the itinerary visits the localizations in order, using the weighted contour metric of [B84b, (2.45)–(2.46)]. Each possible itinerary pays this cost, even when the two matrix indices coincide. All closing paths stay in the padded factors, so no additional escape estimate on their lengths is needed for this confinement.

For the directly compressed collar precision this check can be made in each factor of the composite resolvent. Its active slots are on the outer side of the prepared box, up to the fixed one-step stencil. Every local inverse reads only its buffer, which meets such a slot and has diameter $CR\xi_q$. With M chosen after R, the buffer cannot reach the old core. Between local inverses each precision factor is compressed to active slots. If such a factor reaches the core, its own native walk or tree must pay the inner escape from an active endpoint. Use the native tree distance for the Schur and multiplier

kernels. Its tree meets the constituent localizations. The endpoint condition supplies the root visit when that localization is omitted from the tree convention. The outer slots are within fixed reach of the first and last localizations. Thus if an escape occurs on a multiplier branch, it is still charged from an active endpoint. Keep the attached row stencils in the fixed padding of this test. The bounds on the remaining factors sum by the parametrix majorant, with the count of choices of an escaping factor paid by the geometric series. This argument uses the collar mask before the shear. A factor with additional active slots inside the old core would require a different estimate.

For a buffered inverse use the real gauge on its full buffer. The pair comparison for the local resolvent replaces its kernel there by the kernel at the trivial pair with the same mask. The vacuum matrix block between two bond slots is scalar on colour, by constant gauge invariance and irreducibility of the adjoint representation. When the block is written back in the original gauge, its scalar factor multiplies $\mathrm{Ad}_{u(b_-)^{-1}u(c_-)}$. Join b_- to c_- by a coordinate path in the buffer. At shared slots the segments join without additional paths. In a diagonal trace they add the buffered inverses' segments to the native precision segments in the closed path. The matrix errors are summed by the telescoping resolvent comparison. For the remaining closed path use the shell estimate when the complete loop and its filling are admitted there.

On the outer side, a wall-connected chain from a collar bond to a cell touching the class boundary has at least $2\mathsf{N}-1$ cells. When the padded carrier of the diagonal is filed at such a bond, reaching the boundary costs $Ce^{-c\mathsf{N}}$ at the reduced rate, using part of the filed cell decay. This controls the outer escape for these collar roots. For the other active slots one must check their own outer margin.

For these terms in the pinned sum the number of stages and the normalized anchor count are bounded by a fixed power ℓ^{C_*}. Thus these short terms and the long tail together cost at most

$$C\ell^{C_*}\big(H^C\ell^{C_A}\mathfrak{a}+e^{-cH}\big)$$

at the reduced rate. Choose A after the anchor count. This bounds their contribution to the summed direct norm uniformly. The scalar stage numbers remain separate from this subtraction. The compressed stages may have anchors over the same cells. The outer M-cell layer of $\Omega^c_{k_0+1}\cap X$ lies outside each Z''_q in the compressed range and is inside Ω^c_q by nesting. Thus even a fixed pin can meet all these stages, and the absolute sum needs a gain beyond the count of its anchor layers. For other short carriers crossing the graded interfaces we must still control the closing transport on the complete admitted reads. A chain that closes around a hole can require filling plaquettes beyond those reads.

For the strip part use the kept chains of the external Schur form with their original keep rule. The source supplies their positive floor after the chain selection. The original Schur complement already eliminated the ordinary inner integration variables. File each kept chain with its original strip component, including its one-layer carrier margin. This margin includes the full read of the middle resolvent in a Schur chain. In the class box X, let H_q be the level-q cell hull of $Z_{q-1}\cap X$. The complement $\Omega^c_q\cap X$ is its eight-layer enlargement. The strip component lies in $\Omega_q\cap Z_q\cap X$, so its one-layer enlargement is still separated from H_q by at least seven level-q cell widths. At the first compressed stage this excludes the old hull. At later stages the first prepared box $Z''_{k_0+1}\cap X$ is already contained in $Z_{q-1}\cap X$. A new buffered inverse at an active strip slot has fixed reach in level-q units and stays in this clearance. Thus the kept strip precision and its buffered inverse avoid the old core on their complete physical reads.

At a nonterminal ordinary strip root the same one-scale argument uses the two quiet gaps. Let $a_q=M\check{R}_q\xi_q$. The root lies in $\Omega_q\cap Z_q\cap X$, up to the fixed endpoint reach. Its distance to Z''_q is at least $5a_q$ before compression and $7a_q$ at the first compressed stage, before subtracting that reach. At a later compressed stage the old inset is contained in $Z_{q-1}\cap X$, giving the $8a_q$ gap of the original class geometry. In the other direction $Z_q\cap X$ is at least $8a_{q+1}$ from the unchanged Ω_{q+1}. These roots are also away from the class wall, by the same separation at the top level. The native

towers of the direct strip operator stop at q. Thus the native itinerary and bounded padding put a short trace in a box of side $CH\xi_q$, inside the single grade q of the prospective physical sequence. The real profile and the box gauge give the same small-field estimate. Use the prospective strip quadratic for this direct term. Its difference from the old quadratic is carried in the interaction.

For the terminal strip, this also gives a one-scale box for the short trace on the physical pair. At $q = i$ the active roots are in the original $\Omega_i \cap X$. The prepared inset $Z_i'' \cap X$ is contained in $Z_{i-1} \cap X$, which is separated from these roots by eight top cell widths. The exterior top coarse cells of $\mathcal{P}_i$ touching X belong to the clean region and hence to Ω_i. In the global prepared sequence the first exterior layer stays unchanged. Thus, on either side of the wall of X, a neighborhood of width $cM\check{R}_i\xi_i$ about each strip root is entirely in the global grade i. For a short word of length at most H, the native itinerary, its bounded padding per factor, and any local inverse buffers put the entire trace in a box of side $CH\xi_i$. The real profile controls all plaquettes of that box. The box gauge estimate then bounds the short trace by its majorant times a fixed power of H times $\mathfrak{a}$, as above. Use this on the global physical pair, retaining the original operator masks and native weights. If the strip mask is compressed further at an admitted guarded binary switch, the comparison still uses the fixed physical pair and the surviving carriers. The box filling estimates their closing transport. Its plaquettes are used in the bound and the coefficient continues to read its own carrier.

The chain functions and their read sets are fixed at formation. Evaluate them on the supplied old or prospective pair in the common stored coordinates. An endpoint transport needed for this evaluation fits in one additional layer. At the stage that consumes a crossing slot, use its prescribed endpoint conversion, since the preparation can change its determining row. A response used to construct a prospective pair contributes its own carriers when the coefficient is composed with that response. The original keep rule applies to the coefficient's reads on the supplied pair.

On the native stage grid these margins remain below the next higher member, by the quiet separation of the carried Z_q. Rejected chains keep their old carriers and their separate boundary terms. Compress this kept precision to the strip slots integrated in the stage, carrying mixed terms with fixed exterior slots in the interaction. For a further guarded subset W take the compression

$$D_W(s) = P_W\Big(\sum_{\varpi \text{ kept at formation}} s^{\operatorname{par}(\operatorname{tags}(\varpi))} D_\varpi \Big) P_W.$$

Here par takes each original cell to its parent on the current grid. This compression retains the keep decision made for the original Schur form. Run the local resolvent construction on this compression at the ordinary level-$(j+1)$ grain, then map the old tags to the common graded cells. The root is formed after compression. A row restriction of the ambient root factors the marginal covariance. A square compression of the ambient root need not factor either the marginal or the conditional covariance. Use the root of the compressed precision here and take the direct sum of the two roots of the reference, then apply the shear transport.

Keep the inherited conditional strip form at its prescribed base and put its complete difference at the two backgrounds in the interaction once. In common stored coordinates let D_- and D_+ be the old and prospective kept precisions, and write $a = (a_{\mathrm{I}}, a_{\mathrm{E}})$ for the active and retained slots. The exact split is

$$\begin{aligned} -\tfrac{1}{2}\langle a, D_- a\rangle = & -\tfrac{1}{2}\langle a_{\mathrm{I}}, D_{+,\mathrm{II}} a_{\mathrm{I}}\rangle - \tfrac{1}{2}\langle a_{\mathrm{E}}, D_{+,\mathrm{EE}} a_{\mathrm{E}}\rangle \\ & - \langle a_{\mathrm{I}}, D_{+,\mathrm{IE}} a_{\mathrm{E}}\rangle - \tfrac{1}{2}\langle a, (D_- - D_+) a\rangle. \end{aligned}$$

Use the first term for the integrated reference Gaussian and keep the second in the prospective retained factor. The last two terms go in the interaction. The rejected chains and coupling-ratio terms are boundary entries. Evaluate their old and prospective values with the other boundary entries. In the physical stage the active strip is a union of whole kept components. The kept prospective mixed block against unintegrated components then vanishes. A subsequent Gaussian cut uses the marginal of the integrated reference. Chains coupling distinct original components

are included among the rejected chains. Together with the kept form and the ratio term they give the original conditional weight at each background. Keep the Haar density, the derivative of the linearizing correction, the row elimination factor, and the scalar vacuum contribution in the assembled weight. In particular the row elimination factor is in the collar integral and the vacuum term is in its prefactor. The fixed-ball identification requires these identities and the same retained strip tests on the same active bond sets.

This identity allows the graded expansion to form its own localized logarithm. For equality of the physical kernels one starts with the same incoming density on each labelled fibre and verifies the same measure transformation there. The incoming kept strip in the real kernel has its unnormalized quadratic and its inherited row factors. When the complete reference is written as a probability Gaussian, its full logarithmic prefactor in Lebesgue coordinates is

$$n_{\mathrm{free}}\nu_{\mathfrak{g}} - \tfrac{1}{2}\operatorname{Tr}\log D + \log z_{\mathrm{col}}.$$

Here n_{free} counts the free Lie-algebra slots of both integrals and $\nu_{\mathfrak{g}} = (\dim \mathfrak{g}/2)\log(2\pi)$ for ordinary Lebesgue measure on a slot. The factor z_{col} consists of the new collar pivot factors in their declared pairing convention. Keep the old strip row factors in their original places. The unnormalized quadratic becomes the normalized Gaussian with this one restoration of its mass. If a previously normalized quadratic is rewritten with a new precision, the determinant factor is the ratio of the two masses. The same rule applies when a coupling difference is transferred between the precision and the potential.

For the Haar delta the derivative at the reference pivot is $L\mathsf{m}_c$. The full coarea away from that point uses the nonlinear chart factors. In the convention that files $|\det \mathsf{m}_c|^{-1}$ in z_{col}, the factor $L^{-\dim \mathfrak{g}}$ per row is in the scalar of the same operation. The flat pivot is $\mathsf{m}_c(\mathbf{1}) = L^{-4}I$, so their product is $L^{3\dim \mathfrak{g}}$ per new row. This is the same factor as the inverse determinant of $L\mathsf{m}_c$ in Haar frames. Count the scalar once at the row's owner. The normalized cut determinant in $\mathcal{J}$ is separate from this full prefactor.

The shear preserves the full determinant, and the affine mean translation has no extra scalar after completing the homogeneous reference square. In the direct logarithm subtract the value at the trivial pair from the field-dependent determinant and new pivot factors. File their trivial values with the fixed Gaussian number of that stage and the collar constant $E_0^{(j)}$.

The new pivot logarithm has a local small-field bound. At the reference row centre its Haar differential $L\mathsf{m}_c$ is the pivot coefficient in the relative logarithmic frame. Conjugations at the two endpoint frames have determinant one. In the small gauge on the complete double block write this coefficient as $L^{-3}I + E_c$. The pivot estimate gives $\|E_c\| \le CL^2\varepsilon$ with ε the local chart size. The subtraction at the trivial field is therefore $-\operatorname{Tr}\log(I + L^3E_c)$, whose modulus is at most $C_L\varepsilon$ on the small branch. This estimate uses only the complete double block. The running physical row bound makes $\varepsilon \le C\theta_i^{-1/2}\ell^C$ on the waiting window, so the polynomial count of stages and anchors gives a uniform summed bound for these local pivot terms. The same bound holds on admitted complex sections with this row bound. The inherited strip coarea keeps its original carrier.

The remaining direct terms and the cluster logarithm are functions on their own formed carriers. A term meeting several components occurs once, through the maximum of their executed stage counts. The constants count the slots and rows of each executed component once.

In the convention with the Wilson-weight adjustment in the stage term, the expression also contains $A(x^{(n+1)} - x^{(n)}, \cdot)$. For a component stopped after n integrations all earlier terms are reevaluated at the common background U, with integrated stored slots set to zero. The compensations then combine with the current Wilson exponent as

$$-A(x^{(n)}, U) + \sum_{\nu=0}^{n-1} A(x^{(\nu+1)} - x^{(\nu)}, U) = -A(x^{(0)}, U).$$

This is the Wilson exponent that the stopped component keeps when its stage logarithms are filed separately. The scalar parts are carried with the component factors. At each prefix apply the real operations to the joint measure in the variables retained by that prefix. Use the same labelled tests and chart in the physical integral and in its graded representation. In the local sharp convention, the sharp collar test is made at the local centre before the shift. Its failure keeps the actual prefix with its failure indicator and the still untransformed variables of that stage. If the global sharp convention is used, the failure branch instead uses the transported test and its transported density. In either case the failed stage contributes no collar integral or stage logarithm. These two choices need separate labelled identifications wherever the tests split the fibre differently.

For a fixed output standing part $\mathfrak{o}'$, let $\mathrm{Str}(\mathfrak{o}')$ consist of the real strings whose output has that standing part. For such a string write K_ς for the product of its real kernels and $\pi_{\mathfrak{o}'}$ for the marginal onto the retained variables. The measure of the standing part is

$$\sum_{\varsigma\in\mathrm{Str}(\mathfrak{o}')}(\pi_{\mathfrak{o}'})_*(\hat\tau_{\mathfrak{o}(\varsigma)}K_\varsigma),$$

where $\hat\tau_{\mathfrak{o}(\varsigma)}$ is the incoming measure already summed over its standing part. Once the stage identity holds for each applied real kernel, it holds under continuation by a later kernel and under this marginal and sum.

The continuation uses the completed determining rows, the field on them and the stored data of the components that still stand. On a healed X, the lower rows have been replaced by top rows, including the top bonds meeting X. The restored field is read on these rows just as it is elsewhere. The integration over the healed history is the identity on all remaining coordinates. At a fixed value of these coordinates the same geometric rules give the next tests and operations. The class window cannot read a birth or mark erased by an earlier healing. In particular, the next normalized reference draw is computed from the current exterior field, the prescribed coupling and frame, the tree slice and the local cutoffs and Wilson weight. Its denominator is the integral of that same local weight on the slice. No term in the incoming healed bracket enters this denominator. Repeating this argument gives the same positive continuation on the common retained space. The healed terms remain part of the incoming density to which this continuation is applied. This permits summation over the healed histories before continuation and exponentiation of the resulting bracket. Keep the measure, carrier and internal coordinates of an island that still stands. An absorbed island is removed from the list of standing islands at filing, after its real operation has been included. Equality here is an identity on the retained variables of the construction, with any physical insertions carried by the corresponding kernels. The coupling coefficient still comes from the whole-lattice small-field construction of $\mathbf{T}$, with its own Taylor expansion. The analytic bounds still use the declared arguments of every graded term, including the evaluations at F_+.

The domains are part of the data carried by the induction. At a new level a boundary entry of $\mathbf{T}$ uses the space of the completed ordinary label. A stage entry uses the spaces of its contributing executed stages, restricted to its formed domain. A main-step entry uses the output space. The regular remainder and pointed entries use their single-scale cores. For the exceptional top boundary read of a pointed entry the restriction lies in the core with radii $\bar a_\iota$; the boundary function is given on that core. This read uses its own core radius. Kept forms and elimination logs use the regular pair on their birth carriers. A standing island keeps its birth core, its measure and its inner factors. When it stands inside a new drop-out, restrict its outer arguments to the admitted smaller space.

For an older entry the output structure is restricted to its original level, carrier and stored argument list. Each earlier tower address is still a test of the output structure, with the right-hand radius for that read. The inclusion into the entry's space uses the radius comparison on that address, including on the interior of a fixed-real-factor section. In a re-made member the retained field is evaluated by its actual row map, with its original bond kind where carried. This re-reads

the same function. The boundary and stage entries are formed on the graded domains from their first occurrence.

To verify the real induction on these domains, fix the outer list and the retained real variables of the outcome. The ordinary sum rule gives the incoming exponent of the first stage. At each executed stage the full-switch evaluation, with the same cutoffs and row coordinates, gives the physical collar integral. At the main step use the real restoration and class split on that retained measure. Composition and the marginal on the output variables give the sum over the real strings with the specified standing part. In a healed region the equality is for this sum. For a standing island the same inner measure and factors are compared at equal outer reads. These identities are evaluations on the real history kernels. The analytic estimates for the new entries use their formation spaces. The prospective regularity guard is the bare plaquette test of the real background, with the crossing clauses of the chosen rule. Its split precedes the evaluation of the analytic collar logarithm.

If instead one imports the ordinary boundary total formed on the whole-layer tower domain, its first use in a collar is already at the first active stage. A stage correction imported with that domain first enters the earlier-stage sum at the second active stage. Each such read would require an extension of that entry or bounds on its original tower stencils. An evaluation using that broader condition on a stencil outside the comparison window requires a bound for

$$L^{2\ell+\min\{\mathsf{p},\ell\}}\left|J^0_{\mathsf{p},Z}(W^u)(b)-J^0_{\mathsf{p},Z}(\mathbf{U})(b)\right|$$

by the available tower margin at nominal layer ℓ and depth p, uniformly on the complex sections and strip discs in use. Here $J^0_{\mathsf{p},Z}$ is the tower current in bare units. The exponent follows from the conversion $J^{[\mathsf{p}]}=L^{3\mathsf{p}}J^0$ and the layer factor $L^{\ell-\min\{\mathsf{p},\ell\}}(L^{\ell-\mathsf{p}})^{-3}$ in the allowed current. The broader condition is a requirement on the domains of those particular terms. To see the importance of the domain for the current bound, at a fringe where the full stencil is fixed by bare determining rows, a one-link perturbation of size $c\alpha_{0,\ell}L^{-2\ell}$ at the identity has a bare current of the same order. For $\mathsf{p}\ge\ell$ its normalized current is of order $c\alpha_{0,\ell}L^{\ell}$, even if the independent current coordinate is zero. Using the tower's own local layer a for the current estimate supplies the weight L^{3a}; converting it to the required one costs $L^{2\ell+\min\{\mathsf{p},\ell\}-3a}$. There is a direct comparison for some such reads. Suppose the weighted value and first difference of the levelled potential change are at most $Ae^{-\gamma d^-(b,\Sigma)}$, where Σ is the source collar and d^- is the ambient weighted distance. Use the tower itself as the ambient sequence for the tower comparison at the common real factor. If its distance dominates d^- on the carriers, the comparison gives

$$CAL^{2\ell+\min\{\mathsf{p},\ell\}-3a}e^{-\min\{\gamma,\delta_{\mathrm{T}}\}d^-(x,\Sigma)}.$$

Indeed, taking the finer scales only decreases the weighted input norm. In the maximum of the tower estimate the two distance factors combine by the triangle inequality. This bound fits the margin when the scale loss is covered by the radius budget or by clearance from the source. At a bare fringe $a=0$ the loss can grow with the depth of the ambient sequence, even at a fixed distance from the source in ambient units. The response estimate for second differences also allows a scale loss in its own ambient layer. Its zero-layer estimate applies at zero in that sequence. The auxiliary tower can have layer zero at a site in a coarse layer of the response sequence. On such a bare fringe the recomputed current is the Wilson current of the shifted links on its full stencil. The physical endpoint identity for this current uses the equations at the full parameter values. Those equations cannot be substituted term by term into the walk series with independent switch parameters. At such a read the argument requires an additional estimate on the decoupled response, or an analytic construction on the settled domains.

4.17.1.39. The crossing test at the main integration. Use the exterior, extendibility, fluctuation and last-shell tests of the main step, together with its regular core and seam data. On this support

the joined datum V'' is $\varepsilon_\star$-regular, so the regular critical orbit $U''_{m,X}$ exists by the real main-step admission assertion [B89a, (1.89)–(1.98)], which uses these inputs before the crossing test is evaluated.

Put $h = m_\flat$. The frozen core is a nonempty component of Z_h, while the input large region at level zero is empty. Thus $h \geq 1$. Work for the moment in the original step-h frame. In level-$(h-1)$ units a coarse cell of this step has side $LM\check{R}_h$. The side of the test cube enlarged by four test margins, with both endpoint blocks allowed for in its averaging reads, is at most

$$(L^2 + 8L)M_2\check{R}_h + 4L < LM\check{R}_h.$$

Here $L^2M_2 \leq M$ and $L \geq 13$. If the enlargement straddles $\partial\Omega_h$, its entire read lies within one coarse layer on either side. The pre-operation region Z_h contains $(\Omega_h^c)^{\sim 2}$, so the connected read lies in the component that meets the exterior at the seam. For the seam of the frozen component this component survives the operation of level h. A healed component would have disappeared, and the class rule excludes a drop-out or a second-class mark at h itself. Operations on disjoint components preserve its entries. The preceding input region is at least eight coarse layers from Ω_h when $h > 1$. For $h = 1$ the initial rule gives the same test buffers with the empty input region and the five-layer margin at P'_0.

Read the seam field of level $h-1$ from the retained one-step factor of $\mathbf{T}_h$ on this core. In the exterior of Ω_h this factor integrates the level-$(h-1)$ links with their averaging delta. In the interior it stores the nonpivot fluctuations, with the pivots fixed by the averaging equation. On the strip read the links through its substitution. The resulting field v satisfies $\mathcal{M}(\mathsf{v}) = V_h$ on the coarse reads. The lower determining rows are unchanged by preparation, and the level-h rows on the frozen core read the original V_h. Consequently the seam fields extend these rows in the original frame of the retained operation.

The two-layer buffer around the approximate failures and the three-layer gauge buffer give the passing approximate test and the passing coarse plaquette test on the test bases in $\Omega_h^{\sim 2}$. The ordinary step estimate on $\Omega_h^{\sim}$ therefore gives $|\partial\mathsf{v} - 1| < \varepsilon_{h-1} + \varepsilon_h$ and the contour bound $CL\delta_{h-1} < \varepsilon_{h-1}$ on the seam reads. These are statements about the retained fields in their original frame. Under a simultaneous change of gauge, lift the level-h transformation constantly on its blocks. The average transforms at the block nodes, and the contour and the relative link against the axial center are conjugated. The latter uses uniqueness of the center on the tested bonds in that axial gauge.

This gives an identity of the retained factors on an ordinary seam carrier whose moved sites belong to the joint integration. The complete lower double blocks lie on the Ω_{h-1} side of its outer boundary, since the old large region Z_{h-1} is separated from $\partial\Omega_h$ by eight coarse layers. The complete level-h blocks for the lift fit in that margin. There are no determining rows below level $h-1$ on these blocks. The level-$(h-1)$ rows are read through the retained Haar factors, the solved pivots or the strip inverse, as above.

Fix the exterior of the main step. Its reference transformation is then fixed. On a union of these complete blocks on which every moved lower coordinate is carried by the joint law, lift its restriction constantly on each block. Change variables in the retained Haar integral and conjugate the free logarithmic coordinates at their initial sites. The Haar and Lebesgue reference measures are preserved. At a row c, the argument of the old delta becomes

$$\mathcal{M}(\mathsf{v}^u)(c)(V_h^u(c))^{-1} = u(c_-)\,[\mathcal{M}(\mathsf{v})(c)V_h(c)^{-1}]\,u(c_-)^{-1}.$$

The delta is unchanged. Evaluate the old indicators and weights on the inverse reads of this same change, including the original strip and reconstructed pivots. Thus their joint integral gives the transported factor at the new V_h with the guards still in place. This applies where the full changed carrier is within the joint law and has no moved genuinely fixed lower endpoint or older mark with independent stored data.

There is also a comparison of the density factors that only reads the level-h field. In the first prepared box the inner cut leaves one coarse $(h+1)$-layer about the hull of the old core. For an old density cube in $\Omega_h \cap Z_h$, the fourfold enlargement fits inside that layer because $4M_2\check{R}_h L^h + L^h < M\check{R}_{h+1}L^{h+1}$, including its bond reads. The last-shell artificial datum keeps the level-h links on this whole test box, in its compensating site gauge. Lifting that gauge to the localized tower identifies the two backgrounds up to gauge and gives the same tested plaquette norms. Thus the passing half-threshold implies the old density factor on these cubes. This implication uses only the literal level-h test reads. In the full last-shell split it also applies to a tested box crossing $\partial\Omega_h$: inside the old core the level-h field is still a target of the retained graph there. When the split is restricted to the inset whose whole test box lies in Ω_h, keep the old density factors at the other cubes. The small-energy estimate for the inset continues to use that full-box condition.

One can keep the old frame on the ordinary seam without changing the reads of the two outer tests. The seam and its full level-h test halo lie strictly inside the inner cut. All genuine rows below level h of the frozen core have their endpoints in Z_h, by the no-inward convention. Choose a site gauge equal to one on those endpoints and the seam halo, and equal to the mixed compensator off an interior neighborhood of them. Use this only to change coordinates of the retained datum. Every endpoint of a fluctuation row lies outside the change, so the mixed reference and the relative fluctuation reads on $\mathbb{B}_0$ keep their values. On the artificial last-shell field the additional gauge is supported strictly inside the kept side, with a bond margin to the cut. The bonds set to one therefore remain one, and the whole artificial datum changes by a site gauge. The last-shell indicator is unchanged. With this gauge the old lower rows and the seam averages are read in their original frame.

For the guarded integral, let τ be the mixed compensator and u the gauge just chosen, both fixed by the exterior and the frame. Write $Y = V_h^u$ for the new target. The old factor reads $V_h = Y^{u^{-1}}$, and a factor written in the mixed frame reads $V_h^\tau = Y^{\tau u^{-1}}$. The change from the mixed to the reset target uses only Haar links in the interior of the inner cut. In the old core these are the dV_h targets of its retained operation. Outside the old core and inside this cut the level-h links belong to the prepared level-h member, since they are in Ω_h and clear of Ω''_{h+1}. They lie in the second Haar integral before the split. At the common face use the original ownership of the links, so the two stocks remain disjoint.

Keep the lower integration variables ξ in their original charts. A native factor $F(V_h, \xi)$, including its stored gauge factor, its contour, its reconstructed pivot and its indicator, is then read as $F(Y^{u^{-1}}, \xi)$. The averaging delta in that factor is

$$\delta\big(\mathcal{M}(\mathsf{v})(Y^{u^{-1}})^{-1}\big) = \delta\big((\mathcal{M}(\mathsf{v}))^u Y^{-1}\big)$$

row by row, by conjugation at the initial endpoint. This transports the output graph and leaves the lower rows and gauge factors in their original variables. Haar measure on the changed targets is preserved at each fixed exterior. Factors that read the mixed target keep the argument $Y^{\tau u^{-1}}$, with the same rule for all their other reads. Thus this change is made with the guards still in the integral.

In the prepared datum use the transformed value at both ends of each retained row. The old lower rows are fixed by u at both endpoints. The level-h rows in the inner cut are the targets just described, and all fluctuation rows and the outer join retain their mixed-frame values. Consequently the prepared datum is the original prepared datum transformed by u on its full row set. Gauge covariance of the averages and of the regular critical orbit identifies the prepared guard with its original read, including its domain of definition. The change of variables does not use a passing value of that guard.

At an earlier face $\partial Z''_{s+1}$, with $m_\flat \le s \le m-2$, the adjoining shell scales are $s, s+1$. The first shell is $Z''_{m_\flat+1} \cap \Omega_{m_\flat}$. Consider a crossing whose corners are all in the inset $\Omega_{m_\flat} \cap X^\natural$ of the

completed main-step estimate. The separation of successive prepared faces is more than the bare plaquette diameter, so every corner has one of these two profiles. For $s \le m-2$ the completed coefficient on shell s satisfies

$$1-\beta_{\mathrm{s}}(1-2^{-(m-s+1)}) \le 1-7\beta_{\mathrm{s}}/8.$$

On shell $s+1$, the unmultiplied threshold is at most $(L_\flat/L)^2(\varepsilon_{s+1}/\varepsilon_s)$ times $F_s\varepsilon_s L^{-2s}$. The ratio of consecutive radii is $1+o(1)$, and $L_\flat < L/2$, so this too lies below $(1-3\beta_{\mathrm{s}}/4)F_s\varepsilon_s L^{-2s}$ for small coupling. The completed main-step estimate on the inset bounds the curvature by the maximum of these corner thresholds, including for astride plaquettes. It therefore implies the added crossing test there. This uses the completed corner estimate. At the prefinal passing stage one still uses the separate prospective test and the real collar response.

We use the frame of the main fluctuation test and put $h = m_\flat$, $Y = Z''_m(X)$, and

$$I_h = \Lambda^{\mathrm{pr}} \cap ((\Omega''_{h+1})^{\sim 2})^c.$$

The fluctuation bonds $\mathbb{B}_0$ extend from the outer box to this inner cutoff. They include the bonds crossing $\partial\Lambda^{\mathrm{pr}}$ and exclude those crossing the boundary of I_h towards its interior.

We first identify the reads of the tested holonomies of V''. A determining row of level $i < m$ in the prepared sequence has both ends in Y, since neither end can lie in the prepared member of level m. A row of level $i \ge h+2$ has an end outside $Z''_i(X)$. Its length is L^i in bare units, less than the separation of $Z''_i(X)$ from $Z''_{i-1}(X)$. For the early separations this follows from $7a_{i-1} > L^i$, and for the compressed ones from the gap of at least one M-cube of level i. Such a row cannot reach $Z''_{h+1}(X)$. A row of level $h+1$ has one end outside $Z''_{h+1}(X)$. Its other end can enter that box by at most L^{h+1}, so it stays on the fluctuation side of the two-cell enlargement. Thus a genuine row missed at the inner cutoff has level at most h. A top row beyond Λ^{pr} instead has its exterior value $V_m = V_\Lambda$.

At a tested plaquette of level q, the reads are the determining rows on that plaquette and, for each bond completed by one-step averaging, the two full blocks of level-$(q-1)$ sites at its ends. The latter blocks lie wholly in the preceding layer in the convention excluding inward bonds. Consequently a test that reads an inner row missed by $\mathbb{B}_0$ has $q \le h+1$. All its corners lie in $Z''_{h+1}(X)$ or within CL^{h+1} of it. The shell between $Z''_{h+1}(X)$ and $Z''_{h+2}(X)$ has width at least $7a_{h+1}$ and spacing L^{h+1}. Every path from this read to a crossing plaquette at ∂Y must cross that shell. After the footprint allowance its weighted length is at least $cM\check{R}_m$. These holonomies can therefore be estimated by $\varepsilon_\star$ with the weight $e^{-c\delta_{\mathrm{c}}M\check{R}_m}$ in the local regularity estimate.

For the remaining interior holonomies compare with the averages of the basic background U_0 in its mixed axial–Landau gauge. The restriction of this datum to $\mathbb{B}_0$ is the actual center V_0 of the main fluctuation test. On $\mathbb{B}_0$ the relative bond logarithms have norm less than δ'_m, and on the exterior top rows the relative bond equals the identity. All lower-level plaquette carriers lie within CL^m of Y. The same holds for a top plaquette using a completed bond, because that bond reads the layer $m-1$. The outer M-layer of Λ^{pr} and the clearance of this box from the joining collar put these carriers in the top layer of the tower for U_0. By Prop. 4.59 the top datum V_Λ has defect at most $C(M)\varepsilon_m$, using the unchanged exterior and its outer tests off the box. The lift to the tower preserves this bound on the tested holonomies. Regularity on that tower gives $C(M)\varepsilon_m L^{-2m}$ in bare plaquette units on the full backward carriers in its top layer. The real change to the mixed gauge preserves this curvature bound. Averaging on a level-q carrier gives the bound $C(M)\varepsilon_m L^{-2(m-q)}$ for the baseline holonomy. A top holonomy with only top rows uses the plaquette estimate of V_Λ directly. The one-step relative average on a completed bond changes it by at most $C(L)\delta'_m$. Multiplication of the four unitary factors gives a defect of at most $C(M)\varepsilon_m + C(L)\delta'_m$ for each of these actual tested holonomies. The remaining tests at the artificial join are the identity or lifted top plaquette holonomies. Their defects obey the top datum bound.

Use the test-by-test profile eq. 3.ccclxxviii in eq. 3.ccclxxix at a corner of a crossing plaquette p. Here $\check{R}_m$ is formed from the running minimum of the frame, which is at least $\theta_m - c_5$, and the exponent of its logarithm is at least 2. Thus $\varepsilon_\star e^{-c\delta_{\rm c} M \check{R}_m} = o(\varepsilon_m)$. The normalized curvature at p is at most $C(M)\varepsilon_m$. Since p has a corner in the prepared member of level m, its bare curvature satisfies

$$|\partial U''_{m,X}(p) - \mathbf{1}| \le C(M)\varepsilon_m L^{-2m}.$$

Finally, $L^{m-k_0-1} = \check{R}_{k_0+1}$ gives $F_j = L_\flat^{-2}\check{R}_{k_0+1}^{2\log_L L_\flat} \to \infty$. With $\varepsilon_m/\varepsilon_j \to 1$, the last bound is strictly below the threshold of $\kappa_\times$ for small coupling. This removes the crossing factor in the main integration on its stated real support, before the reference-law restoration of the free top field.

How a patch recovers its coupling. Each stage gives back to the collar it integrates the increments that this collar did not receive. After m stages the Wilson term is formed with

$$x^{(m)}(\cdot) := \beta - \sum_{i\le k} b_i\, \varphi[\Lambda_i^{(m)}](\cdot),$$

$$\Lambda_i^{(m)} = \Lambda_i \cup (X \setminus Z_i'') \ (k_\flat < i \le k_\flat + m),$$

$$\Lambda_i^{(m)} = \Lambda_i \text{ otherwise}$$

where $\varphi[\Lambda]$ is the profile of the region Λ. The difference $A(x^{(m)} - x^{(0)}, \cdot)$ is carried separately, as a Wilson piece § 4.17. In this way, at each bare plaquette the weights of all the Wilson terms in the exponent still sum to $-\beta$ §4.17.1.1. Hence $x_k'' = x^{(\mathsf{N}_k)}$ coincides with x_k on the part of X outside the box, and equals $x_k + O(1+k-j)$ on the shell of level j. This is what makes the three Wilson terms in the prepared-component operation cancel; two of them carry the constant x_k.

What a patch retains. A component that has passed every test carries the operation below. It is (1.71) of 122 (1989) 355, in which the summation extends over r and over all sequences of regions contained in X, with the prefactor $1/(2^d d!)$ in front. The notation is that of § 4.17, and χ' denotes the test $|B| < \delta'_k/g_k$.

$$\mathbf{T}'_k(X)F = \frac{1}{|W_4|}\sum_{\text{histories in } X,\, r}\int dB\, \delta_{rT_0}(B)\,\chi' \int dV_{k_\flat}\,\chi\,\mathbf{T}_{k_\flat}(C_{k_\flat})\, e^{-\frac12\|\phi^{1/2}D\mathsf{H}B\|^2 - A(x_k''\phi_{\rm c}, U''(e^{ig_kB}, V'')) + V(X^{\sim}, U_k) + \text{numbers}}\, F.$$

The final test is $\chi_k(X^{\sim -6})$, evaluated after the draw of the new V_k. Write H for the level-k hull of the preceding region in X. In the quiet boxed nest, $\Omega_k^c \cap X = H^{\sim 8}$ and $X = H^{\sim 10}$, with the layers taken in the level-k partition. Thus $X^{\sim -6} = H^{\sim 4}$ supplies the test bases left by the carried $\chi_k(\Omega_k^{\sim 4})$. On the passing branch the two tests give the ordinary level-k density bound on X. The localized-background comparison on the margin gives the extendibility implication of Comm. Math. Phys. 122 (1989), p. 378: the new V_k gives an extension whose localized bare plaquettes on $\Omega_k^c \cap X$ are strictly below the $2\varepsilon_k\eta_k^2$ threshold of $\chi_{k,\Lambda}$.

In the recorded frame both V_k and V_Λ are the identity on the box tree and its entrance bond. For each non-tree bond, close it by the tree path. Its value in each configuration is determined by the corresponding cycle product. Express the cycle products by plaquettes with their transports. The box has fixed size in level-k units, so the number of plaquettes used for each bond is bounded in terms of M. The density and minimizer bounds give $|\log(V_k V_\Lambda^{-1})(b)| \le C(M)\varepsilon_k < M_0\varepsilon_k$, by the choice of M_0. Hence $\chi_{k,\Lambda}$ and $\chi(\Lambda^{\rm pr})$ both equal one on the passing support. Merge the two positive density tests into the test of the enlarged region.

For the complete invariant density, the tree constraint can now be removed. Hold the exterior and the entrance root fixed. Recursion along the tree writes box Haar measure as the product of Haar measure on the box gauge transformations and Haar measure on the non-tree links of the slice. The recursive substitutions on the tree and the left and right translations on the other

bonds preserve Haar measure. The gauge transformations lift constantly on each level-k pillar. They preserve the exterior, the stored variables and the inner quadratic and Wilson factors, and transform the outer background covariantly. The localized interaction factors and the remaining tests are invariant. The integral of this invariant extension against box Haar therefore equals the slice integral. If a field in the original gauge is carried, transport it by the same Haar gauge draw. The healed X is removed from the label and its internal history is summed in the bracket § 4.17. For an island the final test fails. The two positive cutoffs and the tree constraint then remain, and X retains

$$\chi_k^{c}\,\chi_{k,\Lambda}\,\chi(\Lambda^{\mathrm{pr}})\,\delta_{\mathrm{ax}}(V_k V_\Lambda^{-1})\,\mathbf{T}'_k(X)$$

as a single block under its frame sum, for as long as it stands ((1.72), (1.104)). The cut-off $\chi(\Lambda^{\mathrm{pr}})$ is absent from (1.102). A drop-out after n stages retains the following: the one-step operations of the levels that were not reached; the bare integrals $\int dV_l\,\delta(\mathcal{M}(V_l)V_{l+1}^{-1})$ of the levels already treated; the core; and the functions present together with the failing factor $1-\chi$. The terms produced up to that point are added to the boundary terms.

Proposition 4.59 (minimiser in a box; Comm. Math. Phys. 122 (1989) 175, Proposition 1)**.** There exist a radius $a_\Lambda > 0$ and a constant $C(M)$, both chosen after M and before γ, with the following property. Suppose the exterior data satisfy $|\partial V_k - \mathbf{1}| < \varepsilon$ with $C(M)\varepsilon \le a_\Lambda$. In the application $\varepsilon \le C\varepsilon_k$, so this is a ceiling on γ. Take the class of continuations with $|\partial V_k - \mathbf{1}| < a_\Lambda$ at those level-k plaquettes whose corners all lie within distance 1 of Λ^{pr}. On this class the background $U_{k,X}(V_k)$ exists. Within the class, the map $V_k|_{\Lambda^{\mathrm{pr}}} \mapsto A(U_{k,X}(V_k))$, which is a function of V_k on the level-k bonds having an end point in Λ^{pr}, has exactly one critical gauge orbit V_Λ. This orbit is the set of its minima in the class, it is analytic in the data, and it satisfies $|\partial V_\Lambda - \mathbf{1}| \le C(M)\varepsilon$. Bałaban states it for the function on fields of mild regularity and for ε sufficiently small, with the bound $CM^5\varepsilon$. The orbit of this class is the one used in (3) and (4). Moreover, $U_0 := U_{k,X}(V_\Lambda)$ satisfies $J(U_0) = 0$ in Λ^{pr}. ■

The proof is a contraction argument in a ball whose radius depends on M, which is why a class of continuations is fixed. In axial gauge the Hessian is bounded below by $c(M) > 0$; Bałaban obtains the lower bound cM^{-5}. Indeed, the Hessian is at least $c\|\partial B\|^2$ less a small multiple of $\|B\|^2$. In a tree gauge one has the Poincaré inequality

$$\sum_b |B(b)|^2 \le C(M) \sum_p |\partial B(p)|^2$$

(122 (1989) 355, (1.7)–(1.9), with CM^5). The corresponding inequality for a single bond of the nest, $|B(b)|^2 \le C(M\check{R}_k)^C \sum_p |\partial B(p)|^2$, yields the factor of the test in (3). It is (1.78) there, with every bond and every plaquette taken in its own lattice. The power of $\check{R}_k$ has two origins: the side of a shell in its own lattice, which is at most $CML\check{R}_k$ sites, and the number $\mathsf{N}_k + 1$ of shells, where $\mathsf{N}_k = \check{R}_k$. The first form serves the level-k variable V'_k and the uniqueness of V_Λ. The form for one bond serves the multi-scale field B.

A gauge for the configuration generated in a healing. The configuration generated in a healing must belong to the analyticity spaces. To this end it is put in the form $e^{i\eta_k A^{\mathrm{g}}}U$, where A^{g} and its covariant differences $\nabla_U A^{\mathrm{g}}$ (∇_μ^U as in the Notation) are smaller than $(1 + c\beta_{\mathrm{s}})\alpha_{1,k}$ § 4.17. On boxes of side $O(1)$ around the sites y there are local gauges $\hat{u}_y$, with potentials $A^{(y)}$. They are glued together by a partition of unity (χ_y) taken in the quaternions,

$$u^{\mathrm{g}}(x) = \mathcal{N}\Big(\sum_y \chi_y(x)\hat{u}_y(x)\Big),$$

$$\mathcal{N}(m) = (\det m)^{-1/2} m,$$

and then $A^{\mathrm{g}} = \sum_y \chi_y A^{(y)}$ is a mean whose weights sum to 1. This holds apart from quadratic terms and from terms comparable to the differences $\hat{u}_y \hat{u}_{y'}^{-1} - \mathbf{1}$ between local gauges at neighbouring sites. In $\nabla_U A^{\mathrm{g}}$, the term $\sum_y (\partial\chi_y) A^{(y)}$ has weights summing to 0. It is therefore comparable in size to the differences between the potentials of neighbouring sites, which have a leading part in common. The square root is the branch on $|\det m - 1| < 1$ that takes the value 1 at $\det m = 1$. The mean in the display lies in this domain. It is the product of one local gauge $\hat{u}_y$ with $\mathbf{1}$ plus an average of the small differences $\hat{u}_{y'} \hat{u}_y^{-1} - \mathbf{1}$ between local gauges at neighbouring sites. The real linear span of SU(2) is $\mathbb{H}$. There $\det m = |m|^2$, and $\mathcal{N}(m) = m/|m| \in G$ for $0 < |m| < \sqrt{2}$. Wherever the root is defined, $\mathcal{N}$ is holomorphic and bi-covariant: $\mathcal{N}(u_1 m u_2) = u_1 \mathcal{N}(m) u_2$ whenever $u_1, u_2 \in G^c$. Hence the same construction applies to complex fields.

[2.2] Finer sequences: nested constraint sets, nested critical configurations.

Suppose that $\mathbf{S}'$ is finer than $\mathbf{S}$ and that U^* is a real configuration on Ω_0, and put $V := M_{\mathbf{B}}(U^*)$ and $V' := M_{\mathbf{B}'}(U^*|_{\Omega_0'})$. Given a configuration U' on Ω_0', we write $\widetilde{U'}$ for the configuration obtained by extending it by U^*.

(a) Whenever $M_{\mathbf{B}'}(U') = V'$, one has $M_{\mathbf{B}}(\widetilde{U'}) = V$; moreover, the difference $A_{\Omega_0}(\widetilde{U'}) - A_{\Omega_0'}(U')$ is independent of U'.

(b) Suppose that $M_{\mathbf{B}'}(U') = V''$, where $V'' = V'$ holds on the bare member Γ_0'. Then $(\mathcal{M}^q \widetilde{U'})(c) = V''(c)$ holds for each bond $c \in \Gamma_q \cap \Gamma_q'$, and the difference of the two actions takes the same value.

(c) When U^* is a regular critical configuration for $(\mathbf{B}, V)$, its restriction $U^*|_{\Omega_0'}$ is a regular critical configuration for $(\mathbf{B}', V')$.

[2.4] Comparison of two backgrounds, at real and at complex parameters.

Suppose that $\mathbf{S}, \mathbf{S}'$ agree on a region W which is collared in $\mathbf{S}$. Let p be a bare plaquette lying well inside W, in the unit cell y, and set $D := d_{\mathbf{B}}(y, W^c)$. Let f_1, f_2 be holomorphic functions on $\{\|w\| < r\}$ whose modulus is at most $\frac{1}{2}\mathsf{m}^2 \eta^4 \xi(p)^{-4}$. Suppose further that for each real w there exist real data V_w on $\mathbf{B}$ and V_w' on $\mathbf{B}'$ that are both ε_1-regular, with $\varepsilon_1 \le \mathsf{m}$, and equal on W, and for which $f_1(w) = a_p(U_{\mathbf{B}}(V_w))$ and $f_2(w) = a_p(U_{\mathbf{B}'}(V_w'))$. Then

$$|f_1 - f_2| \le C \varepsilon_1^2 \, e^{-\delta_0 D} \, \eta^4 \xi(p)^{-4} \text{ at real } w,$$

$$|f_1 - f_2| \le C \, \mathsf{m}^2 \, e^{-\frac{2}{3}\delta_0 D} \, \eta^4 \xi(p)^{-4} \text{ for } \|w\| \le \tfrac{1}{5} r.$$

[2.5] Averages of a complex configuration near 1.

Let $\mathbf{A}$ be a bare 1-form with values in $\mathfrak{g}^c$, and suppose that $s := \sup |\mathbf{A}|$ is sufficiently small. Then, for $0 \le n \le k$ and for each bond c of $\mathbb{T}^{(n)}$, the complex average is defined, and

$$\mathcal{M}^n(e^{i\eta \mathbf{A}})(c) = e^{i \mathcal{Q}_n(\mathbf{1}; \mathbf{A})(c)},$$

$$|\mathcal{Q}_n(\mathbf{1}; \mathbf{A})(c)| \le C \, L^n \eta \, s = C \, \xi_n \, s,$$

where $\mathcal{Q}_n(\mathbf{1}; \mathbf{A})(c)$ is holomorphic in $\mathbf{A}$ and real when $\mathbf{A}$ is real. It depends only on the values of $\mathbf{A}$ in the two blocks $B^n(c_\pm)$, so the supremum may be taken over these blocks alone. (Here the map $\mathcal{Q}_n(\mathbf{1}; \cdot)$ is formed with the single spacing $\eta = \eta_k$ for every $n \le k$.)

[2.10] The basic and the glued background from the exterior field alone.

Let V^{e} be a configuration on $\mathsf{C}(Z) \setminus E$ with values in G, with ε small and with $|\partial V^{\mathrm{e}}(p') - \mathbf{1}| < \varepsilon$ at every plaquette made up of bonds of this configuration. Let G be an arbitrary gauge tree.

First part (the mixed gauge). The objects V_Λ, U_0, U_0°, B^Λ, $\mathbb{A}_0$, w, $\tilde{w}$, t_0, $\tilde{U}_0 = (U_0^\circ)^{\tilde{w}^{-1}}$ and $V_0 = M_{\mathbf{B}''}(\tilde{U}_0)|_{\mathbb{B}_0}$ are well defined and real. They are determined by V^{e} and G, and they satisfy

$$|\partial V_\Lambda - \mathbf{1}| < C\varepsilon;$$

$$|\mathbb{A}_0|, |\nabla^\eta \mathbb{A}_0|, |D_{\mathbf{1}}^* D_{\mathbf{1}} \mathbb{A}_0| \le C\varepsilon \text{ on } \Lambda^-;$$

$$|\mathsf{t}_0 - \mathbf{1}| \le C\varepsilon;$$

$$|V_0(c) - \mathbf{1}| \le C L^{i-k}\varepsilon \ (c \in \mathbb{B}_0 \text{ of level } i < k).$$

Second part (the quadratic form). Assume in addition that $(\mathbf{1}, V^{\mathrm{in}})$ is ε-regular on $\mathbf{B}^{\mathrm{in}}$. Then the glued datum V^0 is $C\varepsilon$-regular, and U^0, Φ_{V^0}, $\mathcal{H}_{\mathbf{B}^{\mathrm{f}},V^0}$ and H_1 are defined. The operator H_1 is complex-linear and takes real values on real increments. In the unit cell y it obeys $\xi|\mathsf{H}_1\mathsf{f}|$, $\xi^2|\nabla_{U^0}\mathsf{H}_1\mathsf{f}| \le \mathsf{h}(y;\mathsf{f})$. Finally, for real f one has $\mathsf{q}_0(\mathsf{f}) = \sum_p \eta^4 \zeta(p) |(D_{U^0}\mathsf{H}_1\mathsf{f})(p)|^2 \ge 0$.

The minimiser on Λ^{pr} and the inner background. **[1.6] Regular data.** (a) *Stability.* Suppose that $|\partial V(p') - \mathbf{1}| < \varepsilon$, that on the double blocks $B(b_-) \cup B(b_+)$, where b runs over the outer bonds of p', the configuration V is moderately regular, and that b is real and $|\mathsf{b}|_\infty = s$ is small. Under these conditions $|\partial(e^{i\mathsf{b}}V)(p') - \mathbf{1}| < \varepsilon + K_{\mathrm{s}} s$. (b) *Averages of a regular configuration.* Let $\Omega'_\bullet$ be finer than $\Omega_\bullet$, and let $U \in \mathfrak{U}(\mathbf{B};\varepsilon)$. Then $M_{\mathbf{B}'}(U)$ is $C\varepsilon$-regular. The local form is as follows: whenever $|\partial U(p) - \mathbf{1}| \le \alpha\eta^2 \xi_j^{-2}$ holds in the blocks $B^j(x)$ around the corners of a plaquette p' at level j, one has $|\partial(M_{\mathbf{B}'}U)(p') - \mathbf{1}| \le 2\alpha$. (c) *Lifts.* Each holonomy of $V^\downarrow = M_{\mathbf{B}_k(\Omega)}(Q_k^{s*}V)$ is either $\mathbf{1}$ or a plaquette variable of V. Moreover $(e^{i\mathsf{b}}V)^\downarrow = e^{i\mathsf{b}^\downarrow}V^\downarrow$. Here $\mathsf{b}^\downarrow(b) = \mathsf{b}(c)$ when b crosses from the block of c_- into the block of c_+, and the lifted increment takes the value 0 on bonds lying inside a block.

[1.14] The minimiser over Λ^{pr}. Take a geometry of the main step, and let $0 < \varepsilon \le \varepsilon'$ with $C\varepsilon' \le a_\Lambda$. Fix a configuration V^{e} on $\mathsf{C}(Z) \setminus E$ satisfying $|\partial V^{\mathrm{e}}(p') - \mathbf{1}| < \varepsilon$ at the plaquettes made up of these bonds. Let V' be an extension of it to $\mathsf{C}(Z)$ that satisfies $|\partial V'(p') - \mathbf{1}| < \varepsilon'$ on $S(P)$. We denote by $\mathcal{V}(V^{\mathrm{e}})$ the set of extensions V for which $|\partial V(p') - \mathbf{1}| < a_\Lambda$ on $S(P)$.

(o) There is always an extension for which $\varepsilon' = 4N_{\mathrm{sh}}\varepsilon$, with the inequality taken in its non-strict form.

(a) On $\mathcal{V}(V^{\mathrm{e}})$ the configuration $U_{k,Z}(V)$ is defined. The map $V \mapsto A_Z(U_{k,Z}(V))$ is real-analytic and is invariant under gauge transformations at the sites of P.

(b) The critical points of this map form a single orbit. The minimum value is attained on that orbit and nowhere else. The orbit contains exactly one element $V_\Lambda = V_\Lambda(V^{\mathrm{e}})$ that is equal to $\mathbf{1}$ on Tr.

(c) On $S(P)$ one has $|\partial V_\Lambda(p') - \mathbf{1}| < (1 + 4K_\Lambda)\varepsilon'$. Every bare plaquette p of Z, lying in the cell y of $\mathbf{B}^Z$, satisfies

$$|\partial U_{k,Z}(V_\Lambda)(p) - \mathbf{1}| \le |\partial U_{k,Z}(V')(p) - \mathbf{1}| + K_5\, \varepsilon'\, e^{-\delta_0 d_{\mathbf{B}^Z}(y,\Lambda^{\mathrm{pr}})}\, \vartheta_y.$$

(d) *Continuation.* If ε' is reduced further, a unique map $\mathsf{b} \mapsto B_\Lambda(\mathsf{b}) \in \mathcal{X}^{\mathbb{C}}$ exists with the following properties. It is defined on the complex increments b on $\mathsf{C}(Z) \setminus E$ with $|\mathsf{b}|_\infty < a_\Lambda$. It satisfies $|B_\Lambda|_\infty \le r_\Lambda$. At every such increment, its value $B_\Lambda(\mathsf{b})$ is a critical point, in the directions of $\mathcal{X}^{\mathbb{C}}$, of the function

$$\delta \mapsto \sum_p \left[a_p(\mathsf{W}_{V_\Lambda^\downarrow}(\mathsf{b}^\downarrow + \delta)) - a_p(\mathsf{W}_{V_\Lambda^\downarrow}(\mathsf{b}^\downarrow)) \right]$$

. This map is holomorphic and satisfies $B_\Lambda(0) = 0$, and

$$|B_\Lambda(\mathsf{b})|_\infty \le 2K_\Lambda |\mathsf{b}|_\infty,$$

$$V_\Lambda(e^{i\mathsf{b}}V^{\mathrm{e}}) = e^{iB_\Lambda(\mathsf{b})}V_\Lambda(V^{\mathrm{e}}) \text{ on } E \text{ for real small } \mathsf{b}.$$

4.17.1.40. Rare patches: gains per creation and costs per site.

Lemma 4.60 (one factor per creation)**.** The following holds on the support of a term, at step $t = k+1$. (i) When the plaquette test of step t fails at $\square$, each real U that has the stored averages satisfies $\sum_{p \text{ near } \square} a_p(U) \geq c\,\varepsilon_t^2$. (ii) When the approximate fluctuation test fails, this sum, increased by the part of GF_k located at the blocks near $\square$, is bounded below by $c\,\delta_k^2$. (In what follows, $\mathrm{GF}_j(X;V_j)$ denotes the part of $\mathrm{GF}_j(V_j)$ located at the blocks in X.) (iii) One has $\langle B, \Delta^{(k)}B\rangle \geq c\|B\|^2$, and the bound extends to the kept conditional forms §4.17.1.3. Consequently a failed fluctuation test yields

$$\tfrac{1}{2}\langle \mathcal{A}_k^{\mathrm{s}}, \Delta^{(k)}\mathcal{A}_k^{\mathrm{s}}\rangle \geq c\,\delta_k^2/g_k^2$$

. The same is true of a failed collar test or rim test, because the threshold of either differs from δ_k by a constant factor, namely $1/(4\Theta_1)$ or θ_c §4.17.1.1. ■

For (i) and (ii) the contraposition also establishes existence of the objects read by the tests. For (iii), once the actual background is admitted, use the group angle, including the value π at the cut of the logarithm. Let d be the tested threshold, including the fixed collar or rim fraction where appropriate. On the cutoff zone an angle below d lies where the cutoff is zero, so the substitution leaves it unchanged. At the other substituted bonds take the strip comparison bound $C\varepsilon_k e^{-\check{R}_k}$ below $d/2$, using the fixed lower bound on d/δ_k. The triangle inequality then shows that an old angle at least d requires a new angle at least $d/2$. This includes an undefined old logarithm. The energy payment uses the coercive form in the retained free coordinates of that test. Since the coupling at that place is x_{t-1}, every created cell produces the factor $e^{-c\,p_0(g_t)^2}$. Inside $\mathbf{R}$ the tests work with the threshold δ_j', and the gauge trees they use have length at most $C\check{R}_j^C$. When a bond variable is large in a tree gauge, all that follows is that some plaquette exceeds $c\check{R}_j^{-C}\delta_j'$. For this reason these tests give no more than $e^{-c\check{R}_j^{-C}p_1(g_j)^2} \leq e^{-p_0(g_j)}$, and this inequality requires $2\mathfrak{p}_1 - Cr > \mathfrak{p}_0$.

The energy of the actual averages. The small-action alternative admits a depth-uniform estimate even when the bare curvature does not satisfy eq. 3.xii. The additional ingredient is an ℓ^1 estimate for the *local quadratic remainder*, followed by its propagation through the positive flux matrices. We give the argument with its exact carrier. All plaquette sums count each independent orientation once. For a real SU(2) field write

$$a_p(U) = 1 - \tfrac{1}{2}\operatorname{Tr} U_p = \tfrac{1}{2}\|1 - U_p\|_{\mathrm{op}}^2.$$

All group logarithms used in the proof are the branches near the identity. The actual total measurable average retains its prescribed fallback outside those branches.

Lemma 4.61 (Local quadratic flux remainder)**.** Fix the odd block size L. There are $d_L > 0$ and $C_L < \infty$ with the following property. For a coarse plaquette C, let $D(C)$ be the rectangular site box formed by its four centered fine endpoint blocks. If the fine plaquette logarithms $F_p = -i\log U_p$, for plaquettes internal to $D(C)$, satisfy $\max|F_p| \leq d_L$, all averages used by C are on their regular branches, and

$$F_C^+ = \sum_p T_{C,p}O_{C,p}F_p + R_C, \qquad |R_C| \leq C_L \sum_{p\subset D(C)} |F_p|^2. \tag{4.cdliii}$$

Here T is the positive scalar flux matrix of eq. 3.v, with row sum L^2 and column sum L^{-2}, and the color factors are orthogonal. After periodic identifications, a collapsed coefficient may be a sum of these transported terms; its norm is still dominated by the corresponding scalar coefficient with multiplicity. ■

Proof. The union of the four endpoint blocks is already a rectangular site box. In the two directions of C it contains two adjacent blocks, and in each transverse direction it contains one. Every internal coordinate-order contour and every joining straight segment in the four actual averages stays in this box. The fine plaquettes in the sheet formula eq. 3.v also have all four corners there.

Choose the coordinate comb from the initial corner of C. Its paths stay in this rectangle. The cycle made by a remaining fine edge and its two comb paths is filled by commuting coordinate steps inside the same rectangle. Every inserted elementary plaquette is therefore internal to $D(C)$; no extra layer is needed. The unitary product inequality and the small logarithm give, in this real gauge, $U_b = e^{ia_b}$ and

$$\|a\|_{\ell^2(D(C))} \le C_L \|F\|_{\ell^2(D(C))}. \tag{4.cdliv}$$

Indeed each edge cycle uses a finite number of internal plaquettes, bounded for fixed L, and the resulting finite incidence matrix has bounded row and column sums. This proves the estimate directly, as in eq. 3.viii.

Decrease d_L so that these finite lists of a_b's belong to one common small analytic ball. The local implicit mean and the coarse plaquette logarithm are then defined there. The fine logarithm has linear part $\mathrm{d}a$, and the coarse logarithm has linear part $\mathrm{d}_c Q a$. Their second derivatives on the smaller ball are bounded finite matrices. Their remainders are consequently bounded by $C_L\|a\|_2^2$. The identity $\mathrm{d}_c Q a = T\mathrm{d}a$ follows from eq. 3.iv–eq. 3.v: the endpoint gradient cancels and the remaining sum is the positive sheet flux. Substituting the fine Taylor remainder, using eq. 4.cdliv, and returning to the original real frame proves eq. 4.cdliii. All frame changes are unitary, even when open transports or global holonomies are large.

On a periodic lattice the calculation is made on the finite lifted rectangle and then projected. Repeated images are retained in the finite incidence count. The row and column sums of T are exactly the periodic counts in eq. 3.vi. This is an identity of actual classical averaging functions, not an equality of quantum measures on different covers. □

For any family of such rectangles, each fine plaquette occurs in at most C_L of them, with the same bound for their lifted multiplicities. Thus, if all fine plaquettes read by a selected set of coarse plaquettes belong to a set P, the restricted transported flux matrix A and remainder satisfy

$$\|A\|_{\ell^2\to\ell^2} \le 1, \qquad \|A\|_{\ell^1\to\ell^1} \le \rho := L^{-2} < 1, \qquad \|R\|_{\ell^1} \le C_L \|F|_P\|_{\ell^2}^2. \tag{4.cdlv}$$

For the first inequality use the row sum L^2, the column sum L^{-2}, and Cauchy–Schwarz as in eq. 3.vii. Deleting rows or columns only decreases these positive majorants. The last inequality sums the actual local quadratic bound.

We next specify the backward carriers. Let S be a finite set of plaquettes at level t. For $C \in S$ and $0 \le j \le t$, let $D_j(C)$ be the union of the four centered blocks of side L^{t-j} on the level-j grid, centered at the corners of C. Put

$$P_j(S) = \bigcup_{C\in S} \{p \text{ at level } j : \text{ every corner of } p \text{ lies in } D_j(C)\}. \tag{4.cdlvi}$$

The union is taken without multiplicity. We write $\mathcal{N}_0(S) = P_0(S)$: a bare plaquette is included exactly when all its corners lie in the four blocks $B^t(y)$ belonging to one member C of S. Also $S \subset P_t(S)$.

These masks are closed under all the required one-step readouts. If $C' \in P_{j+1}(S)$, choose a final C whose $D_{j+1}(C)$ contains its four corners. The centered odd-L block tiling decomposes $D_j(C)$ into the children of the sites in $D_{j+1}(C)$. Consequently the four child blocks at the corners of C' lie in $D_j(C)$, and every fine plaquette in their rectangle belongs to $P_j(S)$. The same assertion for a bond uses its two child blocks. It proves locality and regular-branch admission for the actual averages on the cone, including their internal means, without any assumption on the exterior field. Periodic masks can contain additional plaquettes after projection; the inclusion and the restricted

matrix bounds remain valid. They use sets of projected plaquettes and the periodic scalar matrix entries, rather than charging an energy once per image.

Proposition 4.62 (Small total energy on an exact averaging cone)**.** There is $e_*(L) > 0$, independent of depth, compatible volume, real holonomy and the exterior field, such that every real U and every finite S satisfy

$$\sum_{p\in\mathcal{N}_0(S)} a_p(U) \geq \min\left\{ \tfrac{1}{4}\sum_{C\in S} \|1-\partial\mathcal{M}^t U(C)\|_{\mathrm{op}}^2, \tfrac{1}{2}e_* \right\}. \tag{4.cdlvii}$$

When the left side is less than $e_*/2$, all the actual means required by this cone are on their regular branches. ■

Proof. The empty set is immediate. Write $E = \sum_{p\in P_0(S)} a_p(U)$. Choose the local threshold $d_L \leq 1$ in the lemma smaller if necessary. For $0 \leq s \leq d_L$,

$$s^2 \leq \tfrac{9}{4}(1-\cos s).$$

For example $1-\cos s \geq s^2/2 - s^4/24 \geq (11/24)s^2$ proves this for $s \leq 1$. Set

$$b_L = \min\left\{ \tfrac{3}{4}d_L, \frac{3(1-\rho)}{32C_L} \right\}.$$

Choose $E_L > 0$ so small that

$$E_L < 1-\cos d_L, \qquad \tfrac{9}{4}E_L < b_L^2, \qquad e_* = 2E_L.$$

All constants are chosen before the depth or the volume.

Suppose first $E < E_L$. Each fine plaquette in $P_0(S)$ has its small logarithm, and, with F_0 restricted to that mask,

$$a_0^2 := \|F_0\|_2^2 \leq \tfrac{9}{4}E < b_L^2. \tag{4.cdlviii}$$

If $a_0 = 0$, the local remainder and flux identities inductively give zero logarithmic curvature on every cone mask. The flat local means are admitted, so the result follows.

Otherwise construct successive actual averages on the masks. While $a_j = \|F_j|_{P_j(S)}\|_2 \leq (4/3)a_0$, the local threshold is respected, so the next cone means and their plaquette logarithms exist by the lemma. Their exact equations are $F_{j+1} = A_jF_j + R_j$, with eq. 4.cdlv. The color matrices may depend on the actual fields; only their stated norms are used. Unrolling these identities gives

$$F_n = A_{n-1}\cdots A_0F_0 + \sum_{j=0}^{n-1} A_{n-1}\cdots A_{j+1}R_j. \tag{4.cdlix}$$

An empty product is the identity. The first term has ℓ^2 norm at most a_0. For a remainder propagated through $n-1-j$ matrices, use first its ℓ^1 norm:

$$\|A_{n-1}\cdots A_{j+1}R_j\|_2 \leq \|A_{n-1}\cdots A_{j+1}R_j\|_1 \leq \rho^{n-1-j}C_La_j^2.$$

Thus the induction hypothesis gives

$$a_n \leq a_0 + \frac{C_L}{1-\rho}\left(\tfrac{4}{3}a_0\right)^2 \leq \tfrac{7}{6}a_0 < \tfrac{4}{3}a_0. \tag{4.cdlx}$$

The middle inequality uses the specified choice of b_L. This proves the strict bootstrap, and at the same time admits every required local mean. No unregularized exterior plaquette has entered the induction.

For a real small logarithm, $\|1-e^{iF}\|_{\mathrm{op}} \leq |F|$. Since $S \subset P_t(S)$,

$$\sum_{C\in S} \|1-\partial\mathcal{M}^t U(C)\|_{\mathrm{op}}^2 \leq a_t^2 \leq \tfrac{16}{9}a_0^2 \leq 4E.$$

This proves the first alternative. If instead $E \ge E_L = e_*/2$, the minimum in eq. 4.cdlvii is at most E without any regularity assumption. This proves the assertion for all real configurations under the total measurable averaging convention. □

4.17.1.41. The plaquette and approximate fluctuation witnesses. Fix a test cube $\square$ of step $t = k+1$, and put $D = \square^{\sim 4}$. Use the separated M_1-tower of D, with the geometry and smallness floors of the real tower estimates. The test partitions are aligned, $\check{R}_t \le \check{R}_k \le L\check{R}_t$ are powers of L, and there are at least 6ρ top sites in each torus direction. The third enlargement is inside the top member D_t. In bare units one layer has width $w = M_2\check{R}_t L^t$. On the third enlargement the distance from the complement of D is at least w, and the part of D omitted by D_t is within $2M_1L^t$ of that complement. A level-t site of the third enlargement is therefore a node. The noncentral sites of its level-k block are free to be gauged: any node from a lower row is within $2M_1L^t + L^{t-1} < w$ of the complement of D. The blocks themselves lie in the third enlargement by alignment of the grids.

For the plaquette test, let S_t be the level-t plaquettes with all corners in D. Use the Wilson action on $\mathcal{N}_0(S_t)$ from Prop. 4.62. A real evaluation used to pay for this test must reproduce V_t on the bonds of S_t. If the action there is less than $c\varepsilon_t^2 < e_*/2$, then

$$|\partial V_t - \mathbf{1}| < 2\sqrt{c}\,\varepsilon_t \qquad \text{on } S_t.$$

Indeed, since the action is less than $e_*/2$, the minimum in eq. 4.cdlvii must be attained by its squared-defect term. The lifted datum of the tower, obtained by lifting V_t and then taking the determining averages, is ε_1-regular for $\varepsilon_1 = 3\sqrt{c}\,\varepsilon_t$. For the real orbit estimate use the test's regularity radius ε_{v}, with $\varepsilon_1 \le a_1$ and $B_3\varepsilon_1 \le \varepsilon_{\mathrm{v}} \le a_0$. The real orbit exists and its curvature in the top member is less than $B_3\varepsilon_1 L^{-2t}$ in bare units. The plaquette test on $\square^{\sim}$ passes when $3B_3\sqrt{c} < 1$. This also rules out an undefined orbit under the same small-action bound.

For the approximate fluctuation test, also include the level-k plaquettes in the full double blocks used in the one-step rigidity estimate for each tested bond, including the plaquettes crossing the common face. Call their union S_k. Let E be the Wilson action on the union of the two backward carriers. Require that the compatible real field reproduce V_k on the bonds of S_k and that $\mathcal{M}(V_k) = V_t$ at the corresponding top rows. Let $G_\square$ be the unweighted part of the soft axial gauge action containing the contour variables used by these comparisons. At birth the approximate test is placed one coarse-cell layer inside the region of the gauge factors. Since $M \ge L^2M_2$, three test-cube layers fit inside this margin, so the block centers of the third enlargement carry those factors. If $E + G_\square < c\delta_k^2 < e_*/2$, the same energy argument bounds the level-k and level-t plaquette defects by $2\sqrt{c}\,\delta_k$ on their respective sets. The tower estimate now applies with $\varepsilon_1 = 3\sqrt{c}\,\delta_k$, again with $\varepsilon_1 \le a_1$ and $B_3\varepsilon_1 \le \varepsilon_{\mathrm{v}} \le a_0$. The two endpoint blocks needed for a bond in $\square^{\sim 2}$ lie in the top region with their averaging carriers. Averaging the bare background to level k bounds the plaquette defects of $\mathcal{M}^k U_{t,\square}$ on these blocks by $2B_3\varepsilon_1 L^{-2}$. For $B_3\varepsilon_1 \le L^2 c_2^{\mathrm{elem}}$ the contour means of this background exist. The small plaquette bound on V_k ensures the existence of its corresponding contour means as well.

In the chosen block axial representative the background contour means equal $\mathbf{1}$. For the means of V_k, the identity $1 - \frac{1}{2}\,\mathrm{Re}\,\mathrm{tr}\,H = \frac{1}{2}|H - \mathbf{1}|^2$ bounds each contour defect by $(2G_\square)^{1/2}$. On the top bond of a double block the background has average V_t by the determining constraint and the identity that averaging the lift recovers V_t. The block centers are fixed in the axial normalization. The other field has average V_t there by the recorded one-step constraint. By Lem. 3.8 their relative bond defect is at most $C\sqrt{c}\,\delta_k$ on the tested nonpivot bonds. Choosing c smaller makes this less than $2\delta_k$, so the approximate test passes. The contour existence just checked also makes this deduction valid with the sitewise extension of the gauge factor at undefined means.

These two contrapositives apply to every real evaluation with the specified averaging and gauge readouts, with constants independent of depth. To use them in a history integral, the recorded compatible rows must cover these carriers, the gauge action must be the one retained on the required blocks, and the paying sets must have the ownership and floor exclusion in eq. 4.div. The true

fluctuation, collar and rim tests additionally use the coercivity and domination in the actual stored coordinates.

4.17.1.42. Ordinary creation witnesses in a later drop-out. The paying region of an ordinary creation is separated from older large fields when the creation occurs. In a sufficiently later operation it belongs to the protected floor; the new payment of that operation is taken outside the floor. These are different exclusions.

Consider a failed P_t- or Q_t-test on a cube $\square$, put $j = t-1$, and let $\mathfrak{c}$ be the level-t cell containing $\square$. The birth geometry gives

$$\mathfrak{c}^{\sim} \subset \Omega_t^c \cap D_{\mathrm{birth}},$$

where D_{birth} is its component of Z_t and the enlargement is by one layer of level-t cells. Containment in Ω_t^c uses the two layers around Q_t' and the four around P_t'; when $t > 1$, the birth margin also places this neighbourhood inside Λ_j. It also separates it from the older live region and its marks.

The exact averaging cones used above fit in this neighbourhood. Indeed, $M \geq L^2 M_2$, the partitions are aligned, and $L \geq 3$. Thus $\square^{\sim 4} \subset \mathfrak{c}^{\sim}$. Both sets are unions of complete level-t blocks. For a plaquette whose corners lie in $\square^{\sim 4}$, all four blocks in eq. 4.cdlvi therefore lie in $\mathfrak{c}^{\sim}$. The double blocks for the approximate test lie in the third enlargement, so the same conclusion holds for their level-j ancestor cones. Every paying bare plaquette has all its corners in $\mathfrak{c}^{\sim}$; no enlargement of the paying field's domain is hidden in this use of the averaging estimate.

Suppose this creation is carried into a later drop-out X without being absorbed into a healed component or an island. Every ordinary step leaves the older entries unchanged. If an operation of level m contains this creation, its quiet-window condition gives $t \leq m_\flat$. A drop-out from that operation re-makes only entries of levels $l > m_\flat$. It therefore leaves both Ω_j and Ω_t, and hence the determining rows of level j on $\mathfrak{c}^{\sim}$, unchanged. Its stages integrate stored fields only at levels at least $m_\flat$, so the birth field V_j, its gauge factors, and its one-step averaging constraints are retained. This argument applies at every later drop-out on the same branch.

Consequently, for a compatible real evaluation on X, the required identities are

$$\mathcal{M}^j U = V_j \quad \text{on the protected birth rows,} \qquad \mathcal{M}(V_j) = V_t \quad \text{on the retained step-}t\text{ rows.}$$

Together with locality and the semigroup identity, these give $\mathcal{M}^t U = V_t$ on every top row used in the birth test. At $t = 1$, the first identity uses the stored bare field wherever the action field is completed by that field. The recorded gauge readouts in the Q_t case are likewise the original ones. The exception for an earlier main-step drop-out, whose later constraint reads the density argument rather than its integrated datum, does not replace these protected birth rows. A mark older than the birth is outside its paying neighbourhood; a mark containing the birth has its re-made levels strictly above t.

The floor containment has the corresponding precise meaning. For a class component u containing the old creation, the geometric statement $\mathfrak{c}^{\sim} \subset \mathsf{Fl}(u)$ contains the exact cones just checked. It separates this old Wilson payment from the fresh payment of u, which uses no plaquette with a corner in $\mathsf{Fl}(u)$. The same floor rule places each older marked component enlarged by two layers of unit cubes at its own level inside the later floor, so that a fresh payment which uses that neighborhood in the older window cannot spend the later window's complement. At a fixed birth level, one recorded witness per creation cell has its carrier within two layers of that cell. A fixed plaquette or retained gauge-factor site can therefore enter only a bounded number of the same-level witnesses. Divide the available Wilson and gauge coefficients by that multiplicity. For distinct untouched pieces the source of the shares is the disjoint union of their paying neighborhoods. The action sequence still assigns the old payment its preceding-level weight at birth; at later reads the stated lower bound is a fixed multiple of θ_t. The local history must retain the failed birth indicator, the stated one-step constraints, and, for Q_t, the specified gauge factors. The compatible evaluation must reproduce these protected rows on the whole neighbourhood. Under these explicit readout conditions, the two contrapositives above apply uniformly to the later evaluating field. Once an

island absorbs the creation, its payment belongs instead to the island's mass; this argument does not charge it again. Nor does it supply the separate witness needed for the later operation's own failed test.

For an ordinary plaquette or approximate fluctuation witness, the protected birth rows give the same readout in the three places where its payment is used. At a point of a later term, they are defining constraints of the current background. For a drop-out's mass they are imposed by eq. 4.cdlxx. The retained one-step constraints then give the required next average in both cases. The failed birth test is retained in either variant of the mass: the excluded test is the later operation's own root test. At the first step the convention is explicit: V_0 is the stored bare field and Γ_0 consists of bare bonds with both endpoints in Ω_1^{c}. Hence the birth neighbourhood already lies in this prescribed bare readout.

The third place is the real inner Wilson factor of a completed main integration. Let its level be i. The quiet window puts every ordinary birth belonging to its outer history at a level $t \le i_\flat$. Its paying neighbourhood lies in the old core. On that core the localised inner determining set agrees with the prepared set. Its datum is the retained V^{in} on the inner rows, whereas the new increment is supported on rows with no endpoint in the core. Thus the protected level-$t-1$ rows still carry V_{t-1}, and the retained step-t constraints still produce V_t. The first-step bare completion is understood as above.

Here the representative matters for literal averaging identities. The real Landau form used to write the inner Wilson action is gauge-equivalent to a member of the constrained orbit; an arbitrary member of that gauge orbit need not reproduce the fixed stored datum. Use the adapted constrained representative in the preceding identities. This leaves the Wilson sum unchanged, since each plaquette holonomy changes by conjugation, and the gauge-fixing variables in the certificate remain their stored values. The prescribed adaptation acts on the read, not on those stored variables. No equality of every historical coarse field is needed: the protected birth rows and their one-step constraints suffice.

For an island, this paying inner Wilson factor is a function of ξ alone. Taking the supremum over a complex exterior pair does not replace it by a Wilson action at that pair. These observations settle the averaging and recorded-value part of the ordinary witness read. Admission of the read to an analytic core and the one-sided bounds on its kept forms and elimination factors are separate requirements in eq. 4.dxxv.

For a failed ordinary fluctuation cube, a collar creation or a failed rim cube, use the kept Gaussian form of the birth step $t = j + 1$. The split places the failed fluctuation cubes in R and adds the cells of the collar creations and the failed rim cubes to the exploration set. The enlargements in the split put the test bonds in Z_t. They are kept nonpivots of the birth step, and the quiet-window condition $j < t \le i_\flat$ keeps them below the integrations of the containing operation.

Write $a' = g_j \mathcal{A}_j^{\mathrm{s}}$ for the retained coordinate in angular units. An explored collar bond is in the union of the passed cube masks, where the strip substitution leaves the coordinate fixed. The rim mask excludes the ordinary strip $\mathfrak{S}$. The failed fluctuation cubes have their masks in the enlargement of R, so on these masks the substitution either leaves the coordinate fixed or uses the cutoff $\theta_j(a')$. The same alternatives hold on the rim mask, since the plain zone is contained in the bonds meeting $\mathfrak{S}$. On the ball below the corresponding test threshold, $\theta_j(a') = 0$, and the exact product logarithm gives $\mathcal{A}_j = a'$. The logarithm also exists throughout that ball. Thus a failed cube or rim test, or a collar creation with $\chi_b^1 = 1$, has a bond with $|a'| \ge c\delta_j$, where $c > 0$ is the smallest fixed threshold fraction. The coercive reserve of the kept form pays $c'\delta_j^2/g_j^2$ at that original bond.

No integration is undone. For the superrenormalisable model [B82b, Sect. 3.A, Prop. 3.1], the conditional integrations are reversed at the end. This recovers a single positive quadratic form over many scales, and the factors of all the characteristic functions are then extracted from it simultaneously. Here the operations $\mathbf{T}_k(Z)$ keep the integrals, and every factor is obtained at the

place where it sits. It comes from the Wilson weight, through the display above; or from the Wilson weight together with the kept gauge-fixing exponents (Lem. 4.60 (ii)); or from the conditional form, whose lower bound is c. (Taken as a whole, the conditional form inherits the bound because it is a Schur complement; the kept part of this form is treated in §4.17.1.3.) With this, the cost of the stored Gaussian integrals is $e^{C\#_j(Z_j\cap\Omega_j)}$ (122 (1989) 355, p. 383).

One action and many claimants. Gains are added up in the ledger that follows, and this addition is legitimate: nothing is spent twice and the integrals that remain converge. The Wilson, gauge and stored Gaussian terms are assigned once to the witnesses used in the ledger. A *piece* is a pair (t, D) in which D is a component of the region produced by step t on which no $\mathbf{R}$ has acted up to level k. We write $\mathsf{w}_{t,D}$ for the weight of its one-step operation. This weight consists of the gauge-fixing factors with their normalisers, the Jacobians that arise when the averaging constraint is solved for the pivot bonds, and the conditional Gaussian. We write $\xi_{t,D}$ for the variables that belong to the piece. Let the shares of the action be as defined in (1), and extend U_k beyond Ω_0 by means of the stored bare field. Then at each point of the support of the term of a history one has $A(x_k(\cdot), U_k) \geq A_{\mathrm{cr}} := \sum_{(t,D)} x_{t-1} \sum_{p\in\text{share of }(t,D)} a_p(U_k) \geq 0$, so that the only part of the action spent is the Wilson sums over the shares. Moreover

$$e^{-A_{\mathrm{cr}}} \prod_{(t,D)} \mathsf{w}_{t,D} \leq \exp\Big[- c \sum_{\text{created cells } (t,\mathfrak{c}) \text{ in the pieces}} p_0(g_t)^2 \Big] \prod_{(t,D)} \bar{\mathsf{w}}_{t,D}(\xi_{t,D}),$$

$$\int \bar{\mathsf{w}}_{t,D} \leq e^{C\#_t(D)},$$

where each $\bar{\mathsf{w}}_{t,D}$ is a Borel function of the variables of its own piece only (the background no longer enters it), and $C = C(L)$ carries no $\log x$ per site. (1) *The action is divided among the pieces, not held in common.* The share of a piece consists of the bare plaquettes that lie within one cell of those of its cells at which a plaquette test or an approximate fluctuation test has failed. Distinct pieces have disjoint shares, because the tests of a step are carried out several cells away from the hull of the older region. On a share one has $x_k(\cdot) = x_{t-1}$, since the older profiles have completed their transition and the newer ones have not yet begun it. Every other plaquette contributes ≥ 0. (2) *The tests concern averages of the configuration that appears in the action.* The tests were built from localised backgrounds of step t, whereas the Wilson term contains U_k. The two are connected as follows. The identity $\mathcal{M}^{t-1}U_k = V_{t-1}$ on Γ_{t-1} is the constraint that defines the background, and on the same set $V_t = \mathcal{M}(V_{t-1})$ is imposed by the corresponding delta function. To apply the witnesses of Lem. 4.60 to U_k, the retained rows at the read must contain the averaging and contour readouts on their full carriers. This coverage is needed in addition to the identities on the retained rows. (3) *Each exponent is split into two halves*: one half is used for payment and the other is kept for the integration. The only normaliser that depends on the coupling is integrated against half of its own exponent,

$$\int du\, e^{-\frac{1}{2}x(1-\frac{1}{2}\operatorname{Re}\operatorname{tr} u)} \leq C \int du\, \mathbf{1}\{|u-\mathbf{1}| < \epsilon\}\, e^{-x(1-\frac{1}{2}\operatorname{Re}\operatorname{tr} u)}$$

$$(\epsilon \leq 1,\ x\epsilon^2 \geq 1),$$

and both sides are of order $x^{-3/2}$. For a gauge factor at level j, keeping half its exponent leaves the full denominator $z(\theta_j, \varepsilon_j)$ in place. Dropping the numerator cutoff bounds its integral by $z_\infty(\theta_j/2)/z(\theta_j, \varepsilon_j)$, where z_∞ is the untruncated integral. The displayed estimate bounds this ratio uniformly. On the cut-off zone of the strip the shift §4.17.1.3 vanishes for small $\mathcal{A}'$; consequently a large tested field is a large variable of integration. (The approximate test requires GF for the following reason. Take a gauge transformation at a site of $\mathbb{T}^{(t-1)} \setminus \mathbb{T}^{(t)}$. It moves V_{t-1} away from $\mathcal{M}^{t-1}U_{t,\square}(V_t)$, the average of the localised background §4.17.1.1, which is in the block axial gauge

§ 3.1.1. It does so at no cost in action, since it alters neither the action nor V_t.) (4) *Within a patch on which the* $\mathbf{R}$ *of level* m *acts*, a test that fails may not be paid for by the large field from which the patch arose. Whatever is older than the wait was paid for by plaquettes that lie in the *floor*. The floor is made up of those cells of level $m_\flat$ of the old core, $\Omega^{c}_{m_\flat} \cap X$, which do not touch $\Omega_{m_\flat}$; this old core is a part of the core $C_{m_\flat} = X \cap Z_{m_\flat}$ of §4.17.1.3, because $\Lambda_i \subset \Omega_i$. The gauge-fixing factors and stored Gaussians that paid for it are all of levels below $m_\flat$. Let X be a drop-out, and consider stored variables with two properties: each test carried by X takes its recorded value, and the plaquette variables of the datum in the old core, taken layer by layer (V_l on Γ_l), are within $C\check{R}_l^2\varepsilon_l$ of $\mathbf{1}$. (These two properties hold on the supports. They also hold at the points of evaluation that occur below in the mass of a later drop-out that contains X. Within the mass of X itself, no use is made of the test whose failure turned it into a drop-out.) For every real U compatible with stored variables of this kind, one has

$$c\,x_m \sum_{p\subset X^+,\,\text{no corner in the floor}} a_p(U) + \sum_{j=m_\flat}^{m-1} x_j \mathrm{GF}_j(X;V_j) + c\sum_{j=m_\flat}^{m-1} \|\mathcal{A}^{\mathrm{s}}_j\|^2_X \;\geq\; (\log x_m)^{2\mathfrak{p}_1 - Cr} \;\geq\; p_0(g_m),$$

where X^+ denotes X enlarged by two layers of unit cubes of level m and U is compatible on X^+. For the stops with the full witness calculation below, smallness of the left-hand side forces the tested quantity below its threshold. At a final regularity stop this calculation applies to the inset and its prepared-seam test. In every case the bridge runs along the same chain. It starts from the action of a compatible configuration and passes to the plaquettes of the stored fields (by the energy of the averages). From there it passes to the regularity of the background used by the test, and then to the bond variables. That last link comes either from the rigidity of a single averaging step or from loops in the shells. In a shell of side $s \leq CM\check{R}_m$, a loop composed of n straight pieces has a deviation from $\mathbf{1}$ that is bounded by $C\mathsf{n}s^2$ times the plaquette bound, and this is where the loss $\check{R}_m^{-C}$ comes from. The waiting collar screens off the unknown large field in the floor; this collar is what separates the floor from the region $X \cap \Omega_{m_\flat}$ in which the operation acts, and its width is at least one cell in the local units. Where the operation acts, the background of any stage has curvature at most $C(\varsigma + \check{R}_m^2\varepsilon_m e^{-\delta_0 M\check{R}_m})\eta_j^2$ on the layer j, which is the local scale. Here ς is the size of the plaquettes of the stored fields that follows from the smallness of the left-hand side. A drop-out uses no plaquette that has a corner in its floor. By contrast, each plaquette used beneath it lies inside the floor, and each gauge-fixing factor and stored Gaussian used beneath it is of a level below $m_\flat$. The windows of nested operations are disjoint.

4.17.1.43. Filling a loop on one shell lattice. Consider two lattice boxes of side at most s, in units of their common lattice spacing, with the inner box strictly inside the outer one in each direction. Use the lattice sites of the outer box outside the inner box, with their bonds and plaquettes. Suppose each side of the inner box has at least one layer of sites beyond it in the outer box. A closed path in this shell with n straight pieces contracts across at most Cns^2 plaquettes of the shell, counted with multiplicity.

Indeed, the shell is the union of the eight rectangular slabs beyond the faces of the inner box. Each straight piece lies in one slab. Consecutive pieces have a common endpoint in the intersection of their two slabs. Choose once a lattice point in each nonempty slab intersection. Join every change of slab to the chosen point for that pair by a coordinate path in the intersection, inserting the path and its reverse. Within each slab, replace the portion between successive chosen points by fixed coordinate paths through one fixed point of the slab. Each replacement is a loop of length at most Cs in a rectangular box of side at most s. Sweeping its edges to the fixed point one coordinate at a time fills it with at most Cs^2 plaquettes.

It remains to contract the loop of slab labels. The nerve has the eight slabs as vertices and has a simplex for each selection with at most one of the two sides in any coordinate. It is the join of four

pairs of points, hence is simply connected. In this fixed finite nerve, choose paths from one vertex to each vertex and fix a contraction of the loop associated with each edge and the two chosen paths. Any loop of n edges contracts by at most Cn triangle moves. To realize one triangle move in the shell, take a point in the common intersection of its three slabs. Connect it to the three pairwise reference points inside their intersections. The triangle then splits into three loops in the individual slabs. Each has length $O(s)$ and costs $O(s^2)$ plaquettes by the same rectangular sweep. This gives the stated area.

For a real unitary field each plaquette move changes the based loop transport by a conjugate of a plaquette transport or its inverse. Thus the loop defect is bounded by Cns^2 times the maximum plaquette defect on the filling.

For the main-step bond test write $\mathsf{W}_l = \mathcal{M}^l U$ and $\mathsf{W}_l^0 = \mathcal{M}^l \tilde{U}_0$ in the prescribed shell gauge. They must give the tested datum and its reference in the same frame at b. Suppose the fields agree on the shell's gauge tree and exterior bonds. Set $\varsigma_* = c_* \delta'_m \check{R}_m^{-4}$ with $c_* > 0$ fixed. Suppose the stored datum bound is at most ς_*. The screening term is at most ς_* for small coupling, since $\check{R}_m^6 (\varepsilon_m/\delta'_m) e^{-\delta_0 M \check{R}_m}$ tends to zero. For W_l use the small paying energy on the full backward carriers to bound its shell plaquette defects by $C\varsigma_*$. For W_l^0 the basic reference needs its own curvature estimate on these carriers. Where its bare curvature is bounded by $C\varsigma_* L^{-2l}$ there, the averaging estimate gives the same $C\varsigma_*$ bound. On its prescribed top rows the corresponding estimate uses the top datum of the reference. The stage screening estimate above does not establish this reference bound on its own. For a test and return on the same level, take a loop ℓ_b that traverses b in its chosen orientation and otherwise uses these common bonds on the level-l lattice. Writing the common transports before and after b as P and Q, the relative loop holonomy is

$$(P\mathsf{W}_l(b)Q)(P\mathsf{W}_l^0(b)Q)^{-1} = P\mathsf{W}_l(b)\mathsf{W}_l^0(b)^{-1}P^{-1}.$$

Thus the norm of the tested defect is bounded by the sum of the two loop defects. If the chosen loop has a bounded number of straight pieces in a shell of side $s \le CM\check{R}_m$ in level-l units, the stated filling bound gives $CM^2\check{R}_m^2\varsigma_*$ for the defect and, after changing the constant, for its small logarithm. This is below δ'_m when $\check{R}_m$ is sufficiently large. In applying this estimate we must find the filling in the charged shell, with its area counted with multiplicity and its backward carriers outside the old floor. The required rows and the common transports must come from the actual drop-out datum.

4.17.1.44. The datum tested before a stage is integrated. Consider stage $n+1$ of the operation of level m. Put $j = m_\flat + n$. At that point the old determining set is the stage-n set. The only member of the sequence that changes is the one of index $j+1$, which grows from Ω_{j+1} to the prepared member. The level-j determining rows that remain are a subset of the old rows. The margin from the next region leaves the higher row read sets unchanged. The level-$(j+1)$ rows with an end in the old region are already old determining rows. The new rows have both ends outside Ω_{j+1} and at least one end in the part being added. The two order-$(j+1)$ blocks of each such row lie outside Ω_{j+1} by grid alignment. The prepared separation puts both blocks inside the old member at level j, so all their level-j bonds are old determining rows. The averaging delta on the new row is still present when the stage is tested.

Let U be the real field of a compatible evaluation reproducing the old rows on these full carriers. Its level-$(j+1)$ averages on the new rows give the prospective datum by the retained delta and the composition of the averages. The other prospective rows have their old values. In particular the test can be compared with U before the collar variables have been eliminated.

For the no-inward determining set, each tested holonomy in the prospective sequence is a plaquette of $\mathcal{M}^q U$ at its test level q. A bond that is not a determining row has both ends in the layer just below q. Its two blocks lie in that layer, where the determining rows supply the complete one-step average. Thus this identification also holds at a seam. Upon joining to the tower of the component,

an interior holonomy is unchanged. A holonomy on the joining collar is trivial or equals a top plaquette holonomy of the original datum. The top data of this collar are outside the old floor.

If the bare carrier of a tested plaquette avoids the floor, the paying energy bounds its defect by $C\varsigma_*$. Otherwise its level is less than $m_\flat$ and its blocks lie in the old core. The floor does not touch $\Omega_{m_\flat}$, and the adjacent blocks at the outward rows of that level reach only the touching layer. The old plaquette defect is bounded by the regularity of the recorded old datum. This bound is at most $C\check{R}_m^2\varepsilon_m$, using the comparison of the thresholds at earlier levels. The joined datum is therefore regular at a radius tending to zero. On the part of the stage test at weighted distance at least $cM\check{R}_m$ from the old carriers, the local regularity estimate gives

$$|\partial U_{m,X}^{(n+1)}(p) - \mathbf{1}| \le CL^{-2\lambda(p)} \left(\varsigma_* + \check{R}_m^2\varepsilon_m e^{-c\delta_{\mathrm{c}}M\check{R}_m}\right).$$

Here $\lambda(p)$ is the local level of the joined stage sequence at p. This first establishes existence of the tested orbit and then bounds its curvature.

In the interior away from the joining collar, the old prepared shells have their stated levels. Before the compressed part of the nest the exterior region has at least the level prescribed by the test. In the compressed part the loss in level is at most $1 + \log_L(C\check{R}_m)$. Thus changing the curvature units to those of any of the stage thresholds costs at most $C\check{R}_m^2$. The factor $\check{R}_m^{-4}$ in ς_* and the exponential in the old-carrier term suffice for these interior thresholds. This is the inset used in the implication for carried tests. In the outer joining collar the tower can descend to the bare scale. There a bound in its local units gives the top-scale threshold only with an additional bound on the lifted top datum. When the stage tests that collar, we must estimate its failure separately.

At the final stage the literal regularity test includes bare plaquettes of $X \cap \Omega_m$ with the bound $3(1 - \frac{1}{2}\beta_{\mathrm{s}})\varepsilon_m L^{-2m}$. Near the outer boundary of the localized background, an inner bare bond of its level-zero layer is a determining bond and carries the face lift of V_m. Choose a plaquette tangent to a flat outer face, in that bare layer, crossing two faces of the level-m blocks. All four of its bonds are determining bonds. Its plaquette variable is exactly the level-m plaquette variable of V_m at the four block centers. The first-member convention that keeps only a collar of the level-one member still leaves a layer of bare determining bonds. It does not give the factor L^{-2m} on this lifted plaquette.

This mismatch occurs even for a top datum obtained by averaging a low-action bare field. Work in level-m units and put $\eta_m = L^{-m}$. In a fixed box containing the four order-m blocks, take an abelian potential $A_1(x) = ax_2T$, $A_\nu = 0$ for $\nu \neq 1$, where T has eigenvalues $1, -1$. Continue the potential smoothly to zero outside a slightly larger fixed box at the rim, keeping it away from the old core. Sample it on links by $U(b) = \exp(i\eta_m A_\nu(x_b))$. All bare plaquette angles are bounded by $C|a|\eta_m^2$, and their number in the support is at most $C\eta_m^{-4}$. Hence the bare Wilson action on the support is at most Ca^2.

In the affine region a centered averaging step keeps the same affine potential with the next spacing. The formula for the contour mean reduces to arithmetic averaging of its logarithms on the common abelian arc. On a bond in direction 1 the contours at opposite ends are translates with equal logs, and the sum of straight path logs averages x_2 to the coordinate of the block center. On a bond in direction 2, translating the contour changes its logarithm by a fixed multiple of $x_1 - y_1$, where y is its block center. That term averages to zero. Translations in the other two directions change none of the logs. The construction is local on the four order-m blocks, so the same calculation iterates to their top plaquette. Its defect is $2|\sin(a/2)|$.

Taking $a = 8\varepsilon_m L^{-2m}$ for large m therefore fails the literal rim bound, although the available Wilson exponent of this local perturbation is only $C\theta_m\varepsilon_m^2 L^{-4m}$. Thus the Wilson energy alone cannot pay for this failure. We must obtain the additional rim estimate from the other factors of the retained operation.

The same scale discrepancy affects the proposed fresh payment on the retained real support. Fix the top coupling in a plateau of the rounded cube size that contains the whole waiting window,

and put $h = m - \mathsf{N}_m$. Both N_m and the sides of the fresh carriers in level-m units are then fixed as m varies. Create one cell at h by a pure gauge, constant on each order-$(h-1)$ block. Give one block whose centre is outside the level-h lattice a gauge value u_x with

$$2\delta_{h-1} < |u_x - 1| < \varepsilon_{h-1},$$

and give the other blocks the identity. Before step h the gauge is constant within each fixing block and the tested fields are flat. At step h a nonpivot bond from x inside its level-h block fails the approximate fluctuation test. Its gauge-fixing factor still has positive support, and its cost belongs to level $h-1$. Place the failing footprint in one birth cell. With all subsequent tests passing, its single successors stay within the class size bound. Indeed if a_j is the side of a cell at level j, their sides satisfy $s_j \le s_{j-1} + 22a_j$, with $a_j = La_{j-1}$ on the plateau. The creation enters the class at m, at the lower end of the waiting window.

Multiply this field by the commuting perturbation at the rim above, with its support disjoint from the birth footprint. Use its actual successive averages as the retained fields. The lower creation is unchanged, and from level h upward the pure gauge restricts to the identity. The real averaging bound gives plaquette defects at level j of size $C|a|L^{-2(m-j)}$. The joined regular backgrounds exist at radius $C|a|$. On the full double blocks used for the retained relative bond tests, the contour variables and coarse rows in the prescribed frames differ by $O(|a|)$. The one-step comparison and the actual strip and collar translations therefore keep the retained fluctuation coordinates of size $O(g_j^{-1}|a|)$ on the fresh carriers. At the birth the failed bond is outside the strip. The earlier stage tests read away from the outer joining collar and at joined layers at least h, where the bare curvature is bounded by $C|a|L^{-2h}$. Since $m-h$ is fixed, these tests pass for large m.

The fresh gauge and Gaussian payments are $O(|a|^2)$, since there are boundedly many fresh variables at fixed top coupling. Together with the Wilson bound above this tends to zero for $a = 8\varepsilon_m L^{-2m}$, while the last stage test fails. The gauge payment at the birth is already owned below the fresh window. Thus the pointwise certificate must use the joined layer of the rim plaquette, which is zero here, even though the plaquette lies in the original region Ω_m. The inset estimate applies on the inset, and the ordinary rim fluctuation tests have their separate kept-form payments. For the negative branch of the full stage test we must supply a different payment or an accounting that carries this branch without a fresh gain.

For an internal seam at level $l > m_\flat$, the common return traverses the two adjacent shell trees and their single entrance. Indeed, contracting each shell tree gives the chain of nested shells. When the tested bond is itself the entrance, its defect vanishes. Otherwise the resulting cycle uses bonds only at levels l and $l-1$.

We use the following reduction at a compatible real evaluation. The tested bond and the original common return must read the retained averages of the same bare field U, in the specified frame, and the reference values must read the averages of $\widetilde{U}_0$ in that frame. The exterior top datum used to form $\widetilde{U}_0$ must also equal the top averages of U on the exterior bonds of the component. These are the exterior averages used in the real component evaluation. A restored current-stage datum after the main integration does not identify an earlier kept determining bond with the average of the evaluation field. At such a use one needs the retained-row identity for that bond. The extra fine bonds introduced below are computed averages of the evaluation fields on their full carriers and need no stored constraints of their own.

At a descendant drop-out (m, Y), the field used by the main-step bond test is the datum retained in the frame of that drop-out. The two fields carried on a top bond meeting the central box have different roles. The free argument V_m enters the averaging delta functions of step $m+1$. On a determining bond the earlier variable $V''(b)$ is still the datum of the determining set. The same prepared datum is retained on the finer shell rows. Before the central integration, a re-made level instead keeps its bare averaging delta functions. If the drop-out leaves at extendibility, there has been no central integration and these are the constraints still present in the innermost box.

For a descendant whose bond test was formed, the original shell rows are therefore read from the retained variables of the frame operation. The later real Wilson background is constrained at those rows. Indeed, the drop-out keeps its determining regions at departure for as long as it stands. If an intervening island has closed the branch, the outer mass reads that island's factor instead. Otherwise the enlarged component of the descendant lies in the old core of a containing operation, whose stages leave those determining rows in place. In the broader waiting convention a full re-entry at the lower end of a window has the same distinction: the coarse bonds whose averaging reads the free box argument are deep inside the first retained core, and are not data of the first stage. The top exterior of the child's central box remains on the prepared top grid, with its original exterior datum. Thus the bare field of the compatible evaluation reproduces V'' on the tested bond and on the return tree, and it reproduces the child's exterior top datum on its exterior determining bonds. The tree condition compares these values with V_0 in the child's recorded frame.

This check concerns the test of $V''V_0^{-1}$. A test or delta function that reads the free top argument would need its own comparison. The determining datum gives no equality between that argument and the kept prepared value on the same bond. When a descendant's failure is charged in a later mass, use the evaluation on the containing component and the child's charged carriers in Y^+. An evaluation in the mass of the child itself is only defined on Y, and its own failure is omitted in that version of the mass bound.

For the selected waiting rule the child's enlargement lies in the containing floor. Its paying region consists of the plaquettes of Y^+ with no corner in the child's own floor. In a completed ancestor the inner Wilson cutoff is one there. At a stopped ancestor use its carrying Wilson weight on the same region. Use the level-m weight in Y and the bound of the first ordinary successor on the added collar. The latter weight is bounded below by $c\theta_{m+1} \geq c'\theta_m$. The annular carriers in the shell comparison are contained in this paying region. The averaging energy bound, followed by the bond and last-shell comparisons, forces both shell tests to pass if that Wilson share is less than $c\theta_m(\delta'_m \check{R}_m^{-4})^2$. This argument uses the child's prepared rows as reproduced by the ancestor's compatible field in the child's original frame.

These Wilson shares are disjoint. The share of a descendant lies in the floor excluded from the share of a containing mark. For incomparable marks use the separate components at the larger level. The smaller enlargement is inside its ordinary successor and hence inside its later component, and the larger enlargement stays clear of that component by the cell separation. At equal levels the enlarged components are already disjoint.

At main-step entry itself, the prepared real background has the averages V'' on $\mathbf{B}''$, so it gives the test and tree reads in the prepared frame.

For the inner Wilson read, let the child Y stand as a drop-out inside a component Z whose main step is at level i. The waiting rule gives $m < i_\flat$, and Y^+ lies in the protected old core of Z. The parent's inner determining set agrees there with its prepared set. Its inner datum retains the child's determining datum; the parent's new increment has no endpoint in that core. Hence, whenever the parent's real inner background has been formed, its adapted constrained representative reproduces every retained child shell row whose full carrier lies in Y^+. In particular, it reproduces the same V'', the same tree values, and the same exterior V^{e} in the preceding main-step comparison. If the child stopped during preparation, this assertion concerns its actual stopped determining list. The unperformed stages do not supply additional rows. As with the ordinary witnesses, replacement of a real Landau form by this constrained representative leaves its paying Wilson sum unchanged.

Write $P_1 = Z''_{l+1}$ for $l < m$ and $P_1 = \Lambda^{\mathrm{pr}}$ for $l = m$. Write $P_2 = Z''_{l-1}$ for $l - 1 > m_\flat$ and $P_2 = I_2$ otherwise. These boxes are aligned on the level-$(l-1)$ grid. A level-l bond of the outer shell with both ends outside Z''_l has both order-l endpoint blocks in $P_1 \setminus Z''_l$. At either crossing, the inner endpoint lies in the first row of level-l sites of Z''_l. Its block is contained in the one-block skin of Z''_l. The prepared margin between P_2 and the boundary of Z''_l exceeds one level-l block. This follows from the early and late nesting margins, and from the lowest-shell width when $P_2 = I_2$.

Thus every endpoint double block needed for a level-l bond of the cycle is in $P_1 \setminus P_2$. By the same alignment, the bare backward carriers of the level-$(l-1)$ plaquettes used in that annulus stay in the annulus. In particular they avoid the floor in I_2 and lie in the charged part of X^+. The small-paying-energy estimate therefore bounds the curvature of the evaluation field throughout these carriers after averaging to level $l-1$. This use requires the energy on the full charged region and an evaluation field on those carriers. Control of the stored bond values alone would give neither.

For the reference field, take the box Z in the main-step geometry to be the component X in the drop-out estimate. The reference uses the exterior restriction of the top averages on this component. The endpoint blocks of each exterior top plaquette avoiding the free bonds are outside Λ^{pr}. By alignment with the top grid they lie in X if all its corners lie there. For a reference read that reaches across ∂X, use the full blocks in X^+ and their original exterior values. These carriers lie in the charged region of the containing evaluation. The paying energy bounds these exterior top plaquettes by $C(L,M)\varsigma_*$. The extension and reference-minimizer estimates put the same bound on the top plaquettes touching a free bond. A free bond has an end in Λ^{pr}, so each of its incident top plaquettes lies within one top unit of the box, in the minimizer's test set. All other plaquettes are unchanged exterior plaquettes. For $l < m$ the annulus lies in Λ^-, where the basic-reference potential and first derivative bounds give the corresponding bare curvature bound. For $l = m$ use the regular basic-reference tower on Z. The full carrier of the prepared box and its first exterior layer lies inside its top inset. The potential bound on Λ^- alone would only treat the part of that carrier in Λ^-. In both cases the local averaging estimate now gives the required curvature bound of $C(L,M)\varsigma_*$ at level $l-1$ throughout the annulus.

For either field, replace each oriented level-l bond c by the straight level-$(l-1)$ path with the same endpoints. The one-step averaging formula gives the level-l value of c as the straight-path product multiplied by a group element at distance at most $C(L,M)\varsigma_*$ from the identity. This estimate uses precisely the level-$(l-1)$ plaquettes of its endpoint double block. Gauge covariance gives the comparison at the same endpoints in the original frame, including the entrance and tested crossing. For a reversed orientation use the inverse product. Telescoping the unitary products bounds the error on a cycle with $O(s)$ bonds by $C(L,M)s\varsigma_*$, where s is the outer side length in level-$(l-1)$ units. Here $s \le C(L,M)\check{R}_m$.

The resulting cycle lies in the single-grid annulus $P_1 \setminus P_2$. In the prescribed shell tree a contour from the root has at most five straight pieces. The return within one shell is obtained by concatenating two such contours, reversing one of them and removing backtracking. With the entrance and the tested crossing this gives a bounded number of straight pieces on the fine grid as well. The filling therefore has area at most $C(L,M)s^2$. The two original cycle products are each at distance at most $C(L,M)(s+s^2)\varsigma_*$ from the identity. The comparison along the original common tree bounds $V'(b)$ and its small logarithm by $C(L,M)c_*\check{R}_m^{-2}\delta'_m$. This is the comparison in the retained frame. Equality of the auxiliary straight-path products of the two fields is unnecessary.

For a bond crossing the outer boundary of Λ^{pr}, the outermost tree return, the outer entrance, and the return in the first exterior layer are already on the top grid. The single-grid argument applies with this exterior layer included in P_1, provided the full top carriers lie in the charged region and the regular reference inset as above. The prepared test set excludes bonds with an endpoint in I_2, so there is no further crossing at the inner cut.

The last-shell test uses the field obtained by replacing part of the lowest prepared shell by the identity. Put $h = m_\flat$, and let $\square$ be one of its test cubes. Its full reading region $\square^{\sim 4}$ lies in $Z''_{h+1} \cap \Omega_h$. All level-h bonds of this region are therefore determining rows of the prepared set. The artificial datum keeps the original value on bonds with an end in I_2 and sets the remaining bonds to $\mathbf{1}$. Each replaced bond belongs to $\mathbb{B}_0$ and has level h.

Under the small-paying-energy assumption, each original top plaquette of the reading region has defect at most $C\varsigma_*$. Indeed, its full order-h carrier lies in the region of the compatible evaluation and avoids the floor in Ω_h^c, since the reading region and the prepared regions are unions of order-h

blocks. The preceding test χ' has passed. In the retained frame, $V_h'' = e^{ig_m B} V_0$ on every replaced bond, so its distance from $\mathbf{1}$ is at most $\delta'_m + CL^{h-m}\varepsilon_m$ by the basic-reference bound. Replacing the factors of any plaquette one at a time gives the uniform bound

$$C\varsigma_* + 4\delta'_m + CL^{h-m}\varepsilon_m$$

on the plaquettes of the artificial datum. The two ratios δ'_m/ε_h and $L^{h-m}\varepsilon_m/\varepsilon_h$ tend to zero with the coupling under the threshold and waiting choices. Linear regularity of the tower on $\square^{\sim 4}$ then bounds the bare curvature in the top inset $\square^{\sim}$ by less than $\frac{1}{2}\varepsilon_h L^{-2h}$. Thus the last-shell test also passes under small paying energy. This argument uses both the original averages and the bond bound in the retained frame at the artificial cut.

The cutoff of the reference law is distinct from the test on B. After the central integration the term is constant in the free top argument on the box. In each frame the tree constraint and the two shell tests are imposed on the retained variables before a reference field is drawn. The cutoff in the subsequent draw restricts $V'_m = V_m V_\Lambda^{-1}$ to its reference ball. Its complement carries zero mass under that law. There is no failure event for that cutoff on the free Haar argument.

On the support reaching the draw, the exterior plaquette bounds and extendibility give a regular minimizer V_Λ. The reference ball is in the regularity domain of $U_{m,X}(V'_m V_\Lambda)$ for small coupling. In fact the plaquette bound at V_Λ is $C\varepsilon_m$, and the four factors of a plaquette increase this bound by at most $4M_0\varepsilon_m$ on the ball. The centre $V'_m = \mathbf{1}$ belongs to the reference tree slice. The numerator is positive on a relative neighbourhood of that centre in the slice, which has positive product Haar measure on the free bonds. It is bounded by 1 there and on the rest of its support after the tree delta functions have been evaluated, since the real Wilson action with its nonnegative cutoff is nonnegative. Thus $0 < \mathsf{D}_X \le 1$ in the same frame as the numerator. The provision for an invalid denominator defines the move off this support and needs no mark payment on it.

At fixed frame use the same product Haar on the reference tree slice for every exterior. The numerator is jointly Borel in the exterior and the free slice variables. Its integral, and the integral with any bounded Borel insertion, are Borel in the exterior. For the denominator, the continuation of V_Λ in the admitted exterior chart and the regular background continuation give pointwise continuity of the Wilson weight at fixed V'_m. The reference cutoff in these coordinates is fixed and the weight is bounded by one. Dominated convergence gives relative continuity of D_X on this chart. Dividing by its positive value defines the normalized Borel draw.

The later plaquette split does read the restored field. Its failing branch is an island. The restored V_m is the top datum of the healed determining set there. In a containing mass its failed plaquette test is evaluated on these top averages of the compatible field. The test cube lies inside the eroded island, with its reading region inside the island. By the linear regularity estimate, failure implies a top plaquette defect at least $c\varepsilon_m$ in that reading region. The energy of the averages transfers this defect to the bare carrier in the containing Wilson action. With its local weight bounded below by $c\theta_m$, the resulting exponent is at least $c\theta_m\varepsilon_m^2$. This is the island event in the outer genealogy. The island's own operation mass is formed before the later plaquette split and does not count that event.

The cost. Carrying Z_n through step n incurs three costs. The first is a factor $e^{C\log x_{n-1}}$ for each site of $\mathbb{T}^{(n)}$ lying in $T_\ell \setminus \Omega_n$. The logarithm in question is $-\frac{3}{2}\log x_{n-1}$ times the number of free bonds less the number of gauge-fixed sites. It is produced where the fluctuation field is introduced and rescaled, $\mathcal{A}_{n-1} = g_{n-1}\mathcal{A}^{\mathrm{s}}_{n-1}$, which takes place on the whole of Ω_n, whereas the field is integrated only on the smaller set $\Lambda_n \subset \Omega_n$; it is also produced where the gauge is fixed, namely on the region in which the step's plaquette tests were passed, and this region contains Ω_n. The normalisation removes it everywhere. The second is a factor e^C for each site of $\mathbb{T}^{(n)}$ lying in the rest of Z_n enlarged by a layer. It comes from $\mathbf{E}_n, \mathbf{R}_n, \mathbf{B}_n$ and from the stored Gaussians, which are written in the scaled variable. The third is the entropy of the subregions. Altogether, for each component Z of Z_n, the cost is $\exp[CM^4\check{R}_n^5(d'_n(Z)+1)]$, where d'_n is the tree length measured in

cells. Of the five powers of $\check{R}_n$, four account for volume and one for $\log x_{n-1} \le C\check{R}_n$. In the count below, the number $|Z_n|_n$ of level-n cells of the region takes the place of Bałaban's linear size d'_n, because a region that consists of a single cell has $d'_n = 0$ and still incurs a cost.

Proposition 4.63 (the count, the ledger, the credit)**.** Let a history and one of its components be given. Then the count and the ledger displayed below are valid. If moreover the component is neither healed nor marked, the credit inequality displayed below is valid for it as well. In all of these the constants depend neither on the history nor on the number of steps. The ledger and the credit are statements of Bałaban (Comm. Math. Phys. 122 (1989) 355, (1.79)–(1.81), (1.89)), here with volumes counted in cells. ∎

The proof does not follow his induction. It rests instead on counting once, globally, along the whole genealogy of a component.

Shrinking and waiting. We denote by $S(Z)$ the free evolution of §4.17.1.1, that is, the hull of Z in the next partition together with $O(1)$ further layers, boxed. Every step that is not a drop of the cube size $\check{R}$ divides linear sizes, counted in cells, by the factor L. When a step is a drop, the partitions before and after it coincide, so that nothing shrinks; and of two consecutive steps, at most one is a drop. Consequently

$$d'_n(S^{n-j}Z) \le CL^{-\nu} d'_j(Z) + C,$$

$$\nu \ge \lfloor (n-j)/2 \rfloor \quad \text{the number of the steps } j+1, \dots, n \text{ that are not drops}$$

(this display replaces the scaling of the tree length in Bałaban, Comm. Math. Phys. 122 (1989) 355, pp. 384–385, which in the present notation, with $Z^{(n-j)}$ denoting the hull of Z in level-n cells, reads: $d'_n(Z^{(n-j)}) \le L^{-\frac{1}{2}(n-j)} d'_j(Z) \le 2^{-(n-j)} d'_j(Z)$ over $n-j>1$ steps, and $d'_n(S^{n-j}Z) \le C\, d'_n(Z^{(n-j)})$, or $\le C$ when the right-hand side vanishes). The added layers do not pile up, because every change of scale contracts what the earlier levels added. It follows that within $\mathsf{k} \le \mathsf{N}_j + C\log(d'_j(Z)+2)$ steps a component Z of Z_j does one of three things, provided the history continues up to level $j+\mathsf{k}$: it meets a creation, it joins another component, or it enters the class of $\mathbf{R}$.

Why a quiet component is bound to enter the class. Shrinking makes the component small, but smallness alone does not place it in the class. Consider a quiet line, that is, the sequence of components v_i, of the levels i, into which a single component is carried as long as nothing is created in it and nothing joins it. Such a line develops deterministically, $v_i = \Phi_i(v_{i-1})$, where Φ_i is the rule of the step for a lone component, and its side in cells obeys $\alpha_{i+1} \le \alpha_i + C$, $\alpha_{i+2} \le \alpha_i/L + 2C$. This is an affine contraction over two levels; its fixed point is less than half of the threshold of smallness, so that room is left for a drop. Apart from the depth $k_\flat \ge 1$, which is a matter of the arithmetic of the cube sizes, a line of this kind acquires on its own precisely the conditions of the class §4.17.1.3. Moreover, a condition that fails on account of an event in the window also fails at every intermediate level, because $n \mapsto n - \mathsf{N}_n$ is strictly increasing. Hence the carrier of the event cannot have been healed in between. The waiting bound is founded on this property of the class (in Bałaban, a single sentence, p. 385).

The count. An unhealed component of level $n-1$ is a predecessor of the component (n, C) of Z_n that contains its hull. For a component u_*, the genealogy $\mathrm{Gen}(u_*)$ is the tree formed by all $u = (n(u), C(u))$ that equal u_* or are iterated predecessors of it. It is the same object as the two of §4.17.1.1. The cluster of a root is its genealogy together with everything that the history records within it. The lineage of a live component is made up of the members of its genealogy, regarded as regions Z_j, together with the creations in them. None of these three contains a component that was healed earlier and whose place a later region covers again; such a component is the root of a cluster of its own. Write $\mathsf{n}_t^{\mathrm{cr}}(u_*)$ for the number of created cells of level t in $\mathrm{Gen}(u_*)$. Write $\mathsf{n}_t^{\mathrm{mk}}(u_*)$ for the number of its marked components of level t other than u_* itself. These are the drop-outs

and islands, that is, the creations by an operation of §4.17.1.1, and they are counted separately here because, for each of them, the count uses only the factor e^{-p_0}, which is all that a drop-out contributes. Set $\mathsf{T}_t := C\check{R}_t$; this number bounds the length of a wait and does not increase with t. Then for non-increasing costs $\hat{\mathsf{r}}_1 \geq \hat{\mathsf{r}}_2 \geq \cdots \geq 0$,

$$\sum_{u \in \mathrm{Gen}(u_*)} \hat{\mathsf{r}}_{n(u)}\, |C(u)|_{n(u)} \;\leq\; C \sum_t \mathsf{n}_t^{\mathrm{cr}}(u_*)\, \mathsf{T}_t \hat{\mathsf{r}}_t + C \sum_t \mathsf{n}_t^{\mathrm{mk}}(u_*)\, \mathsf{T}_t \hat{\mathsf{r}}_t.$$

In particular, for each history and without any bound on the number of steps,

$$\sum_{n \leq k} \#\{\text{cells of } Z_n\} \leq C \sum_{\text{creations of both kinds, at steps } t} (\mathsf{N}_t + 1).$$

The proof consists of three moves, and nothing is carried through an induction over the levels. (1) Contraction. The cells are counted by way of the occupied cells of a component, which are the hulls of the created cells beneath it. These form a skeleton that commutes with taking hulls, and the component never lies more than $O(1)$ cells away from it. Over a fixed number s_0 of levels, at least half of the occupied cells of a component that has many of them disappear, whereas a light component (one with at most C of them) retains at most C. Let o_n be the number of occupied cells of level n in $\mathrm{Gen}(u_*)$, and let l_n be the number of its light components of level n. Then

$$\mathsf{o}_n \leq \tfrac{1}{2}\mathsf{o}_{n-s_0} + C\, l_{n-s_0} + \sum_{n-s_0 < t \leq n} \mathsf{n}_t^{\mathrm{cr}}$$

(quantities of levels ≤ 0 are 0),

whence

$$\sum_n \hat{\mathsf{r}}_n \mathsf{o}_n \leq C \sum_n \hat{\mathsf{r}}_n l_n + C \sum_t \hat{\mathsf{r}}_t \mathsf{n}_t^{\mathrm{cr}},$$

where the second inequality is obtained from the first by multiplying by $\hat{\mathsf{r}}_n$ and summing, since the costs are non-increasing. (2) Stretches. A member of $\mathrm{Gen}(u_*)$ is called an event if it contains a created cell of its own level, or comes after a marked component, or has two or more predecessors (in which case it is a joining). The genealogy is a disjoint union of stretches. Each stretch starts at an event and continues through components that have a single predecessor and contain nothing new. A stretch that starts at level t has at most T_t light members. Indeed, after $O(1)$ levels a light component is contained in a cube of $O(1)$ cells, and once a further N_t quiet levels have passed it has entered the class, in which it is healed or else marked. (3) For each of the three kinds, the events are paid for through an injective assignment, and no created cell is charged more than twice. An event that contains a created cell is paid by that cell, the successor of a mark is paid by that mark, and a joining is paid by a created cell at a leaf of the tree. For joinings, select at each member that has predecessors one of them as its first predecessor. To a joining v, assign the leaf reached by starting from a predecessor of v other than the first and always moving to the first predecessor. No two joinings receive the same leaf, since on the way up from that leaf the first member entered otherwise than from its first predecessor is v (the leaves of a tree outnumber its branchings). Moreover, the leaf lies at a lower level, at which $\mathsf{T}_t\hat{\mathsf{r}}_t$ is no smaller (because $\mathsf{T}_t = C\check{R}_t$ is non-increasing in t), and each leaf contains a created cell. Thus a joining requires no payment of its own.

The ledger. In the numerical ledger assign gain $\mathsf{g}_t = c\, p_0(g_t)^2$ to each created cell and gain $\mathsf{p}_t = p_0(g_t)$ to each mark. To apply the ledger on a history we must verify the witnesses of Lem. 4.60 on their paying carriers. Against these stands, for every cell and every level, the cost $\mathsf{r}_n^{\mathrm{c}} = C \log x_n\, (M\check{R}_n)^4$ found above, which is bounded by the non-increasing sequence $\hat{\mathsf{r}}_n = C\mathsf{r}_n = CM^4\check{R}_n^5$; here r_n is the weight of a cell, §4.17.1.1. With these choices,

$$\mathsf{F}(u_*) := \sum_t \mathsf{g}_t \mathsf{n}_t^{\mathrm{cr}}(u_*) + \sum_t \mathsf{p}_t \mathsf{n}_t^{\mathrm{mk}}(u_*) - \sum_{u \in \mathrm{Gen}(u_*)} \mathsf{r}^{\mathrm{c}}_{n(u)} |C(u)|_{n(u)}$$
$$\geq\ 2 \sum_t \mathsf{p}_t \mathsf{n}_t^{\mathrm{cr}}(u_*)\ \geq\ (2-c)\, p_0(g_{n(u_*)}),$$

provided that $\mathsf{g}_n \geq 2\mathsf{p}_n + C\mathsf{T}_n \hat{\mathsf{r}}_n$ and $\mathsf{p}_n \geq C\mathsf{T}_n \hat{\mathsf{r}}_n$. An event costs $\mathsf{T}_n \hat{\mathsf{r}}_n \leq CM^4 \check{R}_n^6 \approx (\log x_n)^{6r}$. This cost is made up of $\log x_n \leq C\check{R}_n$ for each site, $(M\check{R}_n)^4$ sites in a cell and a wait of length $\check{R}_n$. Since $\mathfrak{p}_0 \geq 6r+1$, the quantity $p_0(g_n) = A_0(\log x_n)^{\mathfrak{p}_0}$ exceeds this cost, and the extra power of the logarithm absorbs the constants. The final inequality holds for the following reason. The genealogy has a leaf, and so it has a created cell at some level $t \leq n(u_*)$. Moreover $p_0(g_t) \geq (1-c)p_0(g_{n(u_*)})$, because, up to a bounded error, the flow is monotone: $x_t \geq x_{n(u_*)} - C$. When volumes are counted in cells, $e^{-\mathsf{F}(u_*)}$ coincides, up to two modifications, with the quantity whose supremum is taken on the right-hand side of (1.79). First, the $2p_0(g_j)$ that Bałaban reserves for each created region is taken from $c\,p_0(g_j)^2$ (the first of the two conditions). Second, Bałaban's cost of a cell, which in the notation of this text reads $CM^4\check{R}_j^5$, is replaced by the finer form $C\log x_j\,(M\check{R}_j)^4$. Components that consist of a single cell are included: such a component costs $\mathsf{r}^{\mathrm{c}}_n$ at every level, and this cost is paid through the light members.

The credit, as a corollary. Let $z = (j, Z)$ be a component that is neither healed nor marked. We write its factor as $e^{-\mathsf{F}(z)} = e^{-\kappa_j(Z) - 2p_0(g_{j(Z)})}$, where $j(Z)$ is the level of the first creation occurring in its genealogy. We extend the history of z by the fictitious continuation $S(Z), \dots, S^{\mathsf{k}}(Z)$. Nothing is created in this continuation, and it runs at the levels $n \leq K$, where the flow bounds are available; beyond K it is cut off. We mark the last member of this continuation and apply the ledger to the extended history. The extended history has the same created cells as z, and apart from that last member it has the same marked components. The ledger therefore gives

$$\mathsf{F}(z) - \sum_n \mathsf{r}^{\mathrm{c}}_n |S^{n-j}Z|_n \geq 2 \sum_t \mathsf{p}_t \mathsf{n}_t^{\mathrm{cr}}(z) \geq 2\mathsf{p}_{j(Z)},$$

which is to say

$$\kappa_j(Z)\ \geq \sum_{n=j+1}^{\min\{j+\mathsf{k},K\}} \mathsf{r}^{\mathrm{c}}_n \,|S^{n-j}Z|_n,$$

that is, (1.80), in which Bałaban has K in place of k and the summand

$$O(1)M^d R_n^{d+1} d'_n(S^{n-j}(Z)),$$

where R_n is his size, built from g_n itself. Thus the credit $\kappa_j(Z)$ pays for the entire wait. By the shrinking, the sum is bounded by $CM^4L^5\check{R}_j^6(d'_j(Z)+1)$ ((1.81)).

Who pays. At a creation, the deposit $c\,p_0(g_j)^2(d'_j+1)$ has degree $2\mathfrak{p}_0$ in $\log x_j$. It exceeds the total cost $CM^4L^5\check{R}_j^6(d'_j+1)$, whose degree is $6r$, so that per cell p_0^2 covers $\check{R}_j^6$. Now suppose a test fails inside $\mathbf{R}$. All that is known of the old credit is $\kappa \geq 0$, so the renewed wait of a small region, $CM^4\check{R}_j^6$, must be paid by the new factor $e^{-p_0(g_j)}$ on its own. For this reason that factor has to be at least as good as e^{-p_0}. A joining neither pays anything nor releases anything.

Joining: Bałaban's induction and the count. Bałaban proves (1.80) by induction on j and, within a step, by induction on the number of regions that join (pp. 384–387). When X and Y join to form Z, he sets free the reserve $2p_0(g_{j(X)}) + 2p_0(g_{j(Y)}) - 2p_0(g_{j(Z)}) \geq c\,p_0(g_j)$ to pay for the renewed wait. This step relies on the claim of p. 387 that, once S has been applied n_1 further times, the domain built from Y includes the domain built from X; there n_1 is called a rather small

number, with $n_1 < 10$ given as an instance. The count uses no containment of this kind. For the hull operation of this part, whether such a containment holds depends on where the two regions lie relative to the grids. In a single coordinate the hull map is $\mathsf{h}(y) = \lfloor (y + \frac{1}{2}(L-1))/L \rfloor$, and S, taken with ten layers, maps an upper end y to $\mathsf{h}(y)+10$. Set $y_{m_*} = 10$ and $y_m = L(y_{m+1} - 10) + \frac{1}{2}(L-1)$. Then

$$\mathsf{h}(y_m) = y_{m+1} - 10,$$
$$\mathsf{h}(y_m + l) = y_{m+1} - 9$$
$$(0 \le m < m_*,\ 1 \le l \le L).$$

Suppose that Y ends at y_0 and that X, a block of side 5, begins at $y_0 + 1$. The two regions touch. The upper end of $S^m(Y)$ is y_m and the upper end of $S^m(X)$ is $y_m + 1$ (for $m = 0$ it is $y_0 + 5$), so $S^m(X) \not\subset S^m(Y)$ for every $m \le m_*$, where m_* is arbitrary. At each of these steps the two partitions have ratio L, so that none of the steps is a drop. The count never compares $S^m(X \cup Y)$ with $S^m(Y)$.

Proposition 4.64 (the mass bound; where the small factor stands)**.** Consider a component X that has passed every test of the operation $\mathbf{R}$ of some level $i \le k$ before the last decomposition $1 = \chi_i + \chi_i^c$ (a healed component or an island). The operation of §4.17.1.3 on it is written

$$\mathbf{T}_i'(X) F\,(\mathbf{p}) = \frac{1}{|W_4|} \sum_{\omega} \int e^{\Phi_\omega(\xi;\mathbf{p})} F\, \mu_\omega(d\xi),$$
$$\mathbf{p} = (\mathbf{U}, \mathbf{J}) \text{ a pair on } X^{\sim},$$

where ω ranges over the local histories of X, that is, the results of every decomposition of unity inside X together with a frame in W_4 of the gauge tree, ξ ranges over the stored variables, and e^{Φ_ω} contains the core Wilson factor $\exp[-A(x_i'' \phi_{\mathrm{c}}, U''(\xi))]$. (a) For a healed component or an island, in which case $\mathsf{k} = 0$,

$$\mathsf{M}(i, X) = \frac{1}{|W_4|} \sum_{\omega} e^{c\,\mathsf{v}(\omega)} \int \sup_{\mathbf{p} \in U_i^c(X^{\sim}, \alpha_{0,i}, \alpha_{1,i})} \left| e^{\Phi_\omega(\xi;\mathbf{p})} \right| \mu_\omega(d\xi) \le e^{-(2-c')p_0(g_i)},$$
$$\mathsf{v}(\omega) = \sum_{u \text{ listed by } \omega} \log x_{n(u)}\, \#_{n(u)}(C(u)) :$$

here the coupling is taken at the level of the action, and the current coupling then follows from $p_0(g_i) \ge (1-c')p_0(g_k)$; the supremum stands inside the integral; and a weight growing exponentially with the space-time volume of the patch is paid for in advance. It is this bound that the induction carries forward. Bałaban has (1.89) instead, at each fixed pair ((1.73)). (b) Take a single history and a single component Z of Z_k on which no $\mathbf{R}$ has acted. For every value of the exterior variables (in total variation),

$$\left\| \mathbf{T}_k(Z) \big[\chi_{k,\mathcal{S}}\, e^{-A(x_k(\cdot), U_k)} \big] \right\| \le \prod_{\text{created cells } (t,\mathfrak{c}) \subset Z} e^{-c\, p_0(g_t)^2} \cdot \exp\Big[C \sum_{t \le k} \#_t(Z_t \cap Z) \Big],$$

with each factor taken at the coupling of its own step. Bounds of this kind do not multiply over the components, since the background couples the components. The pointwise majorant given above does multiply (Tonelli). Consequently, after integration and for an entire label, there exists a history h carrying the label $\mathcal{S}$ for which the bound below holds, where $(t, \mathfrak{c})$ ranges over the created cells of h lying outside the marked X. (The created cells are not determined by the label: a row of three failing cells and that row with its middle cell removed yield the same regions.)

$$\int \mathbf{T}'_k(\mathcal{S})\,[\chi_{k,\mathcal{S}}\, e^{-A(x_k(\cdot),U_k)}]\,dV_k \le e^{C\sum_j \#_j(Z_j)} \prod_{(t,\mathfrak{c})\text{ outside the marked }X} e^{-c\,p_0(g_t)^2} \prod_{(i,X)\text{ marked, outermost}} \mathsf{M}(i,X).$$

(The bound holds a fortiori when each site carries $C(1+\log x_j)$ and each created cell carries $e^{-c\,p_0(g_t)}$. This logarithmically weighted form is required by the rarity hypothesis and by the source construction.) (c) Consider the sum over the labels, with the costs paid by Prop. 4.63 and the nested sequences inside each component summed. In this sum every component C of Z_k keeps the factor $\exp[-c\,p_0(g_k) - \kappa_1 \#_k(C)]$, in which the volume is counted in sites (and so, a fortiori, the factor with $\kappa_1|C|_k$, in which it is counted in cells; this is the form in the introduction to this step). Since $d_k(C) \le \#_k(C)$, this per-site factor includes the term $-\kappa_1 d_k(C)$, which is what p. 387 asserts for an arbitrary region. The decay is one further cost $O(1)$ per site; like the other costs, it is paid for by the events (Prop. 4.63). If failed plaquette tests have produced a component, then $\mathbf{T}_k(Z)1 \le \exp[C\sum_{t\le k} \#_t(Z_t \cap Z)]$ (119, (2.21), and p. 264, where it is said of the Wilson term that it "yields the small factors for large field characteristic functions"). ■

The bound has to reproduce itself. (i) *Supremum under the integral.* In a term of level $k \ge i$, the factor remaining on X is evaluated at $(U_k, J(U_k))|_{X^\sim}$, and U_k depends on the integration variables of every component. Such an integral is not controlled by a bound at each fixed pair, and bounds that are merely uniform in the other variables do not multiply. For example, take $\mathbf{1}\{|\xi_1 - \xi_2| < \epsilon\}$ on $[0,T]^2$: each integral in one variable is $\le 2\epsilon$, whereas the double integral is about $2\epsilon T$. What does multiply is a majorant given by a Borel function that depends only on the variables of X. The integral of the supremum itself is understood as an upper integral. Such a majorant can be obtained because only two factors depend on the pair: $\Phi_\omega = \Phi^\circ_\omega(\xi) + [-\frac{1}{2}q_X + V(X^\sim)](\xi;\mathbf{p})$, where $q_X = \|\phi^{1/2} D\mathsf{H}B\|^2 \ge 0$ is formed at a real background, and $|V(X^\sim)| \le C\,\#\{\text{stored sites}\}$, with every site counted at its own level. The real background here is the critical configuration of the prepared sequence, taken with $B = 0$ and at the datum of the main step, and it is built with the G-valued factor of the triple. Through that factor, q_X depends on the splitting, whereas the exponent Φ_ω, taken in its entirety, is determined by the pair (see clause (vi) of the class of §4.17.1.45). (ii) *A fixed set.* If the supremum is taken over the arguments that occur at level k, the bound is not stable, since the next step replaces U_k by U_{k+1}. The supremum is therefore taken over a larger fixed set, built only from the data of the levels $\le i$. This set contains every later argument, since on the supports the following bounds hold, with nothing lost in the age $k-j$ of the layer $\Omega_j \setminus \Omega_{j+1}$,

$$|\partial U_k - \mathbf{1}| < C\check{R}_j^2 \varepsilon_j \eta_j^2,$$

$$|J(U_k)| < C\check{R}_j^2 \varepsilon_j$$

$$\text{on } \Omega_j \setminus \Omega_{j+1} \text{ (the current in level-}j\text{ units)},$$

$$C\check{R}_j^2 \varepsilon_j < \alpha_{0,j} \text{ for all } j \ (q \text{ is chosen after } \mathfrak{p}_0 \text{ and } r, \text{ the ceiling on the couplings after } L)$$

(the last inequality holds since the quotient is a negative power of $\log x_j$, since $q > \mathfrak{p}_0 + 2r$, and since the couplings stay below a ceiling; moreover, a layer at index distance a has an influence that decays like $e^{-(a-1)_+}$, while its threshold grows like $(1+a)^{1/2}$). Hence the mass seen at level k does not exceed the mass of level i, and a single step **RT** gives back the bound with unchanged constants. (iii) *The weight* $e^{c\,\mathsf{v}(\omega)}$ has as its only cost a larger constant in the ledger. Since it carries $\log x_j$ per site, it absorbs every perturbation of size $O(1)$ per site of the patch, such as the factor e^{Ψ} of the sources, §5.20.1.2. In the weighted rarity hypothesis, the weight covers whatever the label still exhibits inside a drop-out, since the small factors produced there have already been consumed by the mass; this is why the masses are required with the weight raised. The argument requires a

volume that counts each pair (level, cell) only a bounded number of times. A volume that counts the past again at every drop-out may exceed the total of all the gains; an example is a row of cells all created at the first step, with a drop-out at each completed wait. (iv) *Drop-outs.* The factors kept by a drop-out contain no Wilson action, and no inner background has been formed; the kept factors are evaluated at the background of whichever later term contains X. On the other hand, the configuration enters the Wilson term of the carrying term, and the failed plaquette tests listed by ω, which are the tests of the creations in X, bound plaquettes formed from averages of this configuration. That weight, over the bare plaquettes all of whose corners lie in X, is therefore counted with the operation. The pair is replaced by an *evaluation* at ξ. By this we mean a real U on X with four properties. First, it is compatible with ξ, that is, $\mathcal{M}^j U = V_j(\xi)$ on the bonds of Γ_j in X. Second, it is regular layer by layer, in the same sense as on the supports: on the layer j one has $|\partial U - \mathbf{1}| < C\check{R}_j^2 \varepsilon_j \eta_j^2$, while the plaquette variables of the stored fields differ from $\mathbf{1}$ by less than $C\check{R}_j^2\varepsilon_j$. Third, at this configuration each test listed by ω takes its recorded value, with the exception of the test whose failure made X a drop-out; here the fields not formed by ξ, including V_i on X, are read as averages of U. Fourth, $(U, J(U))|_{Y^\sim} \in U_m^c(Y^\sim, \alpha_{0,m}, \alpha_{1,m})$ for each island (m, Y) in X. Together with this configuration, the supremum also runs over further free parameters subject to one-sided bounds. These are the weight υ of the Wilson term, with $\upsilon \geq c\, x_t$ on Z_t, and the kept forms and Jacobians, which are evaluated at a background §4.17.1.3, with form $\geq c$ and Jacobian $\leq C$:

$$\frac{1}{|W_4|} \sum_{\omega} e^{c\,\mathsf{v}(\omega)} \int^{*} \sup_{\text{evaluations at } \xi} e^{-A(\upsilon \mathbf{1}_X, U)}\, (\text{kept factors})\, \mu_\omega(d\xi) \leq e^{-(2-c')p_0(g_i)}$$
$$(\upsilon \geq c\, x_t \text{ on } Z_t).$$

(Over the empty set the supremum is 0.) Take a term of some level $k \geq i$ in which X occurs, and a point of its support. Put $\upsilon = x_k(\cdot)$ and take the forms and Jacobians at the background of that term. To apply the mass bound we must verify membership of this later read in the compatible fibre, using its original rows, carried tests, and form and density bounds. On prepared rows the read uses the retained datum, with the restored free outgoing field in its separate slot. For a drop-out, the left-hand side is its mass $\mathsf{M}(i, X)$. Where X has no sum over frames, nothing depends on the frame listed by ω, by the identity $1 = |W_4|^{-1} \sum_r 1$. This bound does not use the test whose failure made X a drop-out. The gain $p_0(g_i)$ of that test is reserved for the renewed wait, and it is drawn on once X occurs as a mark within a subsequent component (Prop. 4.63). The supremum is taken over a set fibred over ξ. Over a product set it selects a flat U, at which $e^{-A} = 1$, and the factor is lost. In a toy case, take $\Phi = -T(1 - \cos p)$ together with the test $|\xi| \geq \epsilon$: its mass is $e^{-cT\epsilon^2}$ on the graph $p = \xi$, but approximately 1 over the product set. For this reason each inequality of Lem. 4.60 is required to hold at every configuration of this set, and not merely at backgrounds. These inequalities do hold for all real configurations having the prescribed averages. Nothing is assumed inductively at a drop-out; the inductive bound is the one for the islands. (v) *Islands inside X.* The count and the ledger are carried out on the outer genealogy of X, that is, on the genealogy cut off at the islands (m, Y) in X. Each such island is a minimal node, and all of its cells, of which there are $O(1)$, are counted as created cells of level m. These cells are paid for in the same way as created cells. The factor χ_m^c of the new field on Y less a margin is present in the term. Consequently there is a test cube of level m in which the test fails at $V_m(\xi)$; this is the test χ_m of a step, and not one of the sharper tests of the stages. Lem. 4.60 (i) then extracts the gain $c\, p_0(g_m)^2$ from the core Wilson factor of X, on plaquettes that are used by no other gain; when X is a drop-out, the gain is extracted instead from the Wilson weight that (iv) counts together with its operation, and this holds at every evaluation. This test does not enter the mass of Y, since that mass is formed before the last decomposition. One evaluates the factor of Y at a real pair

of $U^{c}_{m}(Y^{\sim},\alpha_{0,m},\alpha_{1,m})$, where it is bounded by its majorant. Since v is additive, the sum over the local histories of Y separates and is at most $\mathsf{M}(m,Y)\le 1$. Every leaf of the cut genealogy contains a created cell, and the ledger leaves $2\sum_t \mathsf{p}_t\mathsf{n}^{\mathrm{cr}}_t$, just as it does on the full genealogy.

4.17.1.45. The induction closed: the order of the constants, the sum over histories, exactness. **The class.** Let a frame $\theta_0,\dots,\theta_k$ be fixed (see the frame setting of § 5.2). Each choice of level j that depends on the coupling is made with θ_j. These choices are the thresholds, the radii, the scaling $\mathcal{A}_j=\theta_j^{-1/2}\mathcal{A}^{\mathrm{s}}_j$, the gauge-fixing weight, the Gaussian forms of the stages of $\mathbf{R}$ and the reference laws. The cube size and the waiting depth $\check{R}_j=\mathsf{N}_j$ are made instead with the running minimum $\min_{i\le j}\theta_i$ (a frame can go up by as much as c_5, and taking the minimum ensures that $\check{R}_j$ does not increase). Consequently the tests, the regions, the histories, the domains of analyticity and the measures of the integral operations depend on θ only, and on no entry of the density. In the bounds of this part we put $g_j:=\theta_j^{-1/2}$, so that $g_j\le\gamma$ is the floor $\theta_j\ge\gamma^{-2}$ of a frame (at $\theta=x$ this is the $g_j=x_j^{-1/2}$ of Prop. 4.56). In this way the circle "regions depend on couplings, couplings on activities, activities on regions" is broken. The elements of $\mathfrak{C}_k(\theta)$ are presentations rather than densities: the families are not determined by the density, and locality in the history is a property of how the terms are placed. Each element is an array, specified simultaneously on every admissible torus and cutoff,

$$\mathfrak{P}=\Big((x_j);\,(E^{(j)},\widehat{E}^{(j)},b_j);\,(R^{(j)},\widehat{R}^{(j)});\,(B^{(j)}_{\mathcal{S}}(X));\,(\Phi_\omega)\Big)_{j\le k},$$

$$b_j=x_{j-1}-x_j=b[\widehat{E}^{(j)}]$$

$$(1\le j\le k;\ \text{at } j=0 \text{ the one entry } x_0),$$

whose density $\rho[\mathfrak{P}]$ has the form given in Prop. 4.56. In it, $\widehat{E}^{(j)},\widehat{R}^{(j)}$ denote single families on $\mathbb{Z}^4$ that coincide with the families on the torus on lifts of non-wrapping domains; $b[\cdot]$ denotes the coefficient of § 4.2; and $\Phi_\omega=\Phi^\circ_\omega(\xi)+\sum_f\Phi_{\omega,f}(\xi;\mathbf{p}|_{R_f})$ are the exponents of the integral operations attached to the islands. Membership in the class requires the following. (i) *the tube*: $|\mathsf{z}_j|\le\mathsf{t}_j\approx c\,\theta_j(\log\theta_j)^{-C}$, where $\mathsf{z}_j=\theta_j-x_j$. This relates the frame, which is given, to the weights of the array, and the choice of the frame ensures it. The tube is wide in absolute terms, but narrow enough that the discrepancy between the weight and the choices, regarded as a potential, is small: $|\mathsf{z}_j|\alpha_{0,j}\delta_j\le c(\log\theta_j)^{-c}$. (ii) The bounds of Prop. 4.56 on $E^{(j)},R^{(j)},B^{(j)}$ hold, together with analyticity, reality, and invariance under a single fixed gauge action on the stored data. A boundary term is analytic as well in the switches μ_b that belong to those of its stored bonds lying close to a test, and in those of its stored fields that lie far from every test. Any two splittings of one pair give each term the same value. The boundary terms, terms away from the small-field region and collar corrections are supplied on the graded spaces assigned to their slots, including the formation addresses used for their reads. A carried entry retains its formation space, carrier and stored arguments. The standing-island factors use their birth cores. If the tests of a term take the value 1, then each boundary term and each exponent has in its domain the triple $(U,0,J(U))$ formed from the background U. (iii) *identification*: $E^{(j)}$ coincides with the family produced from the earlier entries, in each of its two chains (see below), by the small-field step at the pair (θ_{j-1},x_{j-1}), carried out on the whole lattice. (iv) *lattice covariance* holds in the forms stated below. Above all, the pointed totals are covariant under every isometry of $\mathbb{T}^{(j)}$, unit translations included (119, (2.29)). (v) *coherence*: whenever a chart §4.17.1.1 identifies, scale by scale, what two histories record within one cell of X, it identifies the terms at X. This single clause contains locality in the history, covariance under translations and independence of the torus. For a standing operation, the chart identifies μ_ω together with the Borel set carrying it, as well as its set of factors and Φ°_ω. It also identifies the factors one by one: $\Phi_{\iota\omega,\iota f}(\iota\xi;\iota\mathbf{p})=\Phi_{\omega,f}(\xi;\mathbf{p})$, for arbitrary components and histories,

provided that the chart ι transports both the record of the history at R_f and ξ on R_f. (vi) For an island, μ_ω is a Borel measure, positive and defined on a Borel set; Φ_ω depends in a Borel way on ξ, is analytic in $\mathbf{p}$, and takes real values whenever the pair is real. Moreover, gauge invariance holds pointwise in ξ and for each factor separately. The bounds of *mass* (Prop. 4.64, with a reserve constant $c_{\mathrm r} \ge 0$ in the weight) and of *oscillation* § 4.17 hold, the coupling in them being taken at the level at which the island was made. The class imposes no bound on the exponent itself, which is large and negative, and no clause concerns a drop-out. (vii) Each term, taken together with its stored variables, is a non-negative measure $\hat\tau_h$. The form and the bounds alone do not give a class that a step preserves. The gain $L^{-c(n-j)}$ of the regular terms does not follow from $\|E^{(j)}\|_{j,\kappa} \le E_0$, and neither do $|\mathbf{E}_k| \le C\sum_n |\Gamma_n| + C\sum_j \#_j(Z_j^+)$ (below) and the input of the next step, which depend on that gain. Clause (iv) cannot be omitted, for the following reason. Take the tents $h_z^{(j)}$ of § 4.5; then $\mathsf{Q}_z := c\,\alpha_{0,j}^{-2} A(h_z^{(j)}, \cdot)$ defines an activity whose norm does not exceed 1, and

$$\sum_z \mathsf{Q}_z = c\,\alpha_{0,j}^{-2} A(U),$$

$$\alpha_{0,j}^{-2} = c\,\theta_j (\log \theta_j)^{-2q} :$$

this is the inverse coupling θ_j itself, up to the factor $c(\log\theta_j)^{-2q}$. For a regular family, such a part is removed by the counterterm $-b_j A$ together with the covariance of the pointed totals. That covariance makes the second-order part at each site equal to the multiple b_j of the action at that site. Take the format of the complex class below, in which each site has its own member. In that format one can find arrays which obey all the bounds of clause (ii) and which, at each level, add no less than the same multiple of the action, with no part of it decaying as the age grows. Such arrays are ruled out by covariance of the pointed totals, already when it is required only for unit translations.

Proposition 4.65 (the step preserves the class)**.** Suppose the following:

(i) $\mathfrak{P} \in \mathfrak{C}_k(\theta)$;
(ii) θ_{k+1} prolongs the frame;
(iii) all $g_j \le \gamma$, and they lie below a ceiling that depends on the reserve constant $c_{\mathrm r}$ and does not increase with it;
(iv) the next weight $x_{k+1} := x_k - b[\widehat{E}^{(k+1)}]$ lies in the tube (here $\widehat{E}^{(k+1)}$ is formed first, by clause (iii), at the pair (θ_k, x_k), and its formation involves no choice of level $k+1$).

Then each move of step $k+1$ is defined. The identity $\mathbf{RT}\rho[\mathfrak{P}] = \rho[\mathfrak{P}']$ holds separately for each standing part §4.17.1.1, every part keeping its stored variables, and $\mathfrak{P}' \in \mathfrak{C}_{k+1}(\theta)$, the constants being unchanged. Moreover, $\mathfrak{P}'$ prolongs $\mathfrak{P}$. An array belongs to the class of level $k+1$ exactly when its cut at k belongs to the class of level k and, in addition, it satisfies the conditions of level $k+1$. Finally, the array whose single entry is $x_0 = \beta$, with $|\beta - \theta_0| \le \mathfrak{t}_0 \le c\,\theta_0 (\log\theta_0)^{-C}$, belongs to $\mathfrak{C}_0$. *Not returned*: the hypothesis that the next weight belongs to the tube. At every step this hypothesis is provided by how the frame is chosen. For $\theta = x$ the deviation is 0, and the requirement is that x_{k+1} prolong the frame, which is the content of the flow inequalities § 5.2.1 and of the nesting of the cube sizes, a consequence of the upper flow inequality § 5.2.2. For the reference line it is supplied by the drift bound of § 5.2.3, below. (In Bałaban, Comm. Math. Phys. 119 (1988) 243, the second remark after Theorem 1 concerns the space of "all densities satisfying the conditions of the inductive assumption", and these conditions include (2.29) and (2.32), together with (2.33), which follows from (2.32).) ∎

Why the induction closes. (a) Room: fix a fraction $\beta_{\mathrm s}$. The terms produced by **T** §4.17.1.3 are defined on the radii $(1+\beta_{\mathrm s})\alpha_{i,k}$ and decay at the rate $(1+4\beta_{\mathrm s})\kappa$. Moreover, $e^{-\kappa d_j(X)} \le e^{-c\kappa d_j(X)} e^{-(1+3\beta_{\mathrm s})\kappa d_k(\widehat X)}$ for $j<k$, where $\widehat X$ denotes the union of all level-k cubes meeting X, taken

without any added layer. The operation **R** uses up this room and nothing beyond it. (b) Drift: for $m < n$ one has $g_m \le (1+c)g_n \le C(n-m)^{1/2}g_m$. This does no harm over the N_k levels that **R** spans, because every threshold changes only by powers of $\log x_k$. (c) Order. Every constant is of one of four kinds:

- free upward: its range has no upper bound (the odd integers for L, the powers of L for M);
- free downward: its range is some $(0, c]$;
- confined to a window;
- determined by earlier constants: a function of those alone.

The text states finitely many conditions on the constants. Each condition is assigned to the last constant on which it depends, after every determined constant in it has been expressed through the earlier ones. For every admissible choice of the earlier constants, the condition is then, at that constant, of one of three kinds:

- a floor on a constant free upward, which holds from some value onward;
- a ceiling on a constant free downward, which holds on some $(0, c]$;
- an endpoint of a non-empty window.

A condition that follows from such conditions is not counted separately, with one exception: the requirement that a window be non-empty. That requirement is a floor or a ceiling on some earlier constant, and it counts at that earlier constant. Two further stipulations apply:

- No equality between thresholds is imposed, since every assertion made with a threshold remains true when the threshold is lowered.
- Some families of conditions are indexed by a quantified number, for instance the floor $c_a \ge C(b)\log L$, $C(b) \to \infty$, with an integer $b \ge 1$. No single c_a satisfies this for all b. Such a family belongs to the statement in which the number is quantified, and it is imposed only at finitely many values of that number, which are fixed before the constant.

Thus, apart from the constant it bounds, each of these conditions depends only on earlier constants, in the order

$$(r, \mathfrak{p}_0, \mathfrak{p}_1, q, \kappa_0, \beta_{\mathrm{s}}, \theta_{\mathrm{s}}, \theta_c) \prec L \prec (M_1, R_1) \prec \kappa \prec (\bar\kappa, \kappa_1) \prec M_1' \prec M_2 \prec (\Theta_1, \varpi_T) \prec M$$

$$\prec \sigma_\star \prec a_\Lambda \prec (A_1, A_0, C_0, C_1, \alpha_1, \alpha_0, E_0, M_0, \alpha', \mathsf{B}) \prec (\underline\lambda, c_5, \bar B) \prec \gamma \prec (\varrho, c_a) \prec (g, \ell, \beta, K)$$

Some of these constants require comment:

- $\underline\lambda = \frac14 c_0$ and $c_5 = 2c_2$, where c_2 is the constant in eq. 5.xviii, are fixed together with L; in the display they appear as members of the triple that defines the frames.
- $\bar\kappa$ is the exponent of the decoupling parameters of § 4.5. The factor $e^{-\bar\kappa}$ of a link of the cluster expansion comes from the decay of the covariance across an M-cube.
- $\delta_0 M \gg \bar\kappa \gg L\kappa$: rates are chosen before the cube sizes M_1', M_2, M. These are floors on $\bar\kappa$ and then on M, both chosen after L and κ.
- M_1 depends on L alone, and R_1 depends on L and M_1.
- $\Theta_1 \ge C/\theta_c$ and $\varpi_T \ge C$, and both are free upward.
- $M \ge \max\{\varpi_T, L^2 M_2\}$ and $A_0 \gg A_1$.
- The later ceilings on g may depend on c_a and on the dial $\mathsf{w} \in [0, 1)$. The dial is a fraction that depends on no constant and is fixed together with the exponents.
- The reserve constant $c_{\mathrm{r}} \ge 0$ of (vi) is free upward and comes before the ceiling that depends on it.

Induction along this order now gives two facts, because finitely many floors hold together from some value onward, finitely many ceilings hold together on some $(0, c]$, and the finitely many endpoints of a window leave it non-empty owing to the conditions that count at earlier constants. Every admissible choice made up to a given position can be extended, and no later condition places

a restriction on a constant chosen earlier. Adding one more floor or ceiling of the same kind leaves both facts true. The choice is therefore not circular, and a condition arising in the construction fits the order if, at the last of the constants on which it depends, it is of the kind named. A bound may contain a number that a statement returns, or a number given as a function of a whole group of constants. Any such number must be fixed before the constant that it bounds; the cycle cut below is a case of this. A representative condition on M or on γ asserts that e^{-cM}, $e^{-c\check{R}_k}$ or a power of $\log x_k$ dominates constants fixed earlier. *The supremum form*: a condition imposed on all couplings of all runs reduces to a single ceiling on γ, namely $\sup_{x\geq\gamma^{-2}} h(x)\leq c$ with $h\to 0$, because the scale appears in it solely by way of x_k (122 (1989) 175, p. 186: the conditions "do not depend on any scale"). *The cycle that is cut*: $\lambda_\sharp$ and $B_\sharp$ depend on γ through $\sup|\mathsf{q}|$ (here q_i is the part of the increment b_i contributed by the remainders; see below), whereas the ceiling γ depends on the flow constants. Frames are therefore defined with constants $(\underline{\lambda}, c_5, \bar{B})$ fixed before γ: $\underline{\lambda}(j-i)-c_5\leq\theta_i-\theta_j\leq\bar{B}(j-i)$ for $i\leq j$. Hence a frame with first member θ_0 has length at most $(\theta_0-\gamma^{-2}+c_5)/\underline{\lambda}$, in the same way that K is bounded in terms of β in § 5.2.1. In addition, $\underline{\lambda}\leq\lambda_\sharp$ and $B_\sharp\leq\bar{B}$. *No caps*: there is no upper bound on $L, M, \kappa, q, \mathfrak{p}_0, c_a$, on the cutoff, the volume, an age or a number of steps, and no lower bound on a coupling. *The role of each exponent*:

(i) $\mathfrak{p}_0-\mathfrak{p}_1>Cr$, for comparing the ratio δ'_j/δ_j with the square root of the waiting depth, and for the accumulation of the stages (§4.17.1.3, § 4.17);
(ii) $2\mathfrak{p}_1-Cr>\mathfrak{p}_0$, so that a failed stage test still gives e^{-p_0};
(iii) $\mathfrak{p}_0>3Cr$, so that p_0 dominates $\kappa\check{R}^4$ and the cost $\check{R}^6$ of a wait, and so that the window left for $\mathfrak{p}_1$ by the two preceding conditions is non-empty;
(iv) $q-\mathfrak{p}_0>Cr$, so that $\mathsf{N}_k\mathsf{s}_k\to 0$;
(v) $q>C\mathfrak{p}_0$, so that the product of an amplitude and an oscillation of degree $2\mathfrak{p}_0$ remains bounded;
(vi) $\kappa_0>C$, for the sum over the scales.

(d) *No circle.* New terms are built from old ones, and the old ones are bounded with the same constants that the new ones must satisfy. The circle is avoided because an old term enters again in one of three ways:

- unchanged;
- through a difference, which carries a small factor. In $\mathbf{T}$ this factor is s_k, the factor that the Cauchy estimate gives for a first difference in the fluctuation field § 4.17.
- as a whole, in the main step of $\mathbf{R}$. In that case there are two possibilities. Either the domain of the term must stretch across $c\check{R}_kL^{k-j}$ cubes of the term's own level $j<k$, in which case its decay makes the term small. Alternatively, the domain lies inside an enlarged component (a collar $X^\sim$ of § 4.17). There only a volume bound $C\sum_{j\leq k}\#_j(Z_j\cap X)$ is available, each scale counted in its own unit, and its constant is chosen later. The list is given below under *Boundary terms.*

Uniformity of the input. A term of level j is defined on the radii at which it was created, and step $n+1$ evaluates it up to the output radius of that step. Let $w_{n,j}$ be the square of the ratio of these two radii. Let $\mathsf{f}_\nu\approx\nu^CL^{-c\nu}$ be forgetting weights; in § 4.5 they are written ω_ν. Then

$$w_{n,j}\approx\frac{\theta_j}{\theta_n}\Big(\frac{\log\theta_n}{\log\theta_j}\Big)^{2q}\leq C(n+2-j),$$

$$\sum_{j\leq n}\mathsf{f}_{n+1-j}\|E^{(j)}\|_{j,\kappa}+\sum_{j\leq n}w_{n,j}\|R^{(j)}\|_{j,\kappa}\leq N_\star$$

uniformly in n and in the frame. This is everything that the small-field step requires of its input. The two factors in the approximation above are never unfavourable at the same time: the upper flow bound gives $\theta_j/\theta_n\leq 1+(n-j)$, and the lower one gives $\theta_n\leq\theta_j+c_5$. The regular terms are

of size $O(1)$ at each level and gain $L^{-c(n-j)}$ through their two counterterms. The remainders gain nothing; they are summed by means of the coupling. *Regular terms*: let $\tau_k = x_k/\theta_k$, and let E_{N} be the bound on the localised Gaussian normaliser. Then

$$\|E^{(k+1)}\|_{k+1,\kappa} \le E_{\mathsf{N}} + C\big(|1-\tau_k| + \delta_k + \mathsf{s}_k N_\star + e^{-c\,p_0(g_k)^2}\big) \le E_0,$$

so E_0 is determined by the one-loop normaliser alone, and C depends neither on E_0 nor on $N_\star$.

The new regular remainder. At output level t, separate the fluctuation clusters which contain a vertex from a remainder of origin j with $M\check{R}_j > L^{t-j}$. Charge each of these clusters to one such vertex. In the absolute cluster bound with one distinguished insertion, this vertex has size $C\mathsf{s}_{t-1} w_{t-1,j} g_j^{\kappa_0}$, using the induction bound of the input. The root sum over the other vertices has a uniform constant at the rate of the fluctuation move. The sum over j must include both the number of origins and their radius losses.

Indeed, for $r = t-j$ the flow gives $x_t - C \le x_j \le x_t + C(r+1)$. Since $\check{R}_j$ is polynomial in $\log x_j$, the inequality $L^r < M\check{R}_j$ implies

$$L^r \le C(1+\log x_t)^C (1+\log(1+r))^C.$$

The last factor on the right is bounded by $CL^{r/2}$. Hence the contributing ages are $O(1+\log\log x_t)$. On this range $g_j^{\kappa_0} \le C g_t^{\kappa_0}$ and $w_{t-1,j} \le C(r+1)$. The fluctuation contribution in the regular remainder range therefore has norm at most

$$C\mathsf{s}_{t-1}(1+\log\log x_t)^2 g_t^{\kappa_0} \le \tfrac{1}{2} g_t^{\kappa_0}.$$

The negative power of $\log x_t$ in s_{t-1} pays for the sum. Use the final rate κ on the domains one cell layer inside the output regular region, with the ordinary contribution supplied on the regular range of the appropriate donor when the filing changes. There the exponentiation of healed histories supplies the other contribution, of norm at most $e^{-p_0(g_t)}$. The domains outside this range are filed as boundary terms. Since $e^{-p_0(g_t)} \le g_t^{\kappa_0}/2$, the new regular remainder has the same bound $g_t^{\kappa_0}$ as the input remainders at their respective levels.

Boundary terms: B is the maximum of the bounds coming from their origins § 4.17, and none of these bounds depends on B. This holds because data bounded by B enter the step in four ways:

- In $\mathbf{T}$, they enter as differences in the fluctuation field, with $C\mathsf{B}\mathsf{s}_k \le 1$.
- In the stages, they enter as differences in the collar field, taken one block of bonds at a time. Each block that is switched off contributes a negative power of $\log\theta_k$, with an exponent larger than the one belonging to (number of stages)$\times$(M-cubes of level k of a component).
- In the main step, outside the enlarged components, they enter either through the difference under the substitution, or as undifferenced functions of a level $j<k$. In the second case the domain must extend over $c\check{R}_k L^{k-j}$ cubes, and $\mathsf{B}e^{-c\check{R}_k} \le 1$.
- Inside an enlarged component there is no smallness, and they enter only through the volume bound on $V(X^\sim)$. The constant of this bound is chosen after B, and the bound is paid by the ledger of §4.17.1.40.

(e) *No growth with the level.* A carried term is literally unchanged: it has the same function, the same domain of analyticity and the same tree length. The bounds of a standing island refer to the level at which it was made and do not involve k. Indeed, the supremum in the mass bound is taken over a fixed set, built from the data of the levels up to that level, and this set contains the arguments of all later levels. Hence the mass at level k does not exceed the mass at the level at which the island was made (§4.17.1.40, "The bound has to reproduce itself", (ii)). The sizes that are returned are maxima rather than sums.

4.18. **Uniform weighted masses of histories.** A large-field factor is an integral operation with a memory. Its arguments include the fields that a later operation is allowed to read; its integration variables include the fields that an earlier operation has retained. These two lists need not describe the same region. We give the lists separate types, specify the mass of the operation, and prove the counting and domination implications needed to propagate that mass. In particular, a supremum over complex arguments is placed inside the integral. An estimate of a partition function at each fixed argument does not establish this stronger assertion.

We prove the geometric counts, scalar reserve estimates and their consequences. Their application to the interacting construction requires the background domains, kept quadratic forms, changes of variables and localized energy bounds stated below. A flat quadratic comparison supplies a special case of the matrix estimates; it does not establish their current-dependent, layered versions.

4.18.1. *The records carried by an operation.* Fix a finite four-dimensional periodic lattice. Work in bare coordinates: the bonds of level j have length $a_0 L^j$, where L is an odd integer. The torus and all partitions are chosen compatibly. A region is a union of partition cells, with a fixed half-open convention when a unique cell address is required. Closed cells are used for collars. Passing from one convention to the other changes only a fixed number of neighboring cells in each estimate below.

Let $\theta_j > 1$ be the reference inverse couplings, and write

$$\ell_j = \log \theta_j, \qquad g_j = \theta_j^{-1/2}, \qquad R_j = \check{R}_j, \qquad b_j^{\mathrm{cell}} = a_0 L^j M R_j. \tag{4.cdlxi}$$

Here M and every auxiliary partition size are fixed powers of L. The symbol g_j in this section uses the reference weight; the physical coupling is $x_j^{-1/2}$ when $x_j \neq \theta_j$. The partitions have cell side b_j^{cell}. The size sequence has $R_{j+1}/R_j \in \{1, L^{-1}\}$, and two size drops are not consecutive. Thus a passage between levels either coarsens these cells by L, or leaves their physical partition unchanged. Bounds are required uniformly in the height and volume, with the fixed geometric parameters held fixed.

A label of height s contains regions

$$\mathcal{S} = (\Omega_j, \Lambda_j)_{1 \le j \le s}, \qquad \Lambda_j \subset \Omega_j, \quad \Omega_{j+1} \subset \Lambda_j, \quad Z_j = \Lambda_j^c. \tag{4.cdlxii}$$

There is an initial collar $\Omega_0 = \Omega_1^{\sim}$; there is no independently generated large-field region of level zero. The state after a step and the state after its large-field operation are different labels. A history records their ordered succession, rather than a single final sequence with an inferred past. This distinction is necessary when an operation heals a region and a later creation covers the same physical location.

The operation also records a class of components and, in each component, the stages that have actually been completed. A component in the dynamic class has small size, the required depth, a quiet preparation window, quarantine from earlier marks in that window including its lower endpoint, and the single-box traces required by the local background construction. The dynamic class contains every eligible component. A static representation may deliberately use a smaller class. Waiting estimates below concern the dynamic rule; they would be false for an arbitrarily withheld class.

For an eligible component X of level t, let $t_\flat$ be the bottom of its preparation window and let $Z_j''(X)$ be its prepared cores. After $n(X)$ stages, with some components $\mathcal{F}$ completely removed, the determining entries have the form

$$\begin{aligned} N_j^{n,\mathcal{F}} &= \bigcup \mathcal{F} \ \cup \bigcup_{\substack{X \notin \mathcal{F} \\ t_\flat < j \le t_\flat + n(X)}} (X \setminus Z_j''(X)), \\ \Omega_j^{n,\mathcal{F}} &= \Omega_j \cup N_j^{n,\mathcal{F}}, \qquad \Lambda_j^{n,\mathcal{F}} = \Lambda_j \cup N_j^{n,\mathcal{F}}. \end{aligned} \tag{4.cdlxiii}$$

The full prepared sequence uses every permitted stage. In the construction its consecutive determining boundaries have a collar of at least one coarse M-cube. This separation, and the joint admission of all interpolated data to the background cores, are geometric and analytic conditions on these actual entries. Merely naming the entries in eq. 4.cdlxiii does not prove either condition.

There is also an action sequence. At a level redone by a drop-out it lists what is still stored, rather than what has just been prepared:

$$T \supset \Omega_1^{\mathsf{a}} \supset \Lambda_1^{\mathsf{a}+} \supset \Lambda_1^{\mathsf{a}} \supset \Omega_2^{\mathsf{a}} \supset \cdots \supset \Lambda_s^{\mathsf{a}}, \qquad Z_s^{\mathsf{a}} = Z_s. \tag{4.cdlxiv}$$

The extra symbol $\Lambda_j^{\mathsf{a}+}$ denotes the specified collared support of the action weights. Determining and action sequences can coincide at recent levels and differ at older ones. Equality at the last level does not permit replacing one by the other everywhere.

The rules for reading these records are as follows. Class membership, the traced old cores and the old integration regions use the stored label entries Z_j. Backgrounds, their data, determining sets, measures and gauge nests use the determining entries. Density tests and the last-shell test use the action regions. Coupling and vacuum weights use their specified action supports. The integral operation uses the retained operations and variables actually listed by the mark. These rules fix five distinct uses of the same geometry. They are part of the meaning of a read, not five interchangeable descriptions of a region.

4.18.1.1. A full re-entry in the broader waiting convention. This example allows a mark at the lower endpoint of the preparation window. The dynamic class used below includes that endpoint in its quarantine. The reason for this separation is visible without an estimate. Denote the old central box by P°, its old remaining core by N°, the old stored domain by the complement of O°, and put $W^\circ = O^\circ \setminus N^\circ$. In a full re-entry the field on W° is the current datum of the old level. It is not a field of the preceding level: those preceding-level variables have already been integrated. If the earlier failure preceded central integration, the field on N° is supplied by its still-present averaging delta function. If the earlier failure occurred during or after central integration, a bond touching P° can instead carry a free Haar argument and a retained datum used by the determining sets.

Substituting the stored region at a determining place would in the first case ask for an integrated-out variable on W°. Substituting the determining region at a test place would in general assert the presence of tests that the term no longer carries. Both errors can occur before any smallness estimate is attempted. Conversely, an argument that preserves the five lists above can check a read by a finite inspection of its variable and test lists. Its remaining analytic question is admission of those data to the required cores.

4.18.1.2. Gauge factors at a retained seam. Each retained gauge factor includes a tag specifying its gauge prescription and its actual background. At the retained inward seam one uses the relative prescription; away from that seam one uses the prescription specified by the corresponding operation. The group element in such a factor must be evaluated by that tag. An absolute gauge factor at a field and a relative factor at a field and background are different functions. A bound for one cannot identify the other. Removing every gauge factor on a bond with an endpoint in the next determining region is a possible different convention, but using it requires a new exact operation identity. No such removal is made by an estimate below.

4.18.2. *Local histories and their two argument spaces.* Write $\mathcal{F} = W_4$ for the finite group of gauge-tree frames and $h = |\mathcal{F}|$. A component that reaches the final decomposition, and hence can be healed or made an island, carries an operation

$$\mathbf{T}_i'(X)F(\mathbf{p}) = \frac{1}{h}\sum_{\omega}\int_{S_\omega} e^{\Phi_\omega(\xi;\mathbf{p})}F\,d\mu_\omega(\xi). \tag{4.cdlxv}$$

The local history ω is a discrete record. It lists the outer frame, the outcomes of the decompositions in its outer genealogy, and recursively a local history for each inner island. The variable ξ lists the variables left free after every surviving averaging delta function has been used as the definition

$V_{j+1}(c) = \mathcal{M}(V_j)(c)$. Its reference measure is a product of normalized Haar measures and Lebesgue measures. Gaussian, chart, elimination and gauge normalizers remain in the integrand; they are not silently changed into probability measures of mass one.

The support S_ω records the tests actually carried by that summand. It is a Borel set when the finite background maps used to define the tests are Borel. At this point Borel dependence of actual multi-level backgrounds is required; continuity of a formal expression in a named background is not a substitute for that property.

The external argument is a pair $\mathbf{p} = (\mathbf{U}, \mathbf{J})$ on $X^\sim$, where $X^\sim$ is the fixed coarse collar, not a rectangular bounding box. Its admitted complex core is denoted $\mathcal{U}_i(X^\sim)$. It is the core with the actual current normalization and substitution rules of the construction. An arbitrary complex current array is not declared admissible by this notation.

To describe the splitting used in the main step, present a pair by

$$\mathfrak{z} = (U, a', \mathbf{J}), \qquad \mathbf{U} = e^{ia'}U, \qquad U \in G^{\mathrm{bonds}}. \tag{4.cdlxvi}$$

Here a' is the dimensionless bond logarithm. If a rescaled potential A' is used instead, its lattice spacing factor must be included in a'. A typical layer bound for a bare bond is $|a'| < \hat{\alpha}_{1,j}L^{-j}$ and that for a bare plaquette is $|\partial\mathbf{U} - 1| < \hat{\alpha}_{0,j}L^{-2j}$. The additional current and local-gauge conditions are retained in the admitted core. These displayed layer inequalities alone do not replace them.

The complete exponent has the special decomposition

$$\Phi_\omega(\xi; \mathbf{p}) = \Phi^\circ_\omega(\xi) - \tfrac{1}{2}q_X(\xi; \mathfrak{z}) + V_X(\xi; \mathfrak{z}), \qquad q_X \geq 0. \tag{4.cdlxvii}$$

The inequality $q_X \geq 0$ here is on the real stored integration fibre. The glued background defining q_X is built at the G-valued factor U, and is real. This is the reason for its nonnegativity, including when the represented pair is complex. The two last summands need not be functions of the pair separately. Their sum is required to take the same value at any two admitted triples representing the same pair, and to be holomorphic in that pair. Cauchy estimates apply to that sum, not to an arbitrarily selected real quadratic summand.

4.18.2.1. Continuing the main-step quadratic form. Keep the real quadratic term in eq. 4.cdlxvii. Its continuation as a function of the pair can be constructed at the admitted glued datum. Let V be the real datum of the joined set of X, using the prescribed inner rows and the exterior averages, and let $V_\gamma = e^{i\gamma}V$. Write the continuation of its critical representative in the form $\mathbf{L}_V(\gamma)^{u_\gamma}$, where $\mathbf{L}_V(\gamma)$ is in the Landau chart about the real critical representative of V. Use the on-shell pair $(\mathbf{L}, J(\mathbf{L}))$, $\mathbf{L} = \mathbf{L}_V(\gamma)$. Let N_{V_γ} be the differential at zero of the map from raw row data to reduced data at V_γ. It is the identity on interior rows. At an outward row c it adds $\mathrm{Ad}(V_\gamma(c))\dot{v}_{c_+}(f)$ when c_+ is the outer endpoint and subtracts $\dot{v}_{c_-}(f)$ when c_- is the outer endpoint. Here $i\dot{v}_z(f)$ is the first derivative at zero of the one-step node factor at z with datum direction f on its block. For a raw datum direction f, put $f^\sharp = \mathrm{Ad}(u_\gamma^{-1})N_{V_\gamma}f$, with the node gauge acting at the initial endpoint of each row.

With the cutoff ζ^{co}_X of the main step and the walk expansion $H_1 = \sum_\omega H_{1,\omega}$ at this pair, define

$$t_{\omega\omega'}(\gamma; V)[f] = \sum_p \eta^4 \zeta^{\mathrm{co}}_X(p)\big\langle (D_{\mathbf{L}}H_{1,\omega}f^\sharp)(p), (D_{\mathbf{L}}H_{1,\omega'}f^\sharp)(p)\big\rangle.$$

Here $D_{\mathbf{L}}$ is the covariant exterior difference and the pairing is bilinear. The ordered pair of walks is counted once. This uses the fixed regular-pair radii of the walk expansion. If a_{D} is their ceiling and K_{S} the profile-to-response constant, choose the real regularity ceiling ε_{w} and the datum radius c_{w} so that

$$C(L, \varrho_0)M_1\varepsilon_{\mathrm{w}} \leq a_{\mathrm{D}}/4, \qquad CK_{\mathrm{S}}c_{\mathrm{w}} \leq a_{\mathrm{D}}/4, \qquad Cc_{\mathrm{w}} \leq \varepsilon_{\mathrm{w}}/2.$$

The layer gaps of the joined set must give the weighted summation for these walks. In particular the exponential decay after the spacing comparison must absorb L^{d/ϱ_0} at distance d. On $|\gamma|_\infty < c_{\mathrm{w}}$, the profile and response bounds admit the pair on the enlarged walk carriers, and the node gauge and reduced datum give $|f^\sharp|_\infty \leq C|f|_\infty$.

At a plaquette based in a cell of spacing ξ_y, the walk estimate gives parameter-independent weights for the differentiated lifts. Summing their termwise suprema with these weights gives $C\xi_y^{-2}|f|_\infty$. Its square costs $C\xi_y^{-4}|f|_\infty^2$, while the cell has at most $6(\xi_y/\eta)^4$ plaquettes based in it. Thus, for the n cells carrying the cutoff, the sum of the suprema of the ordered-pair terms is at most $K_{\mathrm{w}}\mathsf{n}|f|_\infty^2$. The sum $q^{\mathrm{w}}_{0,X}$ is holomorphic on the datum disc. At a real datum the covariance of each walk term removes the gauge u_γ and identifies the sum with the real main-step form there. This uses the differential of the physical response, namely $H_1 N_{V_\gamma}$ in the reduced row coordinates. Recenter at $e^{ib}V$ for real $|b|_\infty < c_{\mathrm{w}}/4$ and $|\gamma|_\infty < c_{\mathrm{w}}/2$. The two formulas agree at real data, so their holomorphic continuations agree on the common datum disc after the logarithmic change of center. This uses the same glued datum in both splittings, including the node and inner-row conventions.

For an actual triple, the real glued datum must be $\varepsilon_{\mathrm{w}}/4$-regular, and its increment from the exterior pair must satisfy $|\gamma|_\infty \le C\alpha_{1,t} < c_{\mathrm{w}}/4$. Schwarz's lemma on the complex line through γ gives

$$\left|\tfrac{1}{2}\theta_t(q^{\mathrm{w}}_{0,X} - q_{0,X})(g_tB)\right| \le \frac{CK_{\mathrm{w}}}{c_{\mathrm{w}}}\,\theta_t\mathsf{n}(\delta_t')^2\alpha_{1,t}.$$

Here $|g_tB|_\infty < \delta_t'$ and $q_X = \theta_t q_{0,X}(g_tB)$ in the real presentation. The coupling ceiling imposes $C\max\{2\alpha_{0,t},\varepsilon_1\} \le \varepsilon_{\mathrm{w}}/4$, where ε_1 bounds the input datum tests, and makes the last bound at most 1. The absolute sum in the exponent is at most $\frac{1}{2}K_{\mathrm{w}}\theta_t\mathsf{n}(\delta_t')^2$. The same ceiling requires this to be at most $(\log\theta_t)^{2\mathfrak{p}_0}/10$ using $\mathsf{n} \le C\check{R}_t^5$. If the analytic form is separated from the exponent, the corresponding remainder is $V_X + \frac{1}{2}\theta_t(q^{\mathrm{w}}_{0,X} - q_{0,X})(g_tB)$. For the modulus bound keep the original nonnegative real term. This comparison concerns the form of the main step at its glued datum. The older conditioned forms carried by the history have separate free coordinates, row restrictions and elimination factors.

An exact consequence worth isolating is

$$\sup_{\mathbf{p}\in\mathcal{U}_i(X^\sim)} |e^{\Phi_\omega(\xi;\mathbf{p})}| \le e^{\Phi^\circ_\omega(\xi)+C_V N_0(\omega)} \quad \text{if} \quad \sup_{\mathfrak{z}} |V_X(\xi;\mathfrak{z})| \le C_V N_0(\omega). \tag{4.cdlxviii}$$

All representatives in the supremum must obey the same bound. The function N_0 counts the stored sites at their own levels, with the fixed finite multiplicities belonging to the operation. Proving the complete localized bound on V_X is an analytic formation task. Once it is proved, eq. 4.cdlxviii is a pointwise envelope before integration; it is stronger information than a pointwise polymer logarithm.

4.18.2.2. The retained inner factors in the complete exponent. In the fixed real reference system, take a component X of the main step at level t and write its kept exponent in eq. 4.cdlxvii as $\sum_R T^1_R$. Its carriers are in the enlargements of older islands or of strips of levels at most $h_t = t - \mathsf{N}_t$, where N_t is the number of preparatory stages. The stored bonds are in the inner core. The enlargement costs at most one cell of level h_t, and the next two shells have widths at least $M\check{R}_t\xi_{h_t}$ and $LM\check{R}_t\xi_{h_t}$. The scale comparison $\check{R}_{h_t} \le L\check{R}_t$ therefore puts every carrier inside Z''_{h_t+2}. Write $l(x)$ for the layer index of the prepared sequence and put $n_R = \max_{x\in R} l(x)$ and $u_R = (h_t - 1 - n_R)_+$. In particular $n_R \le h_t + 1$.

Let $U_\star$ be the adapted real background of the datum $\mathbf{V}_\star$ on the component determining set. This datum equals V_X^{in} on the inner rows and the identity on the other rows. Its regularity follows from the kept tests: the half-threshold test at the top of the prepared nest and the tests inside its last preparatory operation give the levelwise bounds on the holonomies of $(\mathbf{1}, V_X^{\mathrm{in}})$. The real data V_X^{in} remain in that range while the box variable B varies on $|g_tB| < \delta_t'$. Write $q(\xi)$ for the pair of $U_\star$ and use the pinned representative at the stored sites. For every kept factor φ_R, use its original target space, with a bound $b_R^\sharp$ on the admitted spectator range. In the reference evaluation the spectator values are held fixed at their stored values. The factors are invariant, have the tie on real

triples with the same pair and have their data at the prescribed adapted sites. Their structures precede the prepared structure.

To form the new argument, apply the exterior row map $E_X^\natural$ to the decoupled response to the formed belt datum $\mathfrak{b}^Y(s;P,\varsigma[P;\xi])$. Here P is in the space of the output structure on the localization Y and $|s(\Delta)|<e^{\bar\kappa}$. On $X^\sim$ the output space has the single level t, so the endpoint blocks of the tower rows lie in its one-scale core. For a tower row c, write $T_c(W)$ for the average of W transported along its two combs to the tops $y_\pm$. Put $U^+=e^{i\eta\mathbf{A}}\mathbf{U}$ for the exterior shift, $v_\pm=v[P;\mathbf{A}](y_\pm)$ for its site factors and $u_-=\mathbf{U}(\mathrm{cb}_{c_-})$. Then

$$e^{i\gamma(c)}=u_-^{-1}v_-^{-1}T_c(U^+)v_+T_c(\mathbf{U})^{-1}u_-.$$

The set read by this product consists of the two combs, the blocks of their tops and the double block of c. It is at distance at least $cM\check R_t$ from the belt. If ϕ is the supremum of $|\mathbf{A}|$ on this set, the product with $z\mathbf{A}$ is holomorphic and within $1/2$ of the identity for $|z|<r_{\mathrm E}/\phi$, by the site factor and relative average bounds. The product is the identity at zero. Schwarz's lemma bounds its logarithm at $z=1$ by $\phi/r_{\mathrm E}$. The response bound for ϕ therefore gives $|\gamma|\le Ce^{C\bar\kappa}\varepsilon_\beta e^{-c\delta_0 M\ell_t^r}$, where $\ell_t=\log\theta_t$. The logarithm and the composed maps are holomorphic at fixed real factor throughout the given cube polydisc.

Form $\mathbf{V}$ on the component rows using $e^{i\gamma}\mathcal{M}^m(\mathbf{U})$ on the tower rows of level m, $\mathcal{M}^t(\mathbf{U})$ on the remaining exterior rows, the formed box averages with their left factor e^{ig_tB} on the box rows, and V_X^{in} on the inner rows. Put

$$B^\natural=\frac{1}{i}\log(\mathbf{V}^{\hat w}\mathbf{V}_\star^{-1}),$$

where $\hat w$ is the comb of $\mathbf{U}$ at the exterior nodes and the identity at the nodes of the core. It acts on the datum at the nodes. The low box rows have both ends in the core and there

$$e^{iB^\natural(c)}=e^{ig_tB(c)}e^{i\nu_P(c)},\qquad |\nu_P(c)|\le C_1'L^{m-t}a_C,\qquad a_C=\max_\iota\alpha_{\iota,t}.$$

The factor $e^{i\nu_P}$ is the continuation of the box average in the exterior datum. At an entrance row the closed contour through the gauge tree and the exterior path has $O(M^2)$ plaquettes. Its curvature bound and the exterior comb bound give the bound $\epsilon_{\mathrm{out}}=C_1'M^2\check R_ta_C$ on the remaining rows, including the small complex correction to the comb. On the inner rows $B^\natural=0$. Thus the whole formed datum is in the continuation ball $\|B^\natural\|_\infty<r_{\mathrm B}$.

Use the Landau response $(\mathcal{H}_\star,\mathsf{j}_\star)$ at $\mathbf{V}_\star$, transported to the adapted anchor. Its current increment is $J(e^{i\eta\mathcal{H}_\star(B^\natural)}U_\star)-J(U_\star)$. On the bonds of R define the actual argument by

$$\mathfrak{S}_R(\lambda;\mathfrak{z},\xi)=\mathfrak{p}[U_\star]|_R\mathbin{\dot+}(\lambda\mathcal{H}_\star(B^\natural),\lambda\mathsf{j}_\star(B^\natural))^\delta|_R.$$

The superscript denotes levelling with all the stored sites pinned. Both increments are multiplied before levelling. The normalized potential, first difference and current of the unlevelled response are bounded by a constant times the datum profile. The current bound follows from the continued current difference and the deviation of the response gauge from the identity, since the scaled current is bounded in the chart.

For $h_t\le m\le t$ let $D_m(x)$ be the prepared weighted distance to the sites outside the innermost region I_2 with layer index at least $m-1$. Convolving the row bounds with the decaying response gives the slowly varying profile

$$s_\star(x)=C\left[\delta_t'e^{-\theta_\flat D_{h_t}(x)}+a_C\sum_{m=h_t}^{t-1}L^{m-t}e^{-\theta_\flat D_m(x)}+\epsilon_{\mathrm{out}}e^{-\theta_\flat D_t(x)}\right].$$

Separation gives $D_m(x)\ge\varrho_0(m-2-l(x))_+$. Sum the middle series using $Le^{-\theta_\flat\varrho_0}\le1/2$. Since $\mathsf{N}_t\gtrsim\ell_t^r$, both $a_CL^{3-\mathsf{N}_t}$ and $\epsilon_{\mathrm{out}}e^{-\theta_\flat\varrho_0(\mathsf{N}_t-3)}$ are smaller than a fixed multiple of δ_t' at small coupling. Thus for $l(x)\le h_t+1$ the profile is at most $C\delta_t'e^{-\theta_\flat\varrho_0(h_t-1-l(x))_+}$.

The anchor has half the radius of each target clause. Its scaled curvature and current follow from the profile of the regular datum. Local gauges follow on the required cubes from the curvature bound, using one finer layer for cubes touching the boundary. On a subordinate tower the restricted anchor is critical over its own averages. The tower therefore has the same curvature and current up to gauge. This also applies to the towers of the single-scale cores after truncation. These checks use separation of the component sequence, which can have holes near its exterior boundary.

The available shift is $\kappa_{\mathrm{R}} \min_\iota \alpha_{\iota,l(x)}$ in prepared units for a slowly varying profile. For a target index $m \le l(x)$ the shift gains at least $L^{-(l(x)-m)}$ in its own units. The radii change by at most a factor $C(1+l(x)-m)^{1/2}$, so the rescaled profile spends only a fixed small part of the pointwise radii. The gauges of the unchanged real factor still apply. For each subordinate tower the local Lipschitz bound on its curvature and current takes the supremum of the rescaled profile with an exponential distance penalty. The tower decay rate exceeds $\theta_\flat + 2\log L/\varrho_0$, which absorbs the variation of both layer indices and of the profile. The same bounds apply to the single-scale cores and their towers. This gives the stated allowance for the pinned shift, including the fixed cost of levelling. The allowance also puts its local potential below the levelling threshold on the neighboring tops.

Finally, the running radii satisfy $\min_\iota \alpha_{\iota,l} \ge c(1+t-l)^{-1/2} \min_\iota \alpha_{\iota,t}$, and $1+t-l \le (2+\mathsf{N}_t)(1+(h_t-1-l)_+)$. The ratio $\delta'_t/\min_\iota \alpha_{\iota,t}$ is a constant times $\ell_t^{\mathfrak{p}_1-q}$, where q is the radius exponent. Absorbing the remaining square root into the layer exponential shows that the normalized pinned shift on R costs at most $|\lambda| a_R/2$ of the allowance, with

$$a_R = C_* \ell_t^{-(q-\mathfrak{p}_1-r/2)} e^{-\delta_\flat \varrho_0 u_R} \le C_* \ell_t^{-(q-\mathfrak{p}_1-r/2)} (4L^8)^{-u_R}.$$

In particular the argument stays in the target space for $|\lambda| < 2/a_R$ uniformly on the cube polydisc and the admitted spectator range. It is holomorphic with the real factors held fixed. It reads $q(\xi)|_R$ at zero. At the real full parameters the belt and the box averages give the actual prepared datum. The pinned response has its current and the prescribed transports on the stored sites. The adapted representative on R can be taken from the prepared orbit because its pillars inside the core are the same as the component pillars. Its plain triple satisfies the target bounds by the real profile comparison, and the tie identifies its value with the pinned value. Thus $T_R^1 = \varphi_R(\mathfrak{S}_R(1;\mathfrak{z},\xi))$.

Set $\delta_R = T_R^1 - \varphi_R(q(\xi)|_R)$. Schwarz's lemma, applied to the difference along this substitution disc, gives $\sup|\delta_R| \le a_R b_R^\sharp$.

For the absolute bound of a kept member, split off the part of each island factor that depends only on its stored variables. The remaining factor vanishes at the trivial triple, for each value of those variables, so its supremum is bounded by its oscillation. A strip factor consists of the quadratic walk sum and the logarithms of its external pivot Jacobians. On the enlarged spectator discs the quadratic sum costs the square of the radius multiplier $(\log\theta_{j-1})^{6r+1}$ at the birth level j. For each pivot, the full logarithm has modulus bounded by $9\log L + c_{\mathrm{P}}$ on the pivot chart. In the convention $\log z^{(j-1)} = -\mathfrak{p}_{c'} + 9\log L$ the second term is the scalar from the pivot normalization. Its carrier has one or two adjacent cubes and there are at most $8M^4$ such pivots per carrier. These bounds give, for each level-j carrier,

$$b_R^\sharp \le B_\Phi^\sharp \widehat{\ell}_j^{\,\mathfrak{p}^\sharp} e^{-\kappa d_j^{\mathrm{in}}(R)}, \qquad \mathfrak{p}^\sharp = 2\mathfrak{p}_0 + 12r + 2, \qquad \widehat{\ell}_j \le \ell_t(1+\log(2+t-j)).$$

Here $\widehat{\ell}_j = \max\{\log\theta_j, \log\theta_{j-1}\}$ and $B_\Phi^\sharp$ absorbs the strip and island constants. If the member is divided into identical copies, the bounds are divided by the number of copies, so their sum is still bounded by $b_R^\sharp$.

Write $z_j(X)$ for the number of side-M cubes in level-j units in the action large-field region of X, and put $Q = 4L^8$. The levels $j \ge h_t - 1$ contain at most $C\ell_t^{5r}$ such cubes in total. A kept carrier has a cube in the enlarged action large-field region of its level. Counting through that cube with the entropy bound, including the bounded multiplicity of exempt island hulls, controls the contribution

from these levels by $CB_\Phi^\sharp \ell_t^{5r+\mathfrak{p}^\sharp}$, since the bounded frame increments give $\theta_{j-1} \le \theta_t + C(\mathsf{N}_t + 2)$ throughout this window.

For $p = h_t - j \ge 2$, the possible rooting cubes are in the level-$(j+1)$ action large-field region. It is contained in the inner region with at most $C\ell_t^{4r}$ cubes of level h_t, so the rooting count at level j costs at most $C\ell_t^{4r} L^{4p}$. The root lies outside a member of the prepared sequence with index $i'+1 \le h_t$. Here i' is j, $j+1$, or the level $i < h_t$ of a drop-out having $i - N_0(i) \le j < i$, where $N_0(i)$ is the number in the old drop-out index $k_0(i) = i - N_0(i)$. If $n_R \ge i' + 2$, the carrier must cross a prepared gap and $d_j^{\mathrm{in}}(R) \ge \frac{1}{2} L^{n_R - j}$. The exempt hulls stay on the lower side of the gap and can reduce the length by at most two level-j cube units. Summing over $m = n_R - j$ in this case costs, after entropy,

$$\sum_{m \ge 2} e^{-cL^m} Q^{-(p-1-m)_+} \le C Q^{-(p-1)}.$$

Otherwise, in the two unmarked cases $n_R \le j + 2$ and $u_R \ge (p-3)_+$. In the drop-out case $u_R \ge (p-2-N_0(i))_+$, so the extra cost is at most $Q^{N_0(i)} \le L^9 \rho_i^9$, where $\rho_i = \check{R}_{j'}$ at $j' = i - N_0(i) + 1$. The frame bound $\theta_{j'} \le \theta_t + C(t - j')$ and $N_0(i) \le 2 + r \log_L \log \theta_{j'}$ give $t - j' \le 2(t-j)$ at small coupling, since $t - j \ge \mathsf{N}_t + 2$ absorbs the logarithmic delay. Consequently

$$\rho_i \le C[\ell_t (1 + \log(1 + \mathsf{N}_t))(1 + \log(1+p))]^r.$$

In all three cases the geometric factor from L^{4p} and Q^{-p} sums against every fixed power of $1 + \log(1+p)$. Since $\mathsf{N}_t \le C\ell_t^r$, summation gives

$$\sum_R b_R^\sharp (4L^8)^{-u_R} \le K_A' B_\Phi^\sharp \ell_t^{\mathfrak{p}^\sharp + 13r} (1 + \log \ell_t)^{9r + \mathfrak{p}^\sharp}.$$

It follows that

$$\sum_R \sup |\delta_R| \le C_* K_A' B_\Phi^\sharp \ell_t^{5r+E+12r+2} (1 + \log \ell_t)^{9r+\mathfrak{p}^\sharp}, \qquad E = 2\mathfrak{p}_0 + \mathfrak{p}_1 + \tfrac{17}{2} r - q.$$

With $E + 12r + 2 < 0$, the coupling ceiling and the geometric bound $N_0(\omega) \ge 2^{-5} M^4 \ell_t^{5r}$ make this at most $N_0(\omega)$. All suprema here are over the common admitted range. Use $b_R^\sharp$ on this range, including the enlarged discs of the one-step quadratic factors.

Let V_X^{col} be the collar sum before the change of inner reads. It consists of the localization of the action difference, the small Wilson sum $\mathfrak{v}(X^\sim)$ and the Wilson weight correction W_X. Use the count $N_0(\omega) = M^4 \sum_{j \le t} z_j(X)$ from the action regions.

In the action difference, cancel each carried trunk with its partner on the new side before estimating the localized sum. The localized differences of a carried entry of size b_e and amplitude a_e have total grouped bound $a_e b_e$ on a collar. Indeed each difference over switched cubes is bounded by $a_e b_e$ times exponential decay in the number of cubes needed to connect its support to its base. Summing the connected extensions uses the cube entropy and the chosen decoupling radius. The same estimate for the nontrunk pieces of an unpaired entry can be absorbed into its bound Cb_e, since $a_e \le 1$. An unpaired entry is counted with its whole trunk, and a plain entry with its whole value. The kept trunks have the separate estimate just proved.

At level t there are at most six ordinary entries on a domain and at most $3^4 z_t(X)$ collar cubes through which to root them. For $j < t$ the index condition on an ordinary entry gives a cube in a one-layer enlargement of the action large-field region of level j. A root of a domain in this collar belongs to the enlargement of X's own trace, by separation of the class components. There are at most $3^4 z_j(X)$ such cubes. The level-j island hulls in the collar have at most $3^4 \mathsf{m} z_j(X)$ cubes in total, where m bounds their multiplicity. Counting domains with their length decay therefore costs at most $C(1 + \bar{c}) z_j(X)$ for the ordinary entries. This count includes the unpaired plain numbers of the gained domains, namely the pointed values and the remainder values at the trivial pair. The

large quadratic strip terms of level t are carried outside the collars. The older strip factors with base in the collar occur among the kept entries.

For the regular members, let m be their level and n the last action layer that their carrier meets. A member with $n < t-1$ is rooted in the action complement of level $n+1$. That complement in X offers at most $L^{4(n+1-m)} z_{n+1}(X)$ possible level-m roots. The carrier has length at least $2L^{n-m-3} - 2$, so after paying the domain entropy and one power of the length for the member norm, the remaining decay sums over $m \le n$ against the root count. The last layer uses the collar cubes as roots instead. This gives another $C(1+\bar{c})\sum_j z_j(X)$. Thus the action difference has the required absolute majorant, with every grouped piece, unmatched trunk and unpaired plain number counted.

In the small Wilson sum, the unpaired functions are the local correction (including the analytic reference normalizer) and the interior Wilson comparison with the actual exterior row increment. Their combined supremum is at most $C(1+\bar{c})\ell_t^{5r}$. The two unsuppressed Wilson differences are supported in at most $C\check{R}_t^4$ and $C\check{R}_t^5$ unit cells, respectively. The difference of weights times the squared field bound is $O(1+\bar{c})$ on these cells. This follows from the tube width $C\theta_t \ell_t^{-2q_t}$, $q_t \ge q$, and the field size $C\theta_t^{-1/2}\ell_t^q$ on the prepared window. For the localized Wilson forms, the regularity of the real inner data is bounded by $C\ell_t^r \varepsilon_t$ on the retained tests, as required by the box construction. The other comparisons have small factors $e^{-c\delta_0 M\check{R}_t}$ or $L^{-\mathsf{N}_t}$, or the Taylor loss $\theta_t^{-1/2}$, which absorb the polynomial logarithmic factors. For the comparison in the deep inner region the cells are summed with their weighted-distance decay. The layer gap absorbs the possible increase of the weight there. The analytic normalizer is uniformly bounded on its box. These estimates are on the complex increment ball used in the formed Wilson comparison.

The remaining Wilson entries are matched exterior-cell terms. On this collar their total localized difference is bounded by $C(1+\bar{c})\check{R}_t^4 \ell_t^{2q+2r}$ times the pinned exterior response amplitude, and that amplitude is bounded by $C\theta_t^{1/2} e^{-c\delta_0 M\check{R}_t}$. This term is bounded by $C(1+\bar{c})\ell_t^{5r}$ at small coupling. There is at least one level-j label cell in the trace for each $h_t \le j \le t$. Each such cell contains $\check{R}_j^4 \ge 2^{-4}\ell_t^{4r}$ side-M cubes, and there are $\mathsf{N}_t + 1 \ge \ell_t^r/2$ levels. Hence $\sum_j z_j(X) \ge 2^{-5}\ell_t^{5r}$. Thus the small Wilson sum is bounded by $C(1+\bar{c})\sum_j z_j(X)$.

Finally, W_X is the sum over plaquettes in X of the Wilson density times the difference between the new weight and θ_t. The density is bounded by $C\eta_t^4 \alpha_{0,t}^2$, and each level-t cube has at most $CM^4\eta_t^{-4}$ such plaquettes. The correction therefore costs $CM^4 z_t(X)\alpha_{0,t}^2(|x_{t-1} - \theta_t| + \bar{c})$. The adjacent-level flow and the tube bound make the last product of the radius squared and the weight difference $O(1+\bar{c})$. This estimate holds after splitting the correction into its local plaquette carriers as well.

Adding the three majorants gives $\sum_\lambda \sup|v_\lambda| \le C_{\mathrm{col}}(1+\bar{c})N_0(\omega)$ for the collected collar terms on their common range. The separate Gaussian counting constant keeps its assignment in the reference normalization. The exact assignment is

$$V_X = V_X^{\mathrm{col}} + \sum_R \delta_R, \qquad \Phi_\omega^\circ = \Phi_\omega^{\mathrm{rest}} + \sum_R \varphi_R(q(\xi)|_R).$$

Here $\Phi_\omega^{\mathrm{rest}}$ contains the retained inner Wilson factor and all other terms depending on ξ alone. This preserves the exponent and proves $|V_X| \le [C_{\mathrm{col}}(1+\bar{c})+1]N_0$. The pair-dependent part of the exponent remains $-q_X/2 + V_X$, with its given holomorphy and independence from the representation of the pair. The bound gives eq. 4.cdlxviii. The integral of $e^{\Phi_\omega^\circ}$ uses the real coordinate estimates below.

4.18.2.3. The pair reader on a formed island. On the output core of the formed island kit, write $f = g_t B$ and $\zeta_X = \zeta_{0,X} - \zeta_{1,X}$. Use the generated Wilson configuration $W^{\mathrm{f}}(b,f)$ of the prepared component. Its datum is the lift of the outer average of the pair, the perturbed collar datum $e^{if}V_0[d;V^{\mathrm{e}}]$, and the retained inner datum V_X^{in}. At fixed real stored variables these give the same

complex datum for all splittings of the pair. On the real slice the glued representatives are related by a gauge equal to one at the stored pins. The Wilson trace is invariant there, and the tied outer factors also have equal values there. On the two prepared leaves use a complex parameter z taking the real interpolations to the desired splitting at $z = i$. For each real collar parameter the two holomorphic reads agree for real z, so they agree at i by the identity theorem on the neighborhood of $[0, i]$. Continuing in the collar parameters gives equality on the common formed core. The prepared leaves use the same pinned data and margins.

Define the weight-free quadratic form

$$q^{\natural}_{0,X}(f; P) = \frac{d^2}{ds^2}\bigg|_{s=0} A(\zeta_X, W^{\mathrm{f}}(b, sf)).$$

It reads the pair P at fixed stored variables. No entry of the source system enters it. The holomorphic remainder

$$T_6(b, f) = -\theta_t \left[A(\zeta_X, W^{\mathrm{f}}(b, f)) - A(\zeta_X, W^{\mathrm{f}}(b, 0)) - \tfrac{1}{2} q_{0,X}(f)\right]$$

is bounded by one on the admitted radius $5\delta'_t$ under the prepared Wilson estimate and coupling ceiling. For $\|f\|_\infty \le \delta'_t$, its second coefficient along sf, bounded by Cauchy on $|s| = 1$, gives

$$\left|\tfrac{1}{2}\theta_t (q^{\natural}_{0,X} - q_{0,X})(f)\right| \le 1.$$

Before transferring the kept trunks to $q(\xi)$, denote the collar interaction by V^{col}_X. The new pair reader is

$$V^{\natural}_X = V^{\mathrm{col}}_X + \sum_R \delta_R + \tfrac{1}{2}\theta_t (q^{\natural}_{0,X} - q_{0,X})(f).$$

Thus $-\theta_t q^{\natural}_{0,X}(f)/2 + V^{\natural}_X$ plus the trunks read at $q(\xi)$ gives exactly the old exponent. The formed-core bounds use the carrier $X^{\sim}$, which already contains the prepared box and the gauge tree. They apply on the output island core to the individual pieces with the stored variables fixed. In the sourced-minus-zero difference the common quadratic correction cancels, leaving the Wilson source on the inner field and $V^{\natural,w}_X - V^{\natural,0}_X$, with the inherited exponents read at their admitted real pairs. This is eq. 4.dxvi on that core. The absolute cost and the source oscillation use its carrier bounds. 4.18.2.4. The factor bound at the birth of an island. On the admitted formed core, split each collar member into its value at the fixed anchor and the change from that value, using the prescribed carrier of the member. In the old core the anchor reads the stored variables alone. File its value in Φ°_{ω}. The oscillation of the change costs at most twice the amplitude on the anchored substitution disc. The factor $(4L^8)^{-u_R}$ at depth u_R pays for the L^{4u_R} root count and its fixed multiplicities. The additional negative power of $\ell_t = \log \theta_t$ absorbs the inherited sizes. Outside the old core, the waiting window contains at most ℓ_t^{Cr} local cells, counted at their own levels. The regular terms use the pointed sums with their two subtractions, and the Wilson terms use their net weights. The collar oscillations therefore use the single-term collar bound with constant b_V, independently of the inherited oscillation constant.

For the kept contributions use the bound on $\sum_R |\delta_R|$ on the common formed range. Their total oscillation is at most twice that bound. Its logarithmic factor, by the choice of q, makes the cost at most $\mathsf{B}_\Phi \ell_t^{2\mathfrak{p}_0}/4$ when the coupling ceiling is chosen after the strip and island constants. The new quadratic and its displayed correction cost at most $CA_1^2 \check{R}_t^5 \ell_t^{2\mathfrak{p}_1} + C$. Use the prescribed tied expression for these pieces. The hierarchy between $\mathfrak{p}_0$, $\mathfrak{p}_1$ and the waiting exponent makes their oscillation at most another quarter. Use the whole carrier $X^{\sim}$ for the quadratic and the retained changes formed through the island's full reader. That carrier is exempt in the output label and has hull length zero. The smaller carriers of the local collar members keep their own decay.

Choose $\mathsf{B}_\Phi \ge 2\mathsf{b}_V$ and keep the preceding quarters as reserves. The new island then has the same real oscillation bound per carrier as the incoming islands. For an island that stands, its exponent,

stored variables and carriers remain those of its birth operation. Restricting its arguments preserves the old oscillation bound. These two cases return a maximum over the formed and carried entries. The bound applies on the formed cores and uses the admission and mass bounds of the actual histories.

4.18.2.5. Why the old Wilson factor is retained. The main action expansion is made only on the small-field part $\zeta_0(1-\zeta_1)$, about the real glued background. On the old core the factor

$$\exp\{-A(x''\zeta_1\mathbf{1}_X, U''(\xi))\} \tag{4.cdlxix}$$

is left intact. The inner background $U''(\xi)$ is real and is formed from the prepared determining sequence, with its old innermost datum and its new fluctuation datum. It is distinct from the glued background used in q_X. The factor in eq. 4.cdlxix is independent of the external pair. Its plaquettes include the old failed tests that have survived in the record. Replacing it by a quadratic Taylor expression throughout the old core would remove the positive reserve used below.

The other factors in e^{Φ° are chart densities, constants, kept gauge and elimination factors, stored Gaussian weights and the inner operations evaluated at real pairs. Their normalization and their domains will be used individually. The phrase "the complete exponent" always includes all of them.

The restored law is combined with the old Wilson action before estimating its normalization. Fix one frame and all exterior data of a component X at level i. Write s for its retained old variables and v for its restored box field, with the tree condition imposed. Set

$$S_{\mathrm{old}}(s) = A(x'', U_i''(s)),$$
$$S_{\mathrm{ref}}(v) = \theta_i A(\zeta_0, U_{i,X}(v)), \qquad S_0 = \theta_i A(\zeta_0, U_0).$$

The denominator has the form $D_X^{-1} = e^{S_0 + I_X - E_X}$, where I_X is the negative logarithm of the centered reference integral after extracting its counting factor e^{E_X}. To combine its center with the Wilson actions, write $w = x''$, $\theta = \theta_i$, $W'' = U_i''$, $W^0 = U_0$, $W^Z = U_{i,X}(v)$, and let $\bar W$ be the completed background. In a succession of completed components these are the backgrounds before and after the current replacement. Use $w_{\mathrm{fr}} = \theta$ on the component and $w_{\mathrm{fr}} = w$ off it. The replacements telescope over the components.

The three parts of the old weight use $1-\zeta_0$, $\zeta = \zeta_0 - \zeta_1$, and ζ_1, with $\zeta_0 = 1$ on the support of ζ_1. Write $\Delta_a(P,Q) = A(a,P) - A(a,Q)$ for weighted action differences. The exterior part of the remainder is

$$\Delta_{w(1-\zeta_0)}(\bar W, W'') + A((w_{\mathrm{fr}} - w)(1-\zeta_0), \bar W) + \theta\,\Delta_{\zeta_0}(\bar W, W^Z).$$

On the middle part put $W_{\mathrm{g}}^0 = W^{\mathrm{f}}(b,0)$ and $W_{\mathrm{g}}^f = W^{\mathrm{f}}(b,f)$, the two glued backgrounds with the same exterior increment b and with fluctuation increments 0 and $f = g_i B$. Its remainder, including the center of the reference law, is

$$\theta A(\zeta_1, W^0) + \theta\,\Delta_\zeta(W^0, W_{\mathrm{g}}^0) - (\theta\,\Delta_\zeta(W_{\mathrm{g}}^f, W_{\mathrm{g}}^0) - q_X/2)$$
$$+ \theta\,\Delta_\zeta(W_{\mathrm{g}}^f, W'') - A((w-\theta)\zeta, W'').$$

The bracket contains the Taylor remainder after the quadratic form $q_X/2$ is extracted. The inner part keeps $S_{\mathrm{core}} = A(w\zeta_1, W^{\mathrm{in}}(f))$. For the difference on this part insert the inner background $W^{\mathrm{in}}(\gamma^\flat)$. Its datum on the rows adjacent to the core is $e^{if}e^{iv_0}$ relative to the inner center, where v_0 is the continued basic datum with $|v_0| \le CL^{-\mathsf{N}_i}\mathsf{s}$. Here s bounds the fields and increments. On the remaining rows, including the joining rows, keep f. The two errors are

$$\Delta_{w\zeta_1}(W^{\mathrm{in}}(f), W^{\mathrm{in}}(\gamma^\flat)), \qquad \Delta_{w\zeta_1}(W^{\mathrm{in}}(\gamma^\flat), W'').$$

The graded row response in the first and the screened background comparison in the second bound them by $C\|w\|_\sharp \mathsf{N}_i \mathsf{s}^2 \mathsf{n}$ times $L^{-\mathsf{N}_i}$ and $e^{-c\delta_0 M \check R_i}$, respectively. Here n bounds the number of remade pillars and $\|w\|_\sharp$ divides the weight on layer j by $1 + i - j$. This places the response to the complex outer variables in the remainders and leaves the retained core at its real configuration.

Let w' be the actual outgoing weight, so that $S_{\mathrm{new}} = A(w', \bar{W})$. Add $\mathsf{W}_X = A(w' - w_{\mathrm{fr}}, \bar{W})$ to the remainder when completing the action. This difference of weights is supported in the replaced component. It has the positive sign since $-A(w_{\mathrm{fr}}, \bar{W}) = -A(w', \bar{W}) + \mathsf{W}_X$. The profiles give $w' = w$ off the components. At the unsourced center, the weight in a completed component is the current bulk weight before the next increment. The preceding bounds on the localized terms include this correction. Summing the three differences and W_X gives P_X and the identity

$$-S_{\mathrm{ref}} - S_{\mathrm{old}} + S_0 = -S_{\mathrm{new}} - \tfrac{1}{2} q_X - S_{\mathrm{core}} + P_X.$$

The exact product of the old weight and the restored law is

$$e^{-S_{\mathrm{old}}} \frac{\chi_X e^{-S_{\mathrm{ref}}}}{D_X} = e^{-S_{\mathrm{new}}}\, \chi_X e^{-q_X/2 - S_{\mathrm{core}}} e^{P_X + I_X - E_X}.$$

This is an identity in (s, v) before either variable is integrated. It remains valid with the actual subsequent averaging graph attached, including at a prescribed terminal raw field. No integration over that terminal field is used to cancel S_0.

The factor $e^{-S_{\mathrm{new}}}$ belongs to the new label's action. The operation retains the core Wilson factor and q_X together with the produced terms, scalar constants and its other carried factors. Thus the original old action is used once in this rewrite. One must not also keep it as a separate reserve, or append the old factor D_X^{-1} to the rewritten operation. The terms $P_X + I_X$ are included once in the complete remainder; E_X is included once in the scalar normalization at its original levels.

For example, on an admitted real fibre suppose the complete remainder bound gives $P_X + I_X \le C N_0$, the scalar count gives $|E_X| \le C V^\circ$, and $q_X, S_{\mathrm{core}} \ge 0$. Then the factor left after $e^{-S_{\mathrm{new}}}$ has been assigned to the new action is bounded by $e^{C V^\circ}$ times the other retained reference factors. The new action itself is nonnegative on a real carrying configuration, so it can also be retained or bounded above by one in an estimate of the complete positive measure. If some of the core energy is used for a failed-test payment, its unspent portion is the reserve in this estimate; the same energy is not available twice.

This handles the nonflat normalization within the complete Wilson product whenever those actual identities and bounds apply. It supplies no upper bound of this size for the isolated probability density $\chi_X e^{-S_{\mathrm{ref}}}/D_X$. The reference integration at fixed terminal output still requires the retained Haar or chart coordinates, including the treatment of tree-fixed pivots. The cancellation changes none of those coordinates or constraints.

4.18.2.6. Drop-outs use a fibre. A drop-out has no inner background formed for its own main operation. Its kept factors have no new core Wilson term. Its mass therefore includes the Wilson factor from the carrying term, on the bare plaquettes whose corners lie in X. The argument is an evaluation $\mathfrak{e} = (e, U, v, Q_1, Q_2, \dots)$ in a set $\mathcal{K}^\sharp(\omega, \xi)$, with the following meaning:

(i) U is real on X and compatible with the stored variables. The exterior datum e supplies the portions of the carried test reads outside X, in the same physical frame and on the same averaging graph;
(ii) every carried test has its recorded value on its complete read, using the reconstructed fields of ξ, the prescribed averages of U and the exterior datum where the test reaches beyond X;
(iii) the real pair restricted to every inner island lies in that island's admitted real core;
(iv) the complete kept quadratic forms and elimination factors obey their stated one-sided lower and upper bounds;
(v) $v(p) \ge c\theta_j$ on the action layer that owns p.

Compatibility means the actual identities

$$\mathcal{M}^j U(b) = V_j(\xi)(b) \quad \text{on every determining bond whose two blocks lie in } X. \tag{4.cdlxx}$$

At level zero these are identities with the stored bare bonds. Layer regularity is imposed both on U and on the relevant stored averages. It cannot be inferred merely from the realness of U.

There are two variants. The mass of the drop-out itself excludes the test whose failure made it a drop-out. A later component may restrict the evaluation set by including that test. It can charge the root when the full paying carrier supplies a witness. The mass of the earlier drop-out leaves this root uncharged.

Write the evaluated factor as

$$\mathsf{E}_{\omega}(\xi;\mathfrak{e}) = e^{-A(v\mathbf{1}_X,U)}\mathsf{K}_{\omega}(\xi;\mathfrak{e}). \tag{4.cdlxxi}$$

For a fixed exterior the actual kernel keeps the exterior tests on their inverse reads. For the upper integral one may take the supremum over admitted exterior values after expressing their kernels in the common free coordinates. The shell and restored tree charts use relative Haar in a fixed recorded frame. The exterior changes the reconstruction and its weight, and these enter the pointwise envelope. The Wilson share in eq. 4.cdlxxi is still the share on the plaquettes owned by X. The set of evaluations varies with ξ. For example, take a probability measure supported on $\epsilon \le |\xi| \le 2\epsilon < 1$, and a factor $e^{-T(1-\cos p)}$. On the compatible graph $p = \xi$ its integral is at most $e^{-cT\epsilon^2}$. If $p = 0$ is admitted independently of ξ, the supremum of the factor is one. For $p = i\eta$ it is $e^{T(\cosh\eta - 1)}$. Neither replacing the fibre by a product nor complexifying the real Wilson argument preserves the same small factor.

4.18.3. *Upper integrals and the strong real induction norm.* For a nonnegative function f on a Borel measure space define

$$\int^{*} f\,d\mu = \inf\left\{\int F\,d\mu : F \text{ Borel},\ 0 \le f \le F\right\}. \tag{4.cdlxxii}$$

All inequalities are pointwise, including on sets on which a parameter-dependent supremum has not been proved Borel. The value of the supremum over an empty evaluation fibre is zero. Monotonicity, positive homogeneity and subadditivity follow directly: majorize each summand by a Borel function within an arbitrary positive error and add the majorants. For a countable sum use errors of size $2^{-n}\delta$ and monotone convergence of the sum of the Borel majorants. These facts do not authorize interchanging an upper integral with an arbitrary parameter supremum.

For an ordinary component put

$$m_{\omega}^{\mathbb{C}}(\xi) = 1_{S_\omega}(\xi) \sup_{\mathbf{p}\in\mathcal{U}_i(X^{\sim})} |e^{\Phi_\omega(\xi;\mathbf{p})}|, \qquad m_{\omega}^{\mathbb{R}}(\xi) = 1_{S_\omega}(\xi) \sup_{\mathbf{p}\in\mathcal{U}_i(X^{\sim})\ \text{real}} e^{\Phi_\omega(\xi;\mathbf{p})}. \tag{4.cdlxxiii}$$

For a drop-out use the supremum of E_ω over its compatible fibre, including the specified variant of the tests. The weighted mass, for a nonnegative function v, is

$$\mathsf{M}_c(i,X;v) = \frac{1}{h}\sum_{\omega} e^{cv(\omega)} \int^{*} m_\omega\,d\mu_\omega. \tag{4.cdlxxiv}$$

An artificial average $h^{-1}\sum_r 1 = 1$ is inserted when the operation does not otherwise depend on a root frame. This gives the same normalization in both classes. The integrals over inner components have their own factors h^{-1}; one does not cancel them a second time in the outer count.

When the core is a fixed finite-dimensional separable space, the ordinary supremum in eq. 4.cdlxxiii is Borel under the stated separate measurability and continuity assumptions. Indeed, choose a countable dense subset of the core. Continuity in the pair identifies its supremum with the supremum over that subset. A countable supremum of Borel functions is Borel. The fibre of eq. 4.cdlxxi need not have such a fixed dense set. We will dominate it by an explicit Borel envelope instead of assuming a measurable optimizing choice.

The input needed in the induction is the real version of eq. 4.cdlxxiv, with the supremum already inside the integral. Uniform fixed-argument bounds are weaker. On the finite probability space $\{1,\dots,N\}$ with uniform measure, let $f(\xi,p) = N1_{\{\xi=p\}}$. For every fixed p, $\int f(\xi,p)d\mu = 1$, while $\int \sup_p f(\xi,p)d\mu = N$. The example is measurable and positive. Thus the issue is not cured by positivity, finite volume or measurability of a partition function.

There is a parallel analytic example. On $\xi \in \{1, \dots, N\}$, let the parameter space be the disjoint union of N unit discs and set $f(\xi, z) = N$ on the disc indexed by ξ, zero on the others. The functions are holomorphic on that parameter space. Holomorphy alone does not interchange supremum and integral. In the application one must use the explicit structure of the complete exponent, such as eq. 4.cdlxvii–eq. 4.cdlxviii, and a common integrable envelope.

A real argument of an inner operation can depend on the outer variables. If it also depends on a variable integrated within that inner operation, its factor is nevertheless bounded pointwise by $m^{\mathbb{R}}$, provided it remains in the admitted real core. The strong real mass norm is precisely what permits this domination. A mere fixed-read estimate would instead require a read-before-sampling condition, absent from that weaker norm. These are two different ways of making a kernel estimate applicable; they must not be conflated.

Finally, upper integrals are used only after a Borel majorant has been constructed on the full product of stored variables. We will apply ordinary Tonelli to that majorant. Bounds for fibrewise upper integrals alone are not a substitute for such a construction.

4.18.4. *Genealogies and a volume that does not recount the past.* A node is a component $u = (n, C)$ of the region made at level n. Unless it is healed, it has one successor, the component at level $n+1$ that contains its propagated hull. Predecessors of a node are disjoint components at the preceding level. The genealogy $\mathcal{G}(x)$ of $x = (i, X)$ consists of x and all its iterated predecessors. A component healed earlier and covered again later is the root of a different genealogy. It is not put back into this tree because its physical location has been reused.

Cut $\mathcal{G}(x)$ at every clearing island below x. The cut tree $\mathcal{G}^\circ(x)$ includes these cut nodes as leaves; their own trees are the inner genealogies. A keeping mark records a drop-out without clearing its earlier history. Its older nodes are not copied every time that mark is subsequently carried.

Write $|C|_n$ for the number of level-n cells in C and define

$$\begin{aligned} w_n &= \ell_n (M R_n)^4, \qquad \mathrm{vol}(u) = w_{n(u)} |C(u)|_{n(u)}, \\ V(x) &= \sum_{u \in \mathcal{G}(x)} \mathrm{vol}(u), \qquad V^\circ(x) = \sum_{u \in \mathcal{G}^\circ(x)} \mathrm{vol}(u), \\ v^\natural(x) &= V^\circ(x) + \sum_{y \text{ inner}} v^\natural(y). \end{aligned} \tag{4.cdlxxv}$$

This is a sum of sites times levels, with the reference logarithm at the level of each site. It is not the volume of the final component multiplied by its age. Nor is it a sum of all successive presentations of its accumulated past.

Lemma 4.66 (Bounded multiplicity)**.** For every finite genealogy,

$$\begin{aligned} v^\natural(x) &= \sum_{u \preceq x} m_x(u)\, \mathrm{vol}(u), \\ m_x(u) &= \begin{cases} 2, & u \neq x \text{ is a clearing node}, \\ 1, & \text{otherwise}, \end{cases} \qquad V(x) \le v^\natural(x) \le 2V(x). \end{aligned} \tag{4.cdlxxvi}$$

■

Proof. Expand the recursion in eq. 4.cdlxxv. A node not on a cut boundary belongs to exactly one outer tree in that expansion. A clearing node below x is the last node of its parent's outer tree and the first node of its own outer tree. No third tree meets it. The root belongs only to its own outer tree. This accounts for every term in the finite expansion and proves the formula. □

For site counts without the logarithm put

$$N^\circ(x) = \sum_{u \text{ listed with multiplicity}} (M R_{n(u)})^4 |C(u)|_{n(u)}. \tag{4.cdlxxvii}$$

Thus $\ell_{\min} N^\circ \le v^\natural$, where $\ell_{\min} = \min_{j\le i} \ell_j$. A fixed-width read collar of one coarse M-layer has at most twice the sites of its owning MR_j-cells once R_j exceeds a fixed dimensional threshold. To see this, enlarge each owning cell separately and sum: its volume is multiplied by at most $(1+C/R_j)^4$, while overlaps only reduce the union. Lattice endpoint conventions change C, not the conclusion. Finite bond directions and color components are included in the per-site bound on a term. Consequently the site budget for such reads can be chosen so that

$$n^\sharp(x) \le 2N^\circ(x), \qquad n^\sharp(x) \le \frac{2}{\ell_{\min}} v^\natural(x). \tag{4.cdlxxviii}$$

The ownership of each read collar is important. Adding its whole past again at each keeping mark would not satisfy this argument.

The part of the earlier label that remains inside a drop-out has volume

$$V_{\mathrm{in}}(i, X; \mathcal{S}) = \sum_{j<i} \ell_j \, \#_j(Z_j(\mathcal{S}) \cap X). \tag{4.cdlxxix}$$

The volume in the left member is the volume of the retained label. On the compatible inner histories the volume rule gives $V_{\mathrm{in}} \le v^\natural(\omega_X)$. The restored action and stored regions also enter the load. Compare their larger volume to V_{in} using the waiting window. At an uncompressed level its retained box is either the old quiet box or the prepared box $H_j^{[3a_j]}$ in eq. 4.cdxliv. It contains at least 7^4 cells of its level. The compressed end of the window has only $O(\log_L \check{R}_i)$ levels. Thus a fixed fraction of the window gives this lower count, while the restored count is at most a fixed multiple of 100^4 at each level. The weights $M^4 \check{R}_j^4 \log \theta_j$ of those cells are comparable up to $O(L^4)$ by bounded drift in the window and rounding to powers of L. Outside the window the entries coincide. This bounds the restored load by $C_L V_{\mathrm{in}}$, while the compatible mass pays with the retained volume in eq. 4.cdlxxix.

4.18.4.1. Why an arbitrary larger volume is not available. Bounded multiplicity is a substantive restriction on a useful weight. For an algebraic example, let a first set of N creations have gain NP^2 and volume Nw. Let r later keeping marks each have gain P. A volume that recounts that first set at every mark is at least $(r+1)Nw$. Choose N so that $cNw > 2P$. Then

$$c(r+1)Nw - NP^2 - rP \longrightarrow +\infty \quad (r \longrightarrow \infty). \tag{4.cdlxxx}$$

The initial gain is finite and cannot pay for this repeatedly copied volume. Additional new volume at the marks only worsens the problem. This example concerns the inference from a gain budget to a volume weight; it does not assert that a particular field realizes every abstract record. It already proves that the scalar ledger alone cannot dominate an unbounded number of copies of the past. The correct comparison is eq. 4.cdlxxvi, or another volume with a proved fixed multiplicity bound.

4.18.5. *Contraction, light stretches and the weighted count.* We now prove the geometric counting statement used in the reserve calculation. We state its local hypotheses precisely so that its application can be checked independently of the analysis of fields. The cell graph at every level has bounded degree. The propagation of an unmarked component takes its next-scale hull, adds a fixed number of layers, and boxes only components whose diameter in cells is bounded by a fixed threshold. A new component is a union of such propagated components and its new creation cells, with these local collars. Equivalently, one can construct an occupied skeleton $O(u)$ from the creation cells below u, so that

$$\begin{gathered} O(u) \subset C(u) \subset O(u)^{[e]}, \qquad O(u) \text{ is } h_0\text{-connected}, \\ |C(u)|_{n(u)} \le C_e \nu(u), \quad \nu(u) = |O(u)|_{n(u)}. \end{gathered} \tag{4.cdlxxxi}$$

Here e, h_0, C_e are fixed. The relation between two levels is the actual cell parent map, with the bounded collars just described. There are no consecutive size drops.

For clarity, the skeleton uses unique cell addresses. The actual closed-cube hull may meet several cells at a boundary. Include that bounded ambiguity in e. The sum of the radii of earlier fixed collars, expressed in the current cell units, is bounded: over every two levels the older radii contract by L^{-1}. Its bound is a geometric series. This proves the fixed-collar part of eq. 4.cdlxxxi under the stated local propagation rule. Boxing a bounded-size component adds only another fixed collar. Taking unions does not increase these constants. Connectivity holds if a merger is made by the specified bounded-distance touching rule. A rectangular hull of a large thin domain would not obey these properties and is not the propagation used here.

Lemma 4.67 (Coarse images of connected sets)**.** Let A be h_0-connected, with N cells, in the fine cell grid. At a coarsening by a factor $q \geq 1$, its occupied coarse hull satisfies

$$|\mathsf{H}_q A| \leq C_0(1 + h_0 N/q). \tag{4.cdlxxxii}$$

The same bound holds with a fixed additional coarse collar by increasing C_0. ■

Proof. A spanning tree of the connected cell graph has $N - 1$ edges. Traverse every tree edge in both directions. Join the cell centres by line segments along this walk. Its total length in the sup norm is at most $2h_0(N - 1)$. Split it into consecutive pieces of length at most q. Each piece lies in a sup-norm ball of radius q about its first point. Such a ball, together with the width of one fine cell, meets a fixed number of coarse q-cells in four dimensions. There are at most $1 + 2h_0N/q$ pieces. Their union contains every visited cell centre and hence the required cell hull, up to its one fixed collar. Counting this collar changes the same fixed dimensional number. □

Choose a fixed number s_0 of levels so large that the net coarsening, at least $L^{\lfloor s_0/2 \rfloor}$, makes the coefficient of N in eq. 4.cdlxxxii at most $1/4$. Choose a fixed $\nu_\star \geq 4C_0$. Propagating a component with $\nu(u) > \nu_\star$ through s_0 levels without new material then leaves at most $\nu(u)/2$ occupied cells. For a component with at most $\nu_\star$ cells, it leaves at most a fixed constant. Call such components light. The estimate concerns occupied cells; a large component need not become light in s_0 levels.

Let o_n be the total number of occupied cells in a fixed genealogy at level n, and let l_n be its number of light nodes there. Unions at mergers reduce the count. A creation in the intervening s_0 levels contributes at most a fixed number of cells to their coarse image. Thus

$$o_n \leq \tfrac{1}{2} o_{n-s_0} + C_1 l_{n-s_0} + C_1 \sum_{n-s_0<t\leq n} n_t^{\mathrm{cr}}, \tag{4.cdlxxxiii}$$

with quantities at nonpositive levels set to zero. At a cut leaf of an outer genealogy its bounded number of boundary seed cells is included among n_t^{cr}. The reserve for those seeds is the last test outside the inner mass, not a second use of the inner component's old gain.

Let r_n be any nonnegative non-increasing sequence. Multiply eq. 4.cdlxxxiii by r_n and sum over the finite levels. The shifted first sum is at most half of $\sum_n r_n o_n$, because $r_{m+s_0} \leq r_m$. The light-node sum is at most $C_1 \sum_n r_n l_n$. A creation of level t occurs in at most s_0 summands, with weights no larger than r_t. Rearrangement therefore gives

$$\sum_n r_n o_n \leq 2C_1 \sum_n r_n l_n + 2C_1 s_0 \sum_t r_t n_t^{\mathrm{cr}}. \tag{4.cdlxxxiv}$$

There is no initial-height term. This is the first reason the estimate is uniform in the number of levels.

4.18.5.1. Waiting only for the light part. A quiet node contains no new creation, has one predecessor and does not immediately follow a mark. Along a quiet stretch the side lengths in cells satisfy, for a fixed A,

$$\alpha_{n+1} \leq \alpha_n + A, \qquad \alpha_{n+2} \leq L^{-1}\alpha_n + 2A. \tag{4.cdlxxxv}$$

Iteration on either parity gives $\alpha_{n+2m} \leq L^{-m}\alpha_n + 2A/(1 - L^{-1})$. The smallness threshold in the dynamic class is chosen strictly above this fixed point and the intervening one-step enlargement. A light node has uniformly bounded side length by eq. 4.cdlxxxi: an h_0-connected set with at most

$\nu_\star$ cells has a spanning path of bounded diameter. After a fixed further number b_0 of quiet levels, the component is small and is a single box evolving by the prescribed free rule.

The preparation depths satisfy $\bar N_n \le R_n + 1$, with a non-increasing majorant, and the lower preparation endpoints are strictly increasing. These are the admitted size-profile conditions of the dynamic construction. After at most another $\bar N_t + 3$ quiet levels from a light node of level t, the entire preparation window lies after the event that began its stretch. Quietness, quarantine including the lower endpoint, depth and single-box traces then all hold. The full dynamic class acts on the component. Hence a stretch begun at level t contains at most

$$T_t = b_0 + \bar N_t + 3 \le C_T R_t \tag{4.cdlxxxvi}$$

light nodes. The numbers T_t can be taken non-increasing. Before these light nodes a stretch can have many heavy nodes; they have already been controlled by eq. 4.cdlxxxiv. Replacing this argument by a uniform bound on the whole stretch would incorrectly discard the time needed to shrink a large component.

There is a uniform terminal alternative on a small torus. If a light component or its fixed required collar has no embedded cell chart, some periodic cell side is at most a fixed constant $C_\star = C_\star(h_0, \nu_\star, e)$, enlarged for the other fixed collars. Otherwise the bounded-diameter connected lift of that component and its collar would embed. After q further levels the same periodic cell side is divided by at least $L^{\lfloor q/2 \rfloor}$. It must remain at least one at every admitted partition. Thus at most $2\lceil \log_L C_\star \rceil + 1$ levels remain. Increase the fixed constant in eq. 4.cdlxxxvi to include them. The proof then stops at the terminal level; it does not claim existence of a nonwrapping box background for a wrapped component.

There are three ways a stretch begins: a node contains a creation of its own level, it follows a keeping mark, or it is a merger with at least two predecessors. Charge the first kind to one of its new creations and the second to its preceding mark. To handle a merger, choose at every non-leaf node a first predecessor. At a merger choose one non-first predecessor and descend through first predecessors to a leaf. Assign that leaf to the merger.

This assignment is injective. If two merger nodes are incomparable, their leaf sets are disjoint. If one lies below the other, a path from the assigned leaf to its merger first enters that merger from a non-first predecessor. A descent by first predecessors from the higher node cannot follow that same branch through it. Thus it cannot reach the same assigned leaf. A leaf contains a creation; one of its creation cells pays for the assigned merger. A creation can pay for its own start and for at most one merger. This fixed multiplicity is the second reason the count has no dependence on height.

Because $T_n r_n$ is non-increasing, paying at the lower level of an assigned creation or mark only increases the available weight. Summing the at most T_t light nodes on every stretch and then using eq. 4.cdlxxxi and eq. 4.cdlxxxiv proves

$$\boxed{\sum_{u \in \mathcal{G}(x)} r_{n(u)} |C(u)|_{n(u)} \le C_2 \sum_t T_t r_t n_t^{\mathrm{cr}}(x) + C_2 \sum_t T_t r_t n_t^{\mathrm{mk}}(x).} \tag{4.cdlxxxvii}$$

The root's own mark is excluded from n_t^{mk}. It has not yet supplied a renewed wait. The constants depend on the fixed local geometry and L, not on the number of levels, the component size or the torus volume.

4.18.6. *The scalar reserve and its coupling threshold.* Let G_t be the gain per creation, P_t the gain per mark and c_t the cost per cell at level t. Choose a non-increasing majorant $r_t \ge c_t$. Define

$$\mathfrak{F}(x) = \sum_t G_t n_t^{\mathrm{cr}}(x) + \sum_t P_t n_t^{\mathrm{mk}}(x) - \sum_{u \in \mathcal{G}(x)} c_{n(u)} |C(u)|_{n(u)}. \tag{4.cdlxxxviii}$$

If

$$G_t \ge 2P_t + C_2 T_t r_t, \qquad P_t \ge C_2 T_t r_t, \tag{4.cdlxxxix}$$

then eq. 4.cdlxxxvii gives

$$\mathfrak{F}(x) \geq 2 \sum_t P_t n_t^{\mathrm{cr}}(x). \tag{4.cdxc}$$

Every nonempty genealogy has a leaf and therefore a creation. If $P_t \geq (1+\beta_0)^{-1} P_i$ for $t \leq i = n(x)$, the last bound is at least $2(1+\beta_0)^{-1} P_i$. The reserve is taken from the creation gain; a mark in this conservative calculation can spend all its credit on the later wait.

Here are sufficient quantitative choices. Assume R_t is comparable to ℓ_t^r, with fixed $r \geq 1$, and put

$$P_t = p_0(g_t) = A_0 \ell_t^p, \qquad G_t = c_G P_t^2, \qquad r_t = C_3 c_1 M^4 R_t^5, \qquad p \geq 6r+1. \tag{4.cdxci}$$

Here $c_G > 0$ is a fixed gain constant, distinct from the bare spacing a_0 in eq. 4.cdlxi. The actual cost $c_1 \ell_t (M R_t)^4$ is bounded by this r_t, since $\ell_t \leq C R_t$. Also $C_2 T_t r_t \leq C_4 c_1 M^4 \ell_t^{6r}$. Thus eq. 4.cdlxxxix follows from a lower bound

$$\ell_t \geq K(1+c_1), \qquad c_G A_0 \ell_t \geq 4, \tag{4.cdxcii}$$

after increasing a fixed K. To verify this explicitly, divide the cost bound by P_t. The quotient is at most $(C_4 M^4/A_0) c_1 \ell_t^{-(p-6r)}$, at most a prescribed small constant once eq. 4.cdxcii holds. Divide the remaining condition $c_G P_t^2 \geq 2P_t + C_2 T_t r_t$ by P_t and use the second condition, increasing K if necessary. Only one extra logarithmic power is needed. In particular the lower threshold may be affine in the coefficient of the volume weight.

For reference sequences with $\theta_t \geq \theta_i - c_5$ for $t \leq i$, one has $\log \theta_t \geq \log \theta_i + \log(1 - c_5/\theta_i)$. For a sufficiently high coupling floor the ratio of its p-th power to ℓ_i^p is at least $(1+\beta_0)^{-1}$, uniformly in $t \leq i$. This proves the comparison used after eq. 4.cdxc, without assuming exact monotonicity of the reference couplings.

There is a useful consequence for an unfinished component $z = (j, Z)$. Here unfinished means that its root is neither healed nor marked. Continue it freely for q levels, stopping before a new creation, merger or completed wait. The genealogy and its gains are unchanged; only the later cell costs are added. Apply eq. 4.cdxc to the extended genealogy. If t_0 is its first creation level, the sum of its creation credits is at least P_{t_0}. Therefore

$$\kappa(z) := \mathfrak{F}(z) - 2P_{t_0} \geq \sum_{n=j+1}^{j+q} c_n |S^{n-j} Z|_n \geq 0. \tag{4.cdxciii}$$

The extension is cut at the terminal level if necessary. It is important to stop before the completed wait: withholding an eligible component would change the dynamic construction. The formula shows exactly what portion of the old reserve is available to pay for the future quiet evolution.

For comparison, if a separately admitted continuation begins with a just-marked root, that mark becomes a non-root mark of the extended genealogy. Its gain is then added once: the corresponding available expression is $\mathfrak{F}(z) + P_j - 2P_{t_0}$, not the unmarked expression in eq. 4.cdxciii. This observation does not assert the admission of such a continuation or spend the same mark a second time.

4.18.7. *The entropy of the outer records.* The outer indices include choices of regions and tests, not just a choice of frame. We give a counting argument that includes their positions. Make a graph whose vertices are cell addresses together with their levels. Join neighboring cells at one level and join each cell to its parent at the next level. The degree is bounded by

$$D \leq L^4 + 3^4 + 2. \tag{4.cdxciv}$$

At a size drop the parent has only one child in this address graph; otherwise it has at most L^4. On a torus some neighboring addresses can coincide, which only decreases the bound. The outer component is rooted at a fixed cell of X. Its active cell addresses form a connected set by the hull and merger rules. If a local convention requires a bounded additional collar, include it in the active record and its already specified volume.

In any graph of degree at most D, the number of connected vertex sets of size N containing a fixed root is at most

$$D^{2(N-1)}. \tag{4.cdxcv}$$

Indeed, put a fixed order on the neighbors. For a connected set choose its canonical rooted spanning tree, and walk around that tree in depth first order, traversing each edge twice. The walk has length $2(N-1)$ and its visited set determines the original set. Each step has at most D choices. This count includes possible birth levels and translations of an old creation within a coarse component; they are encoded in the path down the address graph. There is no extra factor equal to the torus volume or to the total height.

For a fixed active set A, the remaining discrete record has at most

$$\exp\{bV^\circ(A)\} \tag{4.cdxcvi}$$

possibilities, for a fixed b. Here is the finite coding condition behind this estimate. A cell of level n contains $O((MR_n)^4)$ sites and bonds. Each local decomposition has a fixed finite list of outcomes, and a fixed finite number of such tests is attached to each site or bond. Specify these outcomes by letters from a fixed finite alphabet. The stage place and the local failure type have at most a fixed power of R_n+1 possibilities per node; their logarithm is at most $C\ell_n$ since $R_n \asymp \ell_n^r$. Tree frames are treated by their normalized averages below. Lists of owned seam factors, node entrances and retained-variable types use the same finite local addresses, not arbitrary new continuous parameters. These facts prove eq. 4.cdxcvi by multiplying the local counts. A proposed history representation with another discrete choice must include its code and its cost here before this estimate is applied.

There are $1+f(\omega^\circ)$ independently recorded outer frames, including the artificially inserted root frame when needed. Their normalized sum is at most one for each non-frame record. Since $V^\circ(A) \geq |A|$ for $\ell_n \geq 1$ and $MR_n \geq 1$, choose $c_{\mathrm{e}} \geq b + 2\log D + \log 2$. eq. 4.cdxcv–eq. 4.cdxcvi give

$$\begin{aligned}\sum_{\omega^\circ} h^{-1-f(\omega^\circ)} e^{-c_{\mathrm{e}} V^\circ(\omega^\circ)} \\ \leq \sum_{N\geq 1} D^{2(N-1)} e^{-(c_{\mathrm{e}}-b)N} \leq \sum_{N\geq 1} 2^{-N} = 1.\end{aligned} \tag{4.cdxcvii}$$

The outer component is nonempty, which is why the sum starts at one. An empty component instead represents the identity operation and has no rare-mass assertion. This exact upper bound of one will prevent an unwanted constant from accumulating at every induction step.

The coding condition is a condition on the literal finite construction. It must count every tested bond and every stage place. The connected-set argument then proves the uniform entropy bound; it is not an assumption that arbitrarily chosen discrete histories already have small total mass.

4.18.8. *Normalizer bounds with their complex branches.* We next isolate scalar and finite-matrix estimates that enter the integrable envelope. This keeps them distinct from the analytic problem of identifying the actual kept matrix.

4.18.8.1. The truncated gauge normalizer. Use the matrix operator norm and the sharp radial cutoff $|u-1|<\epsilon$, $0<\epsilon\leq 1$. If the class angle is $r\in[0,\pi]$, then $|u-1| = 2\sin(r/2)$. Thus this cutoff is exactly the monotone interval $0\leq t<t_\epsilon$ in $t = 1-\cos r$, with $t_\epsilon = \epsilon^2/2$. The same proof applies to a cutoff explicitly known to be such an interval with $t_\epsilon \geq c\epsilon^2$. Put

$$z(y,\epsilon) = \int_G 1_{\{|u-1|<\epsilon\}} e^{-y(1-\frac{1}{2}\operatorname{tr} u)}\, du. \tag{4.cdxcviii}$$

Haar measure is normalized to one. This is an entire function of y. For real $x\geq 1$ and $x\epsilon^2 \geq 1$ it satisfies $cx^{-3/2} \leq z(x,\epsilon) \leq Cx^{-3/2} \leq C$; also $z(x,\epsilon)\leq 1$. The lower bound follows by integrating a Lie-algebra ball of radius $c_0 x^{-1/2}$: it lies in the cutoff, the exponential is bounded below there, and the Haar chart density is bounded below. For the upper bound use $1-\cos r \geq cr^2$ on $0\leq r\leq \pi$

and the radial Haar density. Both estimates have constants uniform in the cutoff satisfying the displayed condition.

The required complex branch can also be proved uniformly, without assuming that an integral of positive real values remains nonzero after complexification. Write $t = 1 - \frac{1}{2}\operatorname{tr} u = 1 - \cos r$. The radial Haar density is a constant times $t^{1/2}(2-t)^{1/2}\,dt$, $0 < t < 2$; the cutoff restricts this to $0 < t < t_\epsilon$. Thus at $y = a + ib$, $a > 0$, $z(y,\epsilon)/z(a,\epsilon)$ is the expectation of e^{-ibt} under a probability density proportional to $t^{1/2}e^{-at}w(t)$, where $w(t) = (2-t)^{1/2}1_{\{t<t_\epsilon\}}$ is nonnegative and non-increasing.

For completeness, decreasing reweighting lowers increasing moments. If ρ is a probability, f increases and w decreases, then

$$\operatorname{Cov}_\rho(f,w) = \tfrac{1}{2}\iint (f(s)-f(t))(w(s)-w(t))\,d\rho(s)d\rho(t) \le 0.$$

Divide by $\rho(w) > 0$ to obtain $\rho(fw)/\rho(w) \le \rho(f)$. Apply this with the gamma density proportional to $t^{1/2}e^{-at}$ and $f(t) = t^2$. Two integrations by parts show its second moment is $15/(4a^2)$. Since $\cos v \ge 1 - v^2/2$ for every real v, it follows that

$$\operatorname{Re}\frac{z(a+ib,\epsilon)}{z(a,\epsilon)} \ge 1 - \frac{15b^2}{8a^2}.$$

On $|y-\theta| \le \theta/2$, elementary geometry gives $|b|/a \le 1/\sqrt{3}$. Indeed this inequality is equivalent to $3b^2 \le a^2$, whose worst ratio on that disc occurs at its tangent from the origin. It also follows by maximizing $[(\theta/2)^2 - (a-\theta)^2]/a^2$ for $\theta/2 \le a \le 3\theta/2$. Hence the last real part is at least $3/8$. In particular $z(y,\epsilon) \ne 0$ throughout that disc. When $\theta\epsilon^2 \ge 1$, the real bounds, with their threshold changed by a fixed factor if necessary, give $|z(y,\epsilon)|^{-1} \le C\theta^{3/2}$ there.

Here the lower floor can be seen directly. The fixed norm gives $t_\epsilon \ge c_{\mathrm{cut}}\epsilon^2$. Choose a fixed $0 < c_0 < \min(1, c_{\mathrm{cut}}/2)$. The interval $0 < t < c_0/\theta$ lies inside the cutoff because $\theta\epsilon^2 \ge 1$. On it $(2-t)^{1/2} \ge 1$ and $e^{-at} \ge e^{-3c_0/2}$ for $a \le 3\theta/2$. Integration of $t^{1/2}$ on this interval proves $z(a,\epsilon) \ge c\theta^{-3/2}$. Combining it with the $3/8$ real-part bound proves the asserted inverse estimate. The cutoff is frozen at its real reference value throughout: neither ϵ nor its characteristic function is varied with y. Decreasing reweighting alone would not supply this lower floor for an arbitrarily vanishing cutoff.

There is a unique logarithm on the open disc agreeing with the real logarithm at θ. The closed-disc bounds follow by continuity. Thus a kept inverse gauge normalizer costs at most $C + \frac{3}{2}\ell_j$ in the logarithmic budget even on this complex disc. This proves the normalizer part of the parameter extension; it does not assert a parameter extension for the other factors.

4.18.8.2. The pivot factor. On an admitted one-step contour chart the three-color pivot matrix is the per-length averaging derivative m_c. Its identity value is $L^{-4}I$; the raw logarithmic pivot derivative instead has identity value $L^{-3}I$. In the per-length convention it obeys

$$|L^{12}\det \mathsf{m}_c - 1| \le \tfrac{1}{2}, \qquad \ell_c = 12\log L - \log(L^{12}\det \mathsf{m}_c), \qquad e^{\ell_c} = (\det \mathsf{m}_c)^{-1}. \tag{4.cdxcix}$$

The logarithm is its power series about one, so $|\ell_c - 12\log L| \le C$. On the real admitted chart the determinant has the positive identity sign, and this equals the inverse absolute determinant for the per-length averaging coordinates. The actual real operation also retains the conversion factors from raw averaging and Haar coordinates and its other chart Jacobians. There is no holomorphic absolute-value determinant. The local averaging-chart theorem supplies eq. 4.cdxcix once its small-field and embedding hypotheses hold. Its use at every retained layer additionally requires that the actual iterated averages exist and fall in those local charts; a one-step statement alone does not verify that multi-level premise.

Each scalar coordinate, bond direction and local gauge variable is charged to its owning site. The inverse gauge normalizers in eq. 4.cdxcviii, the pivot factors in eq. 4.cdxcix, and the rescaling

powers of $g_j = \theta_j^{-1/2}$ therefore have combined modulus at most $\exp(CV^\circ)$, provided their number at level j is at most a fixed multiple of the stored sites there. Chart Jacobians with uniform local upper and lower bounds have the same property. The identity value of the pivot determinant fixes its power L^{12}; counting the same three colors again in this factor would be an error.

4.18.8.3. The normalization numbers at their own levels. The numerical parts in the collar sum are distinct from the real normalization number retained by an operation. In the notation of the step, the latter is $e_X = n_X - n_G(X)\log(\theta_t^{-3/2}\sigma_0)$, where $n_G(X)$ is the number of integration bonds of the reference law and σ_0 is the Haar density at the chart origin. Here n_X subtracts the normalization of the label with X adjoined to its regions and all marks in X removed, including its own, from the current label normalization. It includes the stage and drop-out numbers. Its ordinary step part is the sum, for $1 \le j \le t$, of $N^{(j-1)}(\Omega_j^{\mathsf{a}}, \Lambda_j^{\mathsf{a}+}) - N^{(j-1)}(\Omega_j^{\mathsf{a}} \cup X, \Lambda_j^{\mathsf{a}+} \cup X)$, with the action region and collared integration region of eq. 4.cdlxiv. In this formula,

$$N^{(j)}(\Omega,\Lambda) = (\log\sigma_0 - \tfrac{3}{2}\log\theta_j)|\Omega^{(j)*}| \\ - (L^4-1)\log z(\theta_j)\,|\Omega|_{j+1} + (\nu_{\mathfrak{g}} - \tfrac{3}{2}\log(x_j/\theta_j))|\Lambda^{(j)*}|.$$

The three counts are respectively the fluctuation bonds, the level-$(j+1)$ sites and the nonpivot integration bonds of level j. Here z is the single-site gauge normalizer and $\nu_{\mathfrak{g}}$ is the logarithm of the standard unnormalized Gaussian integral on $\mathfrak{g}$. The real normalization stays in Φ°_ω or in the identical normalization of the reference measure. The retained powers of θ_j are charged at level j in the volume eq. 4.cdlxxv.

For complex normalization weights y_j with $|y_j - x_j| \le \bar{c}$, while the bare and net Wilson weights stay fixed, let $\mathfrak{g}_j(X)$ count the integration bonds of level $j-1$ added when X is joined to $\Lambda_j^{\mathsf{a}+}$. The exact scalar difference is

$$e_X[y] - e_X[x] = \tfrac{3}{2}\sum_{j=1}^{t} \mathfrak{g}_j(X)\left(\log\frac{y_{j-1}}{\theta_{j-1}} - \log\frac{x_{j-1}}{\theta_{j-1}}\right).$$

Indeed the stage and drop-out numbers here use only reference weights and the first two terms of $N^{(j)}$. In the ordinary step difference, only the last logarithm changes. The logarithms use their common branch near the real positive weights, with $|x_j - \theta_j| + \bar{c} < \theta_j/2$ at every level. If the added bonds are covered by one layer around the $z_j(X)$ owned M-cubes, then $\mathfrak{g}_j(X) \le 4\cdot 3^4 M^4 L^4 z_j(X)$. Each enlarged cube accounts for at most M^4L^4 sites of level $j-1$, and there are four positive bonds per site. Using the bound 2 for the logarithm derivative on the common half-disc and $N_0 \ge M^4\sum_j z_j(X)$ gives

$$|e_X[y] - e_X[x]| \le 972 L^4 \bar{c}\,(\min_{0\le j<t}\theta_j)^{-1} N_0(\omega).$$

In the sourced comparison this difference is added to the new excess in eq. 4.dxvi. The real $e_X[x]$ can carry logarithms of the reference weights, which are counted at their own levels in eq. 4.cdlxxv.

4.18.8.4. The complete quadratic form. The real physical weight x and the reference weight θ have different roles. Write $\tau = x/\theta$. If K_A is the physical action part and K_G is the reference gauge part of the actual free-coordinate Hessian, the complete quadratic exponent uses

$$Q_\tau = \tau K_A + K_G, \qquad K = K_A + K_G, \qquad e^{-B^{\mathsf{T}}Q_\tau B/2} = e^{-\tau B^{\mathsf{T}}KB/2} e^{(\tau-1)B^{\mathsf{T}}K_G B/2}. \tag{4.d}$$

Both matrices are in the actual free coordinates of the constraint chart. The last factor compensates for the use of τK in the normalized reference Gaussian. For unnormalized input the prefactor is the Gaussian mass of τK. With a normalized incoming precision D_0 it is the ratio of that mass to the Gaussian mass of D_0. Using Q_τ directly instead gives its own Gaussian mass and omits the compensating potential.

Here is a sufficient full half-disc estimate. Suppose K_A, K_G are real symmetric, $K_G \ge 0$, $K_A \ge -\varepsilon I$ and $K \ge \gamma I$ with $\varepsilon \le \gamma$. For $|\tau - 1| \le 1/2$, put $s = \operatorname{Re}\tau$. If $s \le 1$, $sK_A + K_G = sK + (1-s)K_G \ge$

$\gamma I/2$. If $s \geq 1$, $sK_A + K_G = K + (s-1)K_A \geq (\gamma - \varepsilon/2)I$. Therefore

$$\operatorname{Re} Q_\tau \geq \gamma I/2. \tag{4.di}$$

If the matrices have complex perturbations with $\frac{3}{2}\|\delta K_A\| + \|\delta K_G\| \leq \gamma/4$, the same argument gives $\operatorname{Re} Q_\tau \geq \gamma I/4$. This is a matrix estimate to be checked on the actual joint core. If instead a free evaluation directly specifies a complete complex form Q with $\operatorname{Re} Q \geq \gamma I$, that one-sided bound is sufficient by itself.

One must not multiply two independently accretive complex objects and retain the same conclusion. In one dimension, $K = 1 + 100i$ and $\tau = 1 + i/2$ have respectively positive real part and $|\tau - 1| = 1/2$, whereas $\operatorname{Re}(\tau K) = -49$. Nor should the compensating potential in eq. 4.d be bounded by its modulus while independently replacing $\operatorname{Re}\tau$ by its worst possible value: their real coefficients are correlated. Keeping the complete form avoids both losses.

4.18.9. *The integrable reference envelope.* We spell out the additional coordinate statement needed to integrate the stored Gaussian reserve. For each outer index there are finitely many real Lebesgue blocks $b_1, \dots, b_s$, together with normalized Haar variables. A permitted reference change of coordinates has triangular form $A_j = F_j(b_j; b_{j+1}, \dots, b_s, U)$ in a chosen order. For fixed later variables it is injective on its integration chart, and its inverse Jacobian is bounded by $J_0^{d_j}$, where d_j is the number of scalar coordinates in that block. It can be a translation, in which case this Jacobian is one. The actual stored-coordinate identity or its explicitly bounded chart Jacobian is required; the mere use of the symbol A_j does not provide it.

Suppose the unspent part of the complete forms gives at least $\beta \sum_j |A_j|^2$ in the exponent, for a fixed $\beta > 0$. Dropping restrictions only enlarges a nonnegative integral. Change the variables one block at a time, starting with the block whose later variables are held fixed. Each integral is at most the full Euclidean Gaussian integral. Induction over the blocks gives

$$\int \exp\{-\beta \sum_j |A_j|^2\}\, d\mu^\circ \leq J_0^{\sum_j d_j} (\pi/\beta)^{\frac{1}{2}\sum_j d_j} \leq e^{C_5 V^\circ}. \tag{4.dii}$$

The last inequality uses the actual coordinate count $\sum_j d_j \leq C N_0^\circ \leq C V^\circ$. Haar variables contribute at most one after positive restrictions are dropped. If the coordinate image is only a subset, the same upper bound holds. Surjectivity onto a product is not needed.

For a more general actual reference map it is enough to construct directly a nonnegative Borel function g_{ω° with this integral bound and with the pointwise domination used below. Such a construction is a real integration estimate. It cannot be replaced by a statement that a complex Gaussian at each fixed external argument has a small partition function.

For a completed main operation whose core contains no earlier marks, the reference coordinates can be read directly from its integral. The one-step operations in that core integrate the stored strip fields $\mathcal{A}_j^{\mathrm{s}}$ against Lebesgue measure. Changing the background changes their quadratic forms and elimination factors, but does not change these integration variables. The main operation also integrates a field B on the shells, with the single scaling g_t. The variable B stays fixed when the external pair changes, even though the reconstruction of the group field uses the background. Its tree gauge sets the tree bonds to zero and has Jacobian one; on the remaining bonds the carried test is

$$\chi'(B) = \mathbf{1}_{\{|B| < r_t\}}, \qquad r_t = \delta_t'/g_t = A_1 p_1(g_t).$$

Here the averaging constraints can be eliminated from the top down: the outgoing coarse field is integrated in the main operation, and integration of its delta function sets it equal to the average of the preceding field. The remaining group variables carry normalized Haar measure. Chart densities and normalizers remain among the factors estimated separately above.

Suppose the complete kept forms leave the reserve $\beta\sum_j|\mathcal{A}_j^{\mathrm{s}}|^2$ after the event gains have been extracted. If there are n_A free strip bonds and n_B free shell bonds, a reference function is

$$g_\omega(B,\mathcal{A}^{\mathrm{s}})=\chi'(B)\exp\Bigl(-\beta\sum_j|\mathcal{A}_j^{\mathrm{s}}|^2\Bigr),\qquad\int g_\omega\,d\mu^\circ\le[C(1+r_t)]^{3n_B}(\pi/\beta)^{3n_A/2}.\tag{4.diii}$$

Indeed, enlarge the domain to the product of the cutoff balls for B, the full Euclidean spaces for the strip fields, and the full compact groups. The three factors are respectively a finite volume, ordinary Gaussian integrals, and a Haar mass of one. This estimate is uniform in the background and uses no change of coordinates for the strip fields.

If N_P pivot-elimination factors J_c remain in the integrand relative to this product measure, use the Borel majorant $J_*^{N_P}g_\omega$, provided the actual pivot charts satisfy $|J_c|\le J_*$. For the convention $J_c=|\det\mathsf{m}_c|^{-1}$, the stated regular-chart estimate is $J_*=2L^{12}$. On an admitted full row the least singular value of $\mathsf{m}_c(V)$ is at least $L^{-4}(1-\kappa_9L^3\varpi)$, where ϖ bounds the plaquette defect of its chart. The determinant bound follows for $\kappa_9L^3\varpi\le1-2^{-1/3}$. In a fixed common real frame change u, the coefficient transforms as

$$\mathsf{m}_c(V^u)=\mathrm{Ad}(u(c_-))\,\mathsf{m}_c(V)\,\mathrm{Ad}(u(b_0(c)_-))^{-1}.$$

Both rotations preserve its absolute determinant. The physical Haar derivative is $L\mathsf{m}_c$, with inverse density $L^{-3}|\det\mathsf{m}_c|^{-1}$. The carried elimination factor above uses its stated normalized convention. This calculation keeps u fixed in the pivot derivative and requires the same admitted row and pivot. The local count $N_P\le CV^\circ$ absorbs this additional factor. Factors already estimated separately are not inserted a second time.

To express the bound in terms of V°, let $n_{B,j}$ count the free shell bonds on the lattice of level j, so that $n_B=\sum_{j\le t}n_{B,j}$. The local coordinate count is $n_A+\sum_{j\le t}\ell_jn_{B,j}\le CV^\circ$; strip bonds of level j belong to their one-step operation at level $j+1$. The fixed lattice ratio is included in this constant. Since $r_t\le C\ell_t^{\mathfrak{p}_1}$ and $\ell_t\le2\ell_j$ for $j\le t$, the logarithm of the right-hand side of eq. 4.diii is at most CV°. Thus this class has an explicit Borel reference function. Keep χ' when discarding the main quadratic form. The event payments in this bound use the retained Wilson and gauge weights and the strip forms with their stated reserve. For a drop-out with fixed outgoing field we must still identify the reference coordinates with that constraint in place.

A drop-out that leaves after the central box integration has a different reference measure from one that leaves during a stage or at the extendibility test. The central integration has already integrated the incoming top field. The fresh Haar field left in the box is a new variable; holding that field fixed does not restore a constraint on the old incoming field. The frame operation retained by a late drop-out includes this completed integration and its tree gauge. Its old averaging chain is therefore eliminated from the top down, just as in the completed main operation.

Suppose the core contains no earlier marks, and retain the shell variables in their original group coordinates. The non-tree shell bonds then carry normalized Haar measure, also when the test χ' fails. The tree gauge has Jacobian one. Thus this case does not need the cutoff volume in eq. 4.diii. Let n_j count the retained gauge normalizers at level j, let n_A count the free stored strip bonds, and let N_P count any remaining pivot factors. Under the actual reserve and chart bounds stated above, a Borel majorant for the reference part is

$$J_*^{N_P}\prod_j\mathfrak{z}(\theta_j,\varepsilon_j)^{-n_j}\exp\Bigl(-\beta\sum_j|\mathcal{A}_j^{\mathrm{s}}|^2\Bigr).$$

Indeed the gauge exponentials and the remaining characteristic functions are at most one. Integration in the old stored coordinates gives the bound

$$J_*^{N_P}\prod_j\mathfrak{z}(\theta_j,\varepsilon_j)^{-n_j}(\pi/\beta)^{3n_A/2}.$$

The scalar estimate $\mathfrak{z}(\theta_j,\varepsilon_j)^{-1} \le C\theta_j^{3/2}$, together with the own-level coordinate count, bounds this by e^{CV°. Scalar factors already included in the normalization estimate are counted only once. This reference bound applies to the late exits at the shell-field or last-shell tests. Merely having completed all preparatory stages is insufficient: an exit at extendibility still precedes the central integration and retains its fixed-output constraints. The complete interaction estimate, the energy payments and admission of the actual evaluation remain separate requirements.

One fixed-outgoing-field case is covered by the regular fibre charts. Consider a drop-out before any stage has re-made a level, with no earlier marks. Suppose every averaging constraint in its retained operations is already consumed by the regular pivot elimination, so that no factor $dV_j\,\delta(\mathcal{M}(V_j)V_{j+1}^{-1})$ on Ω_{j+1}^{c} remains. The outgoing field V_t is held fixed. For each retained step the exact fibre chart solves $\mathcal{M}(V_j)=V_{j+1}$ for the pivot variables; its free strip coordinates are the stored $\mathcal{A}_j^{\mathrm{s}}$. Thus these constraints need not be removed by integrating V_t. The reference integral is already an iterated Lebesgue integral in the free strip coordinates, with the coarea and chart factors in the integrand.

Suppose the actual pivot charts have the bound $|J_c| \le J_*$, the remaining densities have the separately established scalar bound, and the complete forms leave $c_{\mathrm{res}}\sum_j |\mathcal{A}_j^{\mathrm{s}}|^2$ after the required payments, with $c_{\mathrm{res}}>0$ independent of the outgoing field. If there are N_P retained pivot factors and n_A free strip bonds, the reference part is bounded by the Borel function

$$J_*^{N_P}\exp\Bigl(-c_{\mathrm{res}}\sum_j |\mathcal{A}_j^{\mathrm{s}}|^2\Bigr), \qquad \int J_*^{N_P} e^{-c_{\mathrm{res}}\sum_j |\mathcal{A}_j^{\mathrm{s}}|^2}\,d\mathcal{A}^{\mathrm{s}} = J_*^{N_P}(\pi/c_{\mathrm{res}})^{3n_A/2}.$$

Restricting this function to the actual chart only decreases its integral. The local coordinate count bounds the result by e^{CV°, uniformly in the fixed outgoing field for which these same chart and reserve bounds hold. The estimate concerns the reference part; the complete interaction bound and admission of the actual evaluation remain separate requirements.

If an unresolved averaging factor survives, positivity alone does not give this conclusion. Its normalization integrates the outgoing field, whereas the drop-out keeps that field fixed. Nor does disintegration into conditional probability measures remove the problem: their base measure is the actual pushforward of the fine measure, whose density relative to outgoing Haar measure has not thereby been bounded.

A remaining Haar averaging factor can also be estimated when its carried support lies in one of the ordinary regular fibre charts. Keep its outgoing field W fixed and write the exact chart in unscaled free coordinates a as

$$V_W(a) = e^{i\psi_W^{\mathrm{lin}}(\mathsf{C}_W a)}p_W, \qquad \mathcal{M}(V_W(a)) = W.$$

The fixed-fibre coarea formula on this chart gives

$$\int_D F(V)\,\delta(\mathcal{M}(V)W^{-1})\,dV = \int_{D_W} F(V_W(a))\rho_W(a)\,da.$$

The complete chart density ρ_W includes the pivot elimination factors, the determinant of the nonlinear linearising map, the Haar densities, and the fixed powers of L from the group delta functions. Suppose the chart is admitted on $|a(b)|<r_L$, where r_L is fixed, and its stated local estimates give $\rho_W \le C_L^N$, with N the number of fine bonds in these double blocks. There are at most N free bonds, so

$$\int_D \delta(\mathcal{M}(V)W^{-1})\,dV \le C_L'^N.$$

The bounded coordinate box supplies the volume bound for this Haar factor. The variables here are unscaled. If scaled variables are used instead, their scaling Jacobian must remain in ρ_W.

This covers the averaging factors on the belt $\Omega_t^{\sim}\setminus\Omega_t$ wherever the two retained step-t tests pass and the step-t averaging constraint is imposed on the full double blocks. The plaquette and approximate fluctuation tests put the free bonds in the chart of their prescribed background. In

that chart the constraint solves the pivot with contraction defect $O(L^{-3})$. The bound uses these tests at the birth of the factor, in its original gauges. For the remaining Haar factors the contour formula gives a direct bound whenever the averaging pivot is one of the integrated bonds. A regular extension of the coarse datum only supplies a single candidate fine field.

The total contour formula gives a useful description of the remaining one-row problem. Fix all fine bonds except the middle corridor bond of a coarse bond c, and put $q = U[c]$. Haar measure in the middle bond becomes Haar measure in q. For each of the L sites on the central coordinate axis of $B(c_-)$, the contour family has a single member, and cancellation of the backtracking portions gives

$$U(\Gamma)U([x, x'])U(\Gamma')^{-1} = U[c].$$

These terms contribute zero to the logarithmic sum. Every other joining path avoids the middle bond, as do both endpoint contour families. Thus, on the literal-contour branch, the row has the form

$$F(q) = \exp\left(\sum_{r=1}^{N_c} \alpha_r \log(H_r q^{-1})\right) q, \qquad \alpha_r > 0, \quad \sum_r \alpha_r = 1 - L^{-3}, \qquad N_c \le (4!)^2(L^4 - L),$$

where the H_r depend only on the other fine bonds. Its intrinsic logarithms are defined except at the finitely many values $q = -H_r$. Moreover the norm of the exponent is at most $\pi(1 - L^{-3})$. On the regular branch the same form holds with the averaged endpoint contours in place of the literal contours and at most $L^4 - L$ terms. Their values are again independent of the middle bond.

4.18.9.1. Haar measure for a single averaging pivot. Identify $G = \mathrm{SU}(2)$ with the unit round three-sphere. Write $\exp_q$ and $\log_q$ for its Riemannian exponential and principal logarithm. The formula at a fixed set of nonpivot bonds is, on either logarithmic branch,

$$F(q) = \exp_q(w(q)), \qquad w(q) = \sum_i \alpha_i \log_q H_i, \qquad s = \sum_i \alpha_i = 1 - \beta, \qquad \beta = L^{-3}.$$

Indeed right translation to the identity sends $\log_q H_i$ to the intrinsic group logarithm of $H_i q^{-1}$. Each H_i and α_i is fixed while the pivot varies. Consider this formula on the complement of all the antipodes of its anchors, before restricting it to the set on which its branch is used.

For a tangent vector v with $r = |v| < \pi$, set $H(v) = P_v + r \cot r\,(1 - P_v)$, with $H(0) = 1$. In the polar metric $dr^2 + \sin^2 r\, d\omega^2$, this is the Hessian at q of the half squared distance to $\exp_q v$. The logarithm is the negative gradient of this squared-distance function in the base point. Differentiate $\log_q F(q) = w(q)$ to obtain

$$B(w)\, dF_q = H(w) - \sum_i \alpha_i H(v_i), \qquad v_i = \log_q H_i, \qquad B(w) = D_2 \log_q(F(q)).$$

Use parallel transport back to q to compare the tangent spaces. In these coordinates $B(w)$ is positive with radial eigenvalue one and transverse eigenvalue $|w|/\sin|w|$, as follows by differentiating the exponential in polar coordinates.

The matrix function $1 - H(v)$ is convex in quadratic-form order. The cotangent expansion [DLMF, formula 4.22.3] gives

$$1 - H(v) = 2 \sum_{n \ge 1} \frac{|v|^2 I - v v^{\mathsf{T}}}{\pi^2 n^2 - |v|^2}.$$

For a unit vector e each summand tested against e is a positive multiple of $|P_{e^\perp} v|^2/(\pi^2 n^2 - |v|^2)$. The quadratic-over-linear function is convex and decreasing in its positive denominator. Its composition with the linear numerator vector and the concave denominator is therefore convex. Jensen with weights α_i/s gives

$$H(w) - \sum_i \alpha_i H(v_i) \;\; \ge \;\; H(w) - sH(w/s).$$

Writing $r = |w|$, the radial eigenvalue of the lower bound is β. The transverse eigenvalue divided by the transverse eigenvalue of $B(w)$ is $\sin(\beta r/s)/\sin(r/s) \geq \beta$, using concavity of sine on $[0, \pi]$. At $r = 0$ this holds by continuity. Thus the determinant of dF_q is positive and at least $\beta^3 = L^{-9}$.

The multiplicity is at most one for this formula with its fixed anchors. Combine coinciding anchors and let p be one of their antipodes, with weight a_p. As q approaches p along the unit tangent direction ω, the map tends to

$$\exp_p(b_p + \pi a_p \omega), \qquad b_p = \sum_{i:H_i \neq -p} \alpha_i \log_p H_i.$$

The limit is uniform in ω. The ball of vectors of centre b_p and radius πa_p lies inside $|v| < \pi$, since $|b_p| + \pi a_p \leq \pi s$. Replace each puncture by its sphere of directions and attach a ball mapping by $u \mapsto \exp_p(b_p + \pi a_p u)$ for $|u| \leq 1$. Give the attached ball the orientation of the original geodesic coordinates about p. Its interior map preserves orientation. The resulting continuous map of a three-sphere has degree one. To see this, multiply every weight by $t \in [0, 1]$ and use the same construction. At $t = 0$ the map collapses each attached ball to its puncture and agrees with the identity outside these collapses, hence has degree one. For a target off the finitely many cap boundary spheres, the preimages are finite and each has local degree $+1$. Degree additivity [Hat02, Proposition 2.30] therefore bounds the number of original preimages by one. Two original preimages of a target on a cap sphere would give two for an open set of nearby targets, by the local diffeomorphism property. This proves the same bound there.

The total row is a restriction of at most two such injective maps on measurable branch sets and is the identity in the corridor product on the remaining cut set. That set is finite for fixed nonpivots, by the literal-contour formula. Thus the pushforward of normalized pivot Haar measure has density at most $2L^9$ relative to normalized outgoing Haar measure. In particular, for every nonnegative normalized approximate identity δ_ϵ and every outgoing value W,

$$\int_G \delta_\epsilon(F(q)W^{-1})\, dq \leq 2L^9.$$

This upper bound is uniform even at an exceptional output. An exact Borel choice of fibre kernel is available. For each smooth branch take the inverse pivot on the image of its actual Borel branch set, with weight $|\det dF|^{-1}$. The map from the pair of nonpivot data and pivot to the pair of nonpivot data and outgoing value is a Borel injection on each such set. The branch sets and the graph of this map are definable, by the same finite formulas as for the real averaging map. Projection gives the image and the graph of the inverse, so both are Borel by cell decomposition. The Jacobian weight is Borel by the displayed derivative formula. Add the two kernels, using the zero measure on an empty branch. The resulting kernel has mass at most $2L^9$ for every target and gives the exact joint measure by change of variables on each branch. The finite fallback set has zero conditional incoming Haar measure and so contributes zero to this version of the kernel. For the version retaining the pointwise fallback branch, write $D_c(a)$ for its finite pivot set at nonpivots a. Since the row is the identity in the corridor product there, add $\mathbf{1}_{D_c(a)}(W)\delta_W(dq)$ to the kernel. This keeps the exact joint Haar measure and increases the pointwise bound to $2L^9 + 1$. The choice of version has to be identified if a prescribed target comes from a singular lower graph. Equality of the integrated joint measures does not identify their pointwise values on that graph. On a later gauge slice one must also check the actual order and gauge action of the stored operation.

The row kernel is covariant under the real site gauges of the row. The corridor product, the anchors and the output are all multiplied by the same two endpoint factors. The logarithmic branches and their cut sets are preserved. Left and right multiplication preserve Haar volume, so the inverse Jacobian weights are unchanged. In particular the kernel can be used before taking a gauge quotient when that is the order of the operation and the quotient acts on the corresponding joint measure.

4.18.9.2. Gauge draws with an outgoing value held fixed. Before discarding any variables, realize one partial history on the bare field, the frames and the fresh fields of the reference draws. Keep the temporary Haar variables of the reference boxes as separate coordinates until they are overwritten. The history weight is the product of its tests, gauge factors and reference factors, each evaluated on the field at the time of insertion.

Let u be a real gauge admissible for the specified draw. It is constant on blocks already gauged and equals one near the retained drop-outs and the retained second-class slices. At time s, use $u^{(s)} = 1$ on the inner boxes that will be remade after s, and $u^{(s)} = u$ elsewhere. On the bare field use $u^{(0)}$, and on a fresh field use $u^{(s)}$ for the time of its draw. The frames are unchanged. The temporary Haar coordinates can be transformed separately, since they carry no earlier test and are subsequently overwritten. The lifted change of variables preserves the bare Wilson measure, the fresh Haar factors and the retained slice measures. At a retained slice the lift is the identity.

Induct over the moves using covariance of the averages. Outside the boxes already remade, the current field transforms with the mask at the time of the read. On replaced rows later moves take the fresh field at its own level, and earlier factors retain their original arguments. Earlier blocks are either contained in a later inner box or disjoint from it, so the mask is still constant on each previously gauged block. The plaquette tests and the relative bond tests keep their norms. The inner tests use the transported tree or a slice on which the gauge is the identity. Reference normalizers transform with their defining integrals. Thus the lift preserves the history weight and intertwines the gauge action on its stored variables.

In a preparatory stage first impose the next-background regularity test. Then insert the new level-j gauge factors at the coarse centers in $((\Omega^{\sim 3}_{j+1})^c \setminus Z''_{j+1}) \cap Z$ whose blocks do not yet carry the factor. The other collar factors are retained from their earlier steps. The lift uses these actual block groups and the normalizer of each factor at its insertion.

For the ordinary draw the gauges fix all coarse centers. Its raw outgoing average W is therefore unchanged. Insert any bounded Borel $F(W)$ in the invariant history measure. Changing variables in the normalized gauge draw gives the same weighted integral as inserting the gauge factor as a product. This proves the identity of outgoing measures, also in the presence of any other prescribed coordinates fixed by the draw. On the pass support the contour variables used in the factor are defined. Outside that support the total kernel uses its separate normalized convention at undefined contours. A pointwise bound on a singular prescribed fibre still uses the corresponding branch or graph estimate.

On a row with a free Haar pivot the ordinary draw has a stronger fixed-output identity. Hold the nonpivot coordinates fixed before the draw, and write $q = V[c]$ for the straight corridor product. Both coarse endpoints are fixed by the gauge. Thus q, the coarse-endpoint contour anchors in its row map, and the criterion for the averaging branch are unchanged under the draw. The contour density of the draw uses only internal block links and is independent of q. At a prescribed output W, the pivot inverse in q therefore has the same branches and densities before and after the draw, using a common version at exceptional targets. Equivalently each normalized group approximation to the averaging delta has identical arguments on the two sides. The gauge integration in these coordinates is the normalized draw on the nonpivot data. For a later ordinary draw the old large region is excluded by the five-layer buffer. The blocks read by these contours and the neighboring endpoint blocks are in the old small-field region with its positive density tests. Their inherited plaquette bound implies that the contour means in the normalized density are defined. Other prescribed coordinates moved by the draw remain in the joint graph. An older reference-tree gauge that moves coarse endpoints requires its own row calculation.

In a nonwrapping one-step domain a pivot crosses the face between the two endpoint blocks of its row. No other coarse double block contains both ends of that fine bond. Thus, if every constrained row has a free integrated pivot, fixing all nonpivots gives a product of single-pivot maps. The preceding bound is then $(2L^9)^N$ for N constrained rows, uniformly in all the outgoing values. In a

stack of such integrals one may integrate the pivots from the finest level upward, keeping all still unintegrated coarse variables fixed. This supplies the Haar part of a positive reference bound on those stacked domains. The actual kernel requires a check that each pivot is present in its stated integration measure, that no pivot is also used as a separately stored coordinate, and that the stated charge counts the participating rows.

In the completed main-box operation the incoming averaging constraints have already been integrated when the frame tree is imposed. An older island can instead carry a restored field with a tree factor into a later averaging step. An interior middle bond can belong to that tree. For example, in the frame of a box comb whose last coordinate change is in direction one, the interior bonds in that direction are tree bonds. For a later row with a pivot on such a bond we must identify another free coordinate or work with an exact gauge quotient of the joint averaging law. A tree gauge moving the two coarse endpoints also acts on the prescribed output of that row.

The next ordinary block gauge is fixed at the coarse centers, so by covariance its insertion preserves that raw average. In addition it is applied outside the enlargement of the older input region. To see the role of the endpoint condition, take identity exterior and the identity box minimum. The restored cutoff bounds every bond in an interior double block by $C\varepsilon_i$ from identity. The average of its row is then within $C_L\varepsilon_i$ of identity. A Haar draw of an independent old gauge at one coarse endpoint instead gives that row a Haar marginal. Thus integrating those old gauges would change the raw law on this fibre. The Wilson weights can change the density inside its support; an estimate for the raw output still needs the variables of its actual chart.

4.18.9.3. Averaging the restored box in its tree slice. Fix the frame of one restored box $P = \Lambda_i^{\mathrm{prop}}$ and hold its exterior fixed. The box is a union of M-cubes of level i. Since M is a positive power of L on the nested centered grids, P is a union of whole level-$(i+1)$ blocks. Use a lift of the box, so that each coordinate line of blocks in it is a finite interval. Take direction one last in the chosen frame. In the restored variables $V_i' = V_i V_\Lambda^{-1}$ the tree fixes all interior direction-one bonds. It fixes just one boundary-crossing bond, the entrance. The other restored bonds with an endpoint in P carry product Haar measure. A row of the first ordinary average can read one of these variables only if at least one of its endpoint blocks lies in P.

For the derivative at the identity use dimensionless fine bond logarithms A. Let e_μ denote a fine unit vector and let

$$\varphi(y) = L^{-4} \sum_{x \in B(y)} \bar{A}(y, x),$$

where $\bar{A}(y, x)$ is the average of the path integrals along the symmetric contours in $B(y)$. For a row $c = (y, y')$ the derivative in the coarse bond logarithm is

$$(\mathbf{Q}^{\mathrm{lin}} A)(c) = \varphi(y) - \varphi(y') + L^{-4} \sum_{x \in B(y)} A([x, x + y' - y]).$$

In particular, when both blocks are in P and c has direction one, the straight-path term vanishes on the tree slice. Choose in each block $B(y)$ the fine bond $b_y = (y + e_1, y + e_1 + e_2)$. It lies strictly off the first coordinate face supporting the tree's direction-two bonds. Its coefficient ω_y in $\varphi(y)$ is positive. Indeed, the contour to $y + e_1 + e_2$ in order $1, 2$ uses it with positive sign, giving at least $(2L^4)^{-1}$, and every other contour using that bond has the same sign. No other block contour uses b_y.

On each direction-one line through P, leave the selected bond in the first block among the fixed variables. For each interior direction-one row, select $b_{y'}$ in its right block. Order the rows along the line. Each such row reads the current and at most the preceding selected bond. The diagonal derivative is $-\omega_{y'}$ on each color. For each remaining row, select a free fine bond crossing the face between its two blocks. In an interior transverse row the middle crossing bond is off the first coordinate face, hence free. In a boundary row the face has L^3 crossing fine bonds, at most one of which is the entrance. Every chosen face-crossing bond belongs to just that row among the double

blocks and is absent from the endpoint contours. Its coefficient in the straight-path average is L^{-3}. Order these rows after the interior direction-one rows. The square derivative in the selected variables is thus block lower triangular, with these nonzero diagonal blocks.

The same order gives a real chart on the restoration cutoff. Fix all unselected coordinates. On the full double block of a row take a real gauge of the fixed reference V_Λ with links close to identity, using the comb estimate in the admitted small-plaquette domain. The full blocks reach at most L fine spacings outside P. The prepared box is at distance at least $4M$ from Ω_{k_0+1} in level-i units and is inside $X \cap \Omega_i^c$, two coarse cells from X^c. Thus every full double block lies inside the region of the retained exterior tests and the extendibility comparison. The box minimum bounds the plaquettes meeting P by $C(M)\varepsilon_i$; on the remaining plaquettes it agrees with the prescribed exterior, whose retained density tests give the small-plaquette bound. On the cutoff the restored logarithms have size at most $M_0\varepsilon_i$. Conjugating the logarithms at their initial sites preserves the balls and fixes their zeros on the old tree. The output gauge acts by left and right translations at the coarse endpoints. Both changes preserve the corresponding Haar measures.

In the row's gauge the complete field on its double block is uniformly near identity. The analytic averaging formula therefore applies throughout the selected coordinate ball. The derivative of the row logarithm in its selected variable differs from its scalar diagonal derivative at the identity by at most $C(L, M)\varepsilon_i$. Take the coupling ceiling small enough that this error is less than half the absolute diagonal coefficient. On a convex relative-logarithm ball, integration of the derivative along the segment between two inputs bounds the difference of their outputs below by half the coefficient times the input distance. Thus the row map in this coordinate is injective with inverse Jacobian bounded by a fixed C_L for Haar measures. Fixed site conjugations and output translations return the bound in the original frame.

The row dependencies used for the triangular order are exact double-block dependencies of the nonlinear map. An interior direction-one row sees its two selected block links only. The remaining rows can also read previously selected block links, and each reads only its own selected face-crossing link. Use the one-row change of variables in this order to reconstruct the selected coordinates at a raw output. Equivalently, apply change of variables in the resulting triangular chart. The Jacobian product and the remaining normalized Haar coordinates give the bound $C_L^N\, dW$ on the joint output of the N rows meeting the restored box. This is a bound for the Haar slice restricted to the cutoff, before applying its density. The inverse on the chart and zero mass off its image give a Borel version, with the bound at every output. The joint graph over the unselected coordinates and the exterior is Borel, and the inverse is taken on that graph. All these changes hold with the actual fixed exterior values in the fibre.

After combining the restoration law with its old Wilson weight, use this chart with the core factor, the real form and the scalar prices assigned as above. The bound covers the whole first-step row stock of one restored box at fixed exterior. Its use in a subsequent constraint requires the joint-coordinate check below.

4.18.9.4. Disjoint row charts and their outgoing fields. At a fixed level i, let $P_a \subset X_a$ be the boxes restored in the distinct second-class components of the label, whose tree conditions remain in the output. Every double block used by a row meeting P_a lies inside X_a. Indeed $P_a \subset X_a \cap \Omega_i^c$ with the two-cell buffer of eq. 4.cdxliii, and a double block reaches at most L fine spacings past P_a. The X_a are distinct components on the same grid. Thus their first outgoing row sets are disjoint. Conditioning on the complement of the restored bonds fixes all the exterior coordinates in each box chart. In the ordinary step $i+1$ the complement of the new determining member contains the hull of the carried region Z_i enlarged by eight layers. The block-gauge draw is outside its five-layer enlargement. All the first outgoing double blocks of P_a lie inside $X_a \subset Z_i$, so they lie on the actual raw averaging rows and outside the next gauge draw. This applies even when the successor merges with another component. The waiting rule leaves these rows in place, including when $i+1$ is the

ordinary bottom of the later operation. The remaining rows have both blocks outside all restored boxes and use no restored coordinate.

This also identifies the input coordinates at the outer face of each second-class component. The top inner member of the prepared nest lies in P_a. Central integration consumes its last bare averaging graph and the old top bonds meeting P_a. After the draw the determining list contains every level-i bond meeting X_a. The tree constraint is only on bonds meeting P_a. Outside those bonds the output carries the original level-i Haar coordinates with the old weights; there is no remaining averaging constraint there from inside the island. In particular the physical exterior that supplies the centre of the restored law is read in the top coordinates of $X_a \setminus P_a$. The earlier core variables stay in the island integral.

Since X_a is a union of whole level-$(i+1)$ blocks, a row that reads a fine bond meeting X_a has an endpoint block there. If its two blocks miss P_a, its middle fine bond meets X_a and avoids P_a. It is one of these ordinary Haar inputs, even when the other block is outside X_a. The next-step enlargement contains the complete double block in the bare region. The one-cell separation of distinct same-level components prevents any such row from having a pivot in two components. The rows touching P_a and the remaining rows touching X_a together number at most $8\#_{i+1}(X_a)$. Charge them to the actual successor of the island, which contains their full blocks. Use the strong real bound for the old island integral at its admitted argument. The tree condition on the fresh restored field is outside that integral and belongs to the first outgoing chart.

On any additional bare row having an actual free Haar pivot, use its middle face bond. That bond crosses between its own two blocks, so a row of a box chart cannot read it. Conversely an ordinary row with both blocks outside all boxes reads none of their selected coordinates. First solve the ordinary rows outside the boxes at fixed unselected coordinates. These row maps do not use the fresh box fields. Reconstruct the ordinary pivots and fix that resulting physical exterior. Then use the simultaneous chart for each disjoint box stock. The reference field of a box may depend on the reconstructed exterior, so it is fixed at this second step. Fubini's theorem gives the product of the inverse-density bounds in this order. Any retained weights are evaluated at the resulting inverse graphs. In each recorded frame write the fresh field as $V'V_\Lambda(e)$ at its reconstructed exterior e. The reference tree fixes V' on the same bonds for every such e in that frame, and right multiplication preserves the relative Haar measure on the non-tree coordinates. Bound the outgoing density uniformly in e on this relative chart. If an outside input to one of the ordinary rows comes from a lower graph, keep it in that joint measure while reconstructing e. The frame and denominator are those of the original summand. The actual tests restrict the domain of the chart. The number of rows touching a box is at most eight times its number of coarse blocks. The successor contains the propagated component and hence these row blocks. Charge the rows to its sites at level $i+1$. The disjointness at one level and the waiting rule for successive marks count each assigned row once. Thus the product of the first-box chart constants has an exponential cost in the corresponding site-level count of eq. 4.cdlxxv.

There is a different first chart for a component that stops at the shell-field or last-shell test, after central integration and before reference restoration. Central integration has consumed the old box field, including the bonds crossing its boundary. The resulting term has unrestricted fresh Haar coordinates on the bonds with an end in the box. Its frame tree acts on the old shell variables. After bounding the retained weights, the normalized Haar integral over that tree is at most one at fixed exterior root. Any older marked core retains its own joint integral and reference bound.

At this fixed exterior the reference used to define the old shell fluctuation depends only on the old exterior of the prepared box. The tree coordinates on that fluctuation have the rooted-tree Jacobian one. They are disjoint from the fresh Haar pivots of the outgoing rows, so the combined coordinate change has this unit tree factor times the raw row Jacobian. This permits weights to be evaluated on the reconstructed old shell without imposing any tree condition on the fresh pivots.

The box is a union of full level-$(i+1)$ blocks. A first outgoing row of level $i+1$ that reads the box has at least one of its two blocks there, so its middle fine bond has an end in the box. It is one of the free Haar coordinates, even for a row crossing the box face. At fixed exterior the corresponding one-row bounds therefore apply jointly to all these rows. A row whose two blocks lie outside the box reads none of those coordinates. The same count of at most eight rows per coarse block pays for the first outgoing density, using the unrestricted Haar row bound instead of the regular restored chart. The reference-law slice enters only on the branch that reaches restoration.

At a shell or last-shell stop the same order recovers the exterior of the prepared integral. A density cube based in the component uses four test layers of width $M_2\check{R}_i$ in level-i units, and at most one further bond. This reaches less than one level-i cell, of side $M\check{R}_i$, since $L^2M_2 \le M$. The next full double blocks add at most $2L$ in these units. The hierarchy $M \ge L^2M_2$ and $M_2 = L^2M_1$ gives $4M_2\check{R}_i + 1 + 2L < M\check{R}_i$, so the resulting read still lies within one old cell of the component. An old cell is no wider than a new one by $\check{R}_i \le L\check{R}_{i+1}$. The five- and eight-layer enlargements in the next ordinary step therefore put these rows in the raw region outside the gauge draw. Solve the ordinary rows with both blocks outside the box first. Their inverses return the selected exterior pivots. Keep the other exterior coordinates among the unselected variables or in their lower joint graph. A value shared by two tests is reconstructed once. At this recovered exterior solve the remaining rows, each with its free box pivot. The prepared datum and the frame variables are read in the old integral at this exterior. Use the same values for the original positive tests and for the prepared-datum support condition.

Keep the exact inverse charts when using the resulting bound. Write t for the selected variables and s for the unselected ones. At fixed s and raw output w, let $t = \psi(s, w)$ be the reconstructed variables on the image, with zero density off the image. If a one-row change has several branches, keep the corresponding sum of inverse densities. A nonnegative Borel test or weight depending on t is evaluated at these reconstructions. The bound by a product Haar measure on w can be used with an envelope uniform over the reconstructions. This applies in particular to the uniform upper bounds for the complete Wilson product, after the old, new and core factors have been assigned their stated roles.

For the next raw averaging constraint the input is the current-level field. On its full double blocks this field is assembled from w and the other current-level coordinates that actually remain fixed or integrated. A later bare average can use w as a dominated Haar coordinate when these other arguments are fixed by s or supplied by their own joint chart. Older variables in test and energy factors are still evaluated by the inverse charts. The ordinary and prepared averaging deltas both take the physical field at their own level as input. The tree condition at an older island remains in that island's chart. An old fine variable read by a carried weight therefore stays in the inverse kernel for its outgoing row. If an operation prescribes such a fine value as a target in its own right, we must use its joint graph with the outgoing row. The available pivot choices are then those left free under both prescriptions.

The waiting rule protects the first outgoing scale of an old island. A later operation containing it remakes only scales above $i + 1$, so its retained variables below the first outgoing field remain in the old core. The averaging constraint at $i + 1$ reads the restored argument V_i and produces the raw field V_{i+1}; the older determining datum V_i'' is in a separate slot. This assigns the first raw rows once, without giving a second Haar variable to a stored datum. For the continued stack use the row assignment in §4.18.9.5, with the joint outgoing law of the earlier operation on the actual read set. Along a consecutive bare chain whose current-level rows satisfy the joint chart condition, iterate the conditional estimate from the first outgoing field to the last one. The Jacobian product then bounds the chain, with its actual stored weights read at the inverse charts.

The intermediate fields must be read from the retained operations. In an unmarked core, the field of level j has its stored values on Γ_j; inside Ω_j^c its values are the averages of the preceding field, imposed by the preceding averaging kernel. They are not additional independent Haar variables.

The same reading applies when the earlier drop-out left before completing its preparatory stages. In the broader waiting convention, at a full re-entry the remade shell instead carries the old current-level datum; the remaining core carries either the preceding average or the fresh argument from the central integration, according to the recorded place of departure. A fresh argument and a retained determining datum on the same bond remain distinct variables.

Successive graph kernels can be compressed exactly. If x denotes the variables of an earlier operation, $u = A(x)$ its output, and p the other retained arguments, then, for every nonnegative Borel function H,

$$\int \delta_{A(x)}(du) \int \delta_{B(u,p)}(dw) H(x,u,w) = H\big(x, A(x), B(A(x),p)\big).$$

Here B uses the full field assembled from its stored and generated entries. Consequently the compressed terminal constraint is the constraint on this assembled field. It becomes $\mathcal{M}^2(V_{j-1}) = V_{j+1}$ only when all entries used by the second average are supplied by the first. This identity follows by substitution in Dirac measures and preserves the original integration variables and their measure.

For a fixed-output mass estimate, this substitution does not supply Haar measure in a generated pivot. The one-row estimate applies directly only to a pivot that is actually integrated against Haar measure, with the other row arguments held fixed. To apply it to a pivot supplied by an earlier operation one first needs a bound for that operation's joint output density on the variables used. Likewise, a pivot crossing a retained seam must be assigned to its actual integration or reconstruction.

The prepared-stage Haar factor integrates the determining bonds of level j in the nest Z''_{j+1}. Those bonds lie in or meet the shell $Z''_{j+1} \setminus Z''_j$. After the collar change the remaining delta rows are the inner bonds of level $j+1$ of Z''_{j+1}. A row crossing the prepared face belongs to the collar chart below. For a row deep in Z''_j its lower inputs have to be read through the preceding operation. At the outside seam, the middle fine bond of a crossing row may itself cross into Ω''_{j+1}. The no-inward determining set then omits that bond. In an ordinary one-step operation such a row, where it is in the admitted chart, belongs to the pivot reconstruction for the fluctuation step. At a re-made level the distinction is between the old wall and the new prepared face. The following decomposition identifies which reconstruction each uses.

Use the preparatory integral of [B89a, (1.60), (1.71)–(1.72)]. At a preparatory stage put $Y = Z''_{j+1}$ and $C = (\Omega^c_{j+1} \setminus Y) \cap Z$. Divide the rows of the step in this component into three sets. Let R_{ord} be the rows meeting the old Ω_{j+1}, whose pivots are in the ordinary fluctuation and strip reconstruction. Among the rows with both endpoints outside that region, let R_{col} be the ones meeting C, and R_{in} the ones with both endpoints in Y. A row crossing ∂Y belongs to R_{col} by the separation from the old Ω_{j+1}. The regions are unions of complete level-$(j+1)$ blocks. The full double block of a row in R_{in} is contained in Y, and that of a row in R_{col} lies outside Ω_{j+1}. Such a row meets Ω^c_{j+1}, which is contained in the complement of the top determining member. The two-layer buffer of that complement in Z keeps the full double block in the same component. The old-wall and preceding-face margins put it in the level-j member of the preceding stage. All its links are then in the non-inward level-j datum before the promotion. The double block misses the earlier inner face. At the first stage the collar uses at most five of the eight layers separating the old members. At a compressed stage the spacing of the prepared faces is at least one level-$(j+1)$ M-cube, which exceeds the double-block reach. Thus a middle bond selected from this collar stock is a level-j integration coordinate. It is either an old exterior Haar datum or a target left with its carried density after the preceding collar integration. The earlier inner graph has its targets wholly in Z''_j and does not solve this pivot. The soft gauge insertion is a density on this stock. Rows carried outside the component keep their own reconstruction.

Use the collar correction on R_{col},

$$V_j = \exp i[g_j \mathsf{C} B_j - \mathsf{h}\widetilde{\mathsf{D}}(g_j \mathsf{C} B_j)] V^{(j)}.$$

The map C keeps the nonpivot increments, and h acts only on its assigned pivots. The pivot of a crossing row lies on the common face of its endpoint blocks, outside every double block for R_{in}. A row of R_{col} uses no pivot of R_{ord}, since that pivot lies within or crosses into the old Ω_{j+1}. An ordinary row can read the collar field in its exterior block. Its middle bond enters Ω_{j+1} and is inward also in the promoted determining list. Its value was solved by the original strip reconstruction at the prescribed coarse row. In a sharp failure, first recover the collar variables in the branch where the approximate test passed. At fixed prospective datum the two stage centres are independent of the changed collar bonds, since those bonds are omitted from the new determining list. The extra joined datum of the localized centre lies over the old top member and does not reinstate those bonds. The old strip centre may read the collar field. Read it at the reconstructed exterior and use the original inverse at the same prescribed coarse target. The two sets of pivot derivatives are triangular in this order. Keep the old elimination and strip Jacobian factors, and evaluate each surviving old indicator on its complete original carrier. The collar chart supplies only the density for its own rows. On inner fine bonds of Y the field still consists of the retained shell values and those of the earlier operation.

Here is the exact factorization on any carried support on which this collar chart is valid. Denote those remaining variables by s, their measure by $d\nu(s)$, and all the actual collar coordinates by a. Write $\Psi_W(s,a)$ for the reconstructed field at the prescribed coarse datum W. Its full coarea density, with the old densities and tests, is $J_W(s,a)$. If F is the remaining integrand, the collar integration gives

$$I_W(s) = \int F\big(\Psi_W(s,a)\big) J_W(s,a)\, da.$$

The surviving operation is therefore, with unsolved constraints still understood as their original graph kernels,

$$\int I_W(s)\, \delta(\mathcal{M}(V_j(s))W^{-1})\big|_{R_{\mathrm{in}}}\, d\nu(s).$$

Indeed the local coarea formula consumes each collar row once, and the remaining row constraints are independent of a by the double-block containment. All dependence on the prescribed crossing-row values stays in I_W, including the elimination factors and nonlinear Jacobians. No extra Haar variable has been adjoined. The delta factor for each solved row has already been integrated in the chart, together with its coarea factor.

4.18.9.5. The seam after successive stages. At the first stage the prepared-box separation from $Z_{m_\flat} \cap X$ puts the full row blocks near the new face outside the bottom operation. At each subsequent stage the preceding completed collar leaves its level-j graph constraints only on rows with both endpoints in Z''_j. The separation from Z''_j to the new face exceeds the reach of the full row blocks at that face. Thus the input field there is read from the level-j coordinates of the retained law or from the outgoing side of the preceding chart. The earlier inner graph is integrated in its own variables. A read through an inverse chart adds no second constraint. The three-way split at this stage leaves the next inner graph on the rows wholly in Z''_{j+1}. This proves the row assignment for every prefix of completed stages.

A failure of the regularity or approximate collar test, or of the completed ordinary fluctuation test, precedes the collar pivot change. A failure of the sharp collar test occurs after it. In this branch retain the collar nonpivots and the exact translated density, including the factors for the eliminated pivots. The determining list can still be the one before the stage. The stage has no integrated normaliser because its collar integral has yet to be performed.

The row assignment uses the collar chart on its actual real support. We must verify its admission on each support where it is used. A bound for the surviving inner integral also needs the joint law of the old core arguments from their retained operation.

4.18.9.6. The joint law of the retained core rows. Fix the history and its outgoing field W. Unfold each older drop-out into the ordinary and stopped-stage operations it retains, including the remaining averaging graphs. Each unfolding lowers the level of the mark. The evaluation in the upper integral varies the weights and compatible real backgrounds at the stored values. The graph equations in those variables and their target W are fixed throughout the supremum.

Write $h = t - \mathsf{N}_t$ for the bottom of a class window of level t, and $G = Z_h \cap X$ for its core. Every mark in G has level strictly below h. For $h > 0$, the last move in the core is thus the ordinary operation $\mathbf{T}^{(h-1)}$ on the output of the lower operation. It keeps the density test at level h. The unresolved raw targets at that step have their two endpoints in $\Omega_h^c \cap G$. At its birth the component contains two cell layers around $\Omega_h^c \cap G$, so the complete double blocks of these targets are in the ordinary core. In the unmarked part of each block a level-$(h-1)$ bond with an endpoint in Ω_{h-1} is an original Haar datum. There is no inward higher endpoint on this block. A bond wholly in Ω_{h-1}^c is a raw output of the preceding operation. This supplies the ordinary bottom row bound from the joint measure of that lower operation and the original Haar slots. At $h = 0$ there is only the bare Haar input with its Wilson weight and tests.

In the lower operation use the field belonging to each older mark at its recorded departure. For a partial stop, use the original top determining data and the surviving lower graph for the other rows. A fully prepared stop at extendibility has its new top datum on the remade shell and the surviving bare graph in the inner box. Central integration comes later. A stop after that integration and before restoration has the fresh Haar slots and free first pivots described above. In a closed island the fresh field is on its reference tree slice, so the field at that level can be singular with respect to product Haar. The simultaneous first outgoing chart supplies the bound for those rows. The fixed exterior includes the actual retained arguments of each such chart. On a fresh slot used only by the next graph, a same-bond datum retained in the old determining set is a separate variable.

The unrestricted fresh field of a late open stop is carried upward by averaging. To see which later reads can prescribe it, let the mark be born at level i. While it stands, it remains a component of its original Z_i with all entries through level i unchanged. In the input Z_{r-1} of a later ordinary step $r > i$ it lies in the old large region. The ordinary step places Ω_r at least eight coarse cells from that input region. The new plaquette tests are inserted outside the four-layer enlargement of its hull. The approximate tests and their gauge reads are outside the five-layer buffer. Even the complete four-margin test cube with its endpoint blocks has reach less than one coarse cell. These tests, and the density tests with bases in $\Omega_r^{\sim 4}$, miss the fresh box. The immediately carried test of level i uses the separate clearance of the central box from the original level-i density reads. At subsequent ordinary steps the preceding density tests use the same ordinary buffer argument at their own level.

If a later eligible component contains this standing mark, its preparation begins at a level strictly above i. Inside the mark the lower determining entries are therefore the frozen ones. A retained row at a bond address shared by the fresh field still reads its old slot. This argument uses the eight-cell gap only on the original ordinary walls. The prepared walls use their own, possibly compressed, gaps. Outgoing averages can use the fresh slot, and a boundary weight reading it stays in the joint integral. Thus these generated fields remain in the joint measure up to the next average. The bound for their reconstructed row law still has to hold at the actual exterior datum.

These cases identify the measure used at each row of the bottom operation. For an induction through older marks, use unnormalized joint upper measures with these Haar coordinates and reference slices before the first outgoing average. Then use the outgoing row bound for the whole read set of the next operation. The prescribed-output estimate requires this domination with the actual fixed exterior and with all weights read on the reconstructed fibres. If a generated slot is

later used as a spectator, keep it in this joint bound unless a bound for a fixed value of that slot has been proved separately. Dividing a joint upper bound by the spectator's marginal gives no uniform conditional bound without a lower estimate for that marginal. The scalar mass of an older mark, obtained by integrating its outgoing field, does not give that domination.

Write A for the fluctuation coordinates with kept Gaussian forms and a for any free nonpivots of a translated, unintegrated sharp stop, in unscaled logarithmic units. Let v be the group coordinates and ζ the old variables of the inner islands.

For an open subtree of pre-main stops, the stopped factor consists of the Wilson and gauge weights, scalar stage and orientation terms, the elimination factors, the kept quadratics, and the old island factors. Completed stage corrections are in the carrying boundary exponent. After allocating the event payments, the residual Wilson and gauge numerators are bounded by one. The gauge denominators cost at most $C\theta_l^{3/2}$ per normalized factor at level l. On the admitted real chart each ordinary pivot determinant inverse is at most eL^{12}, and the kept forms give a common Gaussian reserve $\beta > 0$. At an admitted real pair use a Borel upper majorant $m_a(\zeta_a)$ for the old island, taking its integral as close to the earlier upper-integral norm as needed.

For a sharp stop the passed approximate test in the translated chart gives $|e^{ia_b} - \mathbf{1}| < 2\delta'_{j(b)}$ on its free collar bonds, including when the sharp test fails. In the principal chart this gives $|a_b| < C\delta'_{j(b)}$. At fixed centre and coarse datum the pre-translation coordinate is also $O(\delta'_{j(b)})$ on the admitted chart. The density on this box keeps the Haar factors and the exact derivative of the linearizing correction. In the correction the range is on the pivots. Ordered after the nonpivots, the pivot blocks are independent because each double block uses only its own pivot. The correction has zero first derivative at the origin and uniformly bounded second derivative in the regular one-row chart. Its Jacobian therefore costs at most a constant per pivot on this small box. Include the Jacobian of the cutoff translation on its own bonds as well. The translated free coordinates need only the volume of their compact box.

Thus on admitted inverse charts of this subtree the complete reference weight has the pointwise bound

$$H_\omega(A, a, \zeta, v) \le C_\omega e^{-\beta \sum_b |A_b|^2} \prod_y m_y(\zeta_y) \prod_{b \text{ at sharp stops}} \mathbf{1}_{\{|a_b| < C\delta'_{j(b)}\}}.$$

Here $\log C_\omega$ is bounded by the sum of the stage and orientation scalar costs and the gauge, pivot, Haar and cutoff density costs just listed, counted at their own levels. Old chart factors are read at their reconstructed arguments. The tree and cutoff of a fresh restored field stay in its coordinate measure. For earlier stops in the main step use the retained measures described below.

At an old island, a later raw row uses the fresh field in the restored box. The old island variables occur in the weights. The pair-uniform envelope allows us to integrate those old variables first and keep the fresh field and its exterior as inputs to the next average.

Start at the lowest remaining scale. Carry a joint upper measure for the full current field read by the next double blocks, adjoining its original stored Haar coordinates. For a fresh restored box use its first-average chart on the whole row stock at fixed exterior. On each other bare row use its middle bond when this is a Haar coordinate of the assembled field. A double block reads no other selected middle bond at the same scale. Rows already solved in the ordinary or preparatory collar charts keep their coarea factors. Use the remade masks in §4.18.9.5. A complete inner double block at a prepared level $j+1$ lies in Z''_{j+1}. For $j > h$ in the completed prefix, each of its level-j bonds with an endpoint outside Z''_j is an original datum coordinate at level j, including a bond straddling that earlier face. Both of its endpoints are outside the new determining member at level $j+1$, so the inward mask does not remove it. A bond with both endpoints in Z''_j is an output of the surviving bare averaging graph at the preceding level. These two sets give all the inputs to the next double block. Once the preceding graph has a joint bound on its whole output, adjoin the original Haar datum coordinates in the same conditional integral. This supplies the next row

bound with no seam coordinate left unaccounted for. The first graph still requires the joint output of the bottom operation, and a stopped level uses the determining mask at departure.

A variable still read by a weight is evaluated at its inverse graph. Every additional argument of the next constraint must be in the same joint measure or fixed among the unselected coordinates of that chart.

More explicitly, fix the genuine exterior e, let v be the selected current Haar inputs and let s be the unselected coordinates with reference measure ν_e. Use the lower joint density $k_e(v,s)$ against $dv\,\nu_e(ds)$. If $\kappa_{e,s}(W,dv)$ is the inverse kernel of the new row chart and f_e is its remaining weight, the composed density is

$$\int \nu_e(ds) \int \kappa_{e,s}(W,dv)\, k_e(v,s) f_e(v,s,W).$$

If the inverse kernel has mass at most B and the product of the two densities on its branches is at most $E_e(s)$, this is bounded by $B \int E_e\, d\nu_e$. This calculation uses the branch versions defined by the original graph equations. If a generated spectator z is itself a prescribed raw target, include its generating row in the same complete lower row stock as the surviving outputs v. If the enlarged list admits a joint inverse chart with independent pivot coordinates at the complete fixed exterior, the inverse-density sum gives a kernel $k_e(v,z,s)\,dv\,\nu_e(ds)$ at the specified target z. Use the chart's actual branch version and its density bound. For example, when v,z are distinct targets of one bare averaging operation with their original middle links still free under Haar, their complete double blocks do not read one another's middle links. Hold the common nonpivots fixed and take the product of the corresponding inverse measures. There is an additional regular case when the spectator z occupies the middle link of the outgoing bare row. Suppose the lower joint law at prescribed z leaves another link b' of the same corridor free under Haar. Restrict to the part of this row with small plaquette defects on the entire double block. Choose the comb starting at the initial top and traversing the row direction first. Every comb crossing the face crosses it at the fixed middle link z, so the frame is independent of b'. The comb estimate puts the links in a small logarithmic box in this same frame for all the admissible b'. Write $f(a)$ for the logarithm of the output in these frames, where a is the logarithmic coordinate of b'. The derivative in a at the flat field is $L^{-3}1$. Indeed, the L^4 straight paths of the average traverse that link for precisely L choices of the starting point, and the averaged contours are internal to each endpoint block. At fixed L, analyticity gives $\|D_a f - L^{-3}1\| \le L^{-3}/2$ throughout a sufficiently small box. Choose a convex coordinate ball in that box containing the admissible free-link values. Integration on a segment gives

$$|f(a) - f(a')| \ge \tfrac{1}{2} L^{-3} |a - a'|.$$

The row thus has one inverse branch on the image of the ball and an inverse Haar density bounded by C_L. Use this density on the actual test subset, evaluated on the inverse, with value zero off its image. The other rows do not read b', since it joins only these two endpoint blocks. Index the constraints by positive orientations and read the reverse as the inverse on the graph. This replaces just the conflicted pivot, with a geometric choice of alternative and the same reference Haar measure before taking the exterior supremum. The lower joint density $k_e(b',z,s)$ at z remains part of the integral, with the old pivot recovered for every old weight that reads it. The alternate solve uses no division by a marginal at z. A tree-fixed alternative or the intermediate logarithmic branch outside the regular box requires its own chart. On the straight-path fallback the output is independent of b'. If a different link b'' of the original straight path still has a free Haar coordinate, hold the other inputs fixed and solve that link instead. The row is $Pb''Q = W$, so its inverse is $P^{-1}WQ^{-1}$ with Haar Jacobian one. Read the original fallback predicate at that inverse. Other rows can read b'', but the fallback row does not read their face pivots. Solve the fallback row first and then the other pivots at the reconstructed inputs. If the straight path is already fixed, its output stays on the prescribed graph. Fix the free-coordinate reference measure separately for each geometry, frame and branch choice.

A relation between prescribed outputs belongs to the graph measure. Adding its generating equation to the list gives no second free output or independent Haar factor. Fix the pivot assignment by the geometry and the frame. The reference measure of the remaining free variables is then the same for the different exterior values. Put the inverse-density factors and the weights read at reconstructed values inside the pointwise supremum on those free variables. Rows whose targets are only used to reconstruct the exterior keep their target variables in the integral. If all inputs of a row are already prescribed, its target remains on the deterministic graph. This argument applies to the complete protected first-average stock of a restored box.

For an ordinary successor of a collar-kind departure of level i, keep the old top density halo through the first outgoing row changes. The old top link of the stopped prefix is either a value of its original determining list or the output of its surviving $\mathcal{M}(V_{i-1})$ constraint. Include the full lower double block of the latter row, as well as the first outgoing blocks. This read lies within the two-layer enlargement of the old component on the next grid, inside the ordinary successor. When the component later enters a containing preparation this read is in its floor. The new prepared rows leave these old graphs in place.

For a halo link used only in evaluating a retained test, use the value $z = \zeta(v, s)$ of that old graph in the weight of the joint row integral. In the notation above the corresponding operation is

$$\int \nu_e(ds) \int \kappa_{e,s}(W, dv)\, k_e(v, s) f_e(v, s, W, \zeta(v, s)).$$

Equivalently the conditional integrand has the graph measure $\delta_{\zeta(v,s)}(dz)$ in that read slot. The test retains this value until it has entered the weight. Its presence uses the original inverse rows and carries no new Haar density or integration volume. In particular, the translated collar variable of the stopped history remains the variable in its recorded reference measure, as does the birth fluctuation in the kept Gaussian. If a new constraint solves one of these variables, insert its inverse value and chart density before taking the supremum and omit its integration volume.

For a prescribed exterior slot outside that stock, classify its generating row at the stage where it was formed, using §4.18.9.5. A promoted collar row uses the original collar chart on its complete double block. An ordinary wall row reads its old inverse at its coarse datum. A row of the surviving inner graph uses the lower joint law. If the backward closure of the read leaves the stored row sets already supplied, we must supply that joint exterior read or keep its relation on the actual graph.

The geometric closure along consecutive bare rows has an exact description. Start with a level-q row and stop the closure at level $u < q$. Each first inverse reads fine links with both endpoints in the union of the two endpoint blocks. For every such link, the next inverse reads only the two blocks of its endpoints. The union of the child blocks of all sites in a parent block is the same parent block in the finer lattice. Induction thus keeps the level-u reads in the two order-$(q - u)$ blocks of the original row. This applies also to the nonpivots required by the inverse, which lie in its full double block. If one of those slots comes from a restored box or a collar change, stop the bare closure there and include the stock of that actual chart. Test and weight carriers are included separately at their own levels.

For an ordinary row outside Ω_q, apply the no-inward rule to its level-$(q - 1)$ inputs. A link meeting Ω_{q-1} is a datum there, since both endpoints are outside Ω_q. A link with both endpoints outside Ω_{q-1} uses its actual lower raw graph if that graph is still carried. The two-cell enlargement of Ω_{q-1}^c in Z_{q-1} keeps its full double block in the same predecessor component. The next growth contains the predecessor in its successor. If the upper row reads several predecessors, keep their inputs together in the same conditional integral. When the recursion reaches the first outgoing step of a closed island, the read ends at its physical field. Use the restored first-average stock and the ordinary Haar inputs at its face. On a region absorbed by healing, the new determining list has dropped the old lower members. Read the current datum there and include the healed contribution

through its weight. For a standing drop-out use its departure list and continue only through the rows it retains.

On a carrier clear of older replaced boxes, compatibility with a real bare field propagates through the same graph. On every complete double block the determining inputs agree by admission and the other inputs agree by the lower rows. Applying the average proves agreement at the new target. For a carrier meeting a box replaced at a late stop, the branch uses its fresh top argument. The nested block inclusion above locates this exception using the whole backward carrier. The older integrated datum stays in the inner weight of the box.

If a later weight reads an older branch or any of its remaining variables, keep that argument in the joint integral, or include the weight in the lower envelope before taking the marginal. An earlier generated coordinate can be supplied as a selected Haar input only after its joint density has been obtained by integrating the lower rows. The test and weight functions still use the inverse values of any lower arguments they read. In the prepared seam, first solve the inner raw rows, then the collar rows, then the ordinary rows that can read solved collar values. This order keeps the actual one-sided dependencies. An inner pivot can enter the collar centre through a retained determining row. Reconstruct it before using the collar chart. In the no-inward convention the ordinary pivot at the old member is absent from the fine determining list of the collar centre, since it has an endpoint in the enlarged member. Thus this pivot is solved only at the last step of the order.

At fixed output the compatible set is read at the inverse of each branch. The pointwise envelope bounds the upper integral in these coordinates before the unselected variables are integrated. Use the Borel inverse-density sum with zero mass off the chart images. For the outputs admitted to the independent charts, iteration on full read sets gives the joint outgoing density bound

$$C_\omega(\pi/\beta)^{3n_A/2} \prod_{b \text{ with remaining } da_b} (C\delta'_{j(b)})^3 \prod_y \int m_y \, d\mu_y \, (2L^9)^{N_{\mathrm{raw}}} (C_L+1)^{N_{\mathrm{alt}}} C_L^{N_{\mathrm{box}}}.$$

Here n_A counts independent Gaussian coordinates still carrying dA after the row solves. A fixed or reconstructed slot has its actual chart weight and no volume factor. For each pivot choice, count the remaining volumes on that branch. Sum the resulting bounds if the branches have different free coordinates. The counts N_{raw}, N_{alt} and N_{box} are for bare rows using the middle link, bare rows using the alternate charts and first-average rows of restored boxes, respectively. The alternate charge allows a regular branch of bound C_L and a straight-path fallback of bound one. Only rows still to be solved enter these counts. Use $2L^9+1$ in place of $2L^9$ for a middle-link row with the pointwise fallback version. Deterministic read slots stay on their graph. The already consumed ordinary and collar coarea factors are in C_ω. Fixed exterior slots keep their prescribed values. The row assignment charges each price at its own level.

For an earlier open operation, start with the full blocks read by the selected outgoing rows and take the closure under lower reads. A row in that closure is either genuine exterior data, a retained Haar datum, part of a restored box's first-average stock, or an output of lower rows. Include the whole stock when using a restored box chart. Keep any unused outputs until all weights that read them have been included. An earlier promoted shell coordinate was the target integrated against Haar in the corresponding averaging integral. Its density already includes the elimination of the old pivot. Use that density in the joint integral, with the old pivot recovered for any weight that still reads it.

At an extendibility stop all preparatory stages have been completed, and the bare averaging rows inside the prepared members survive. The last such row has its target in the old field V_i on Z_i''. This is the field to be used in the next ordinary average. The extendibility indicator reads only the part of V_i outside the central box, which contains Z_i''. The infimum in that test gives a predicate on the exterior. Its trial extensions do not appear as variables or constraints in the retained kernel.

When forming the density of this history, take its old top field as the argument of the inner graph. At the next raw average use the same top field in the outgoing Haar integral. Where the old

field is a target of the inner graph, include its earlier joint density in that integral. The other top bonds have their original Haar factors. Thus the inner graph is evaluated at its prescribed target before that target is used as an input of the next row. Lower coordinates read by the old tests stay with their inverse branches. In particular the negative extendibility indicator is evaluated on the reconstructed top exterior in this joint change of variables. The fine inputs retain their integration and constraints from the earlier graph.

At a shell or last-shell stop the central integration has eliminated the prepared chain. Its old terminal variables and the variables of the old core are disjoint. Indeed, write h for the bottom of this component's waiting window. The shell gauge ends at the two-cell enlargement of the prepared Ω_{h+1}. The prepared inner box at $h+1$ has three cell layers around the hull of the bottom core. After the two layers have been removed, the remaining cell layer still contains the complete bottom-core reads. The frame tree therefore acts only on the retained shell. At fixed reconstructed exterior, the change from the prepared group variables to their relative values preserves Haar measure. Solving the frame tree leaves normalized Haar on the free shell bonds. Use this reference measure and the separate fresh box Haar measure. The shell and last-shell failures are separated before the operation that assigns the reference-law density. Their fresh output therefore carries bare normalized Haar. For a component that remains in the class, combine the reference-law density with the old Wilson weight by the pointwise identity following eq. 4.cdlxix. Assign the new action to the carrying term and keep the core Wilson weight for the ledger. The scalar and remainder costs enter at their own levels. This cancellation holds before imposing any new averaging row, so it also holds on the prescribed-output branch. The subsequent Haar bound still uses the retained tree and averaging coordinates. Keep all earlier variables still read by the weights in the lower joint integral.

Consequently a late node adds a normalized shell factor and the free first-outgoing pivots to the reference measure, with the old lower charts and branch tests retained. If the middle bond of an ordinary bottom row is itself a lower graph output, the joint outgoing bound at that lower level supplies its Haar domination together with the other inputs. At a closed island use the simultaneous first-outgoing chart on its restored slice. The pointwise envelope can be formed before those row integrations.

The upper-integral fibre allows one-sided evaluation coordinates for the quadratic forms and pivot factors. Write q_j for the complete kept quadratic at step j, including its coupling ratio. In the stopped weight this is $\tau_j\langle A_j, K_j A_j\rangle$, where K_j is the sum of the kept chain contributions on the original free-coordinate space. Use $\operatorname{Re} q_j \ge \gamma_{\mathrm{p}}\|A_j\|^2$ and the upper bound eL^{12} for a carried elimination factor. For an actual field read in the original positive strip domain $\mathcal{O}^+$, the local kept form has a real-part lower bound $c\gamma_0$. With the original masks and the same free coordinates, the absolute walk sums give $\|K_j\| \le C_{\mathrm{w}}$. For the ordinary strip the ratio is formed at its original level j. On eq. 4.dxvii, the radius bound $t_j \le C\theta_j(\log\theta_j)^{-2q_{\mathrm{t}}}$ gives

$$|\tau_j - 1| \le C(\log\theta_j)^{-2q_{\mathrm{t}}} + \bar{c}/\theta_j.$$

The radius estimate follows from adjacent frame comparability. At the last level use monotonicity of the tube radii and the preceding bound, or the single-level tube condition. Choose the inverse coupling floor so that twice the right-hand side times C_{w} is at most $c\gamma_0/2$. This leaves at least $c\gamma_0/2$ for the complete kept form throughout the ordinary strip ratio disc.

The ordinary normalization may instead keep the form at $\tau_j = 1$ and place its ratio correction in the boundary potential. The gauge compensation in eq. 4.d also has to be accounted for in the complete exponent. On the stored boxes the compensation costs at most $C|\tau_j - 1|M^4 p_0(g_j)^2$ per cube. This stays bounded on the tube because $q_{\mathrm{t}} > \mathfrak{p}_0$. On the enlarged stored-field discs the squared field bound adds $(\log\theta_j)^{12r+2}$. The same cost tends to zero there with the hierarchy $q_{\mathrm{t}} > \mathfrak{p}_0 + 6r + 1$. If a compensation is included in the form, check the lower bound for the resulting complete form. Preparatory and main restoration Gaussians use θ_j. In those operations the change

of coupling belongs to the Wilson potential. An abstract one-sided evaluation is admitted by the lower bound on the complete q_j itself.

For the event payments, let S_{W} be the real carrying Wilson action on the bare plaquettes with all corners in X, and let G_j be the sum of the kept nonnegative gauge costs at level j. In the prepared component the Wilson weight is the running weight times the core cutoff. The cutoff is one on the one-layer hull of the old core, which contains the charged plaquette footprints. The running weight there is a convex combination of the stage weights. At an event of level t it can run for at most $\check{R}_t$ more levels before freezing. The bounded comparison over this range gives a coefficient at least $c\theta_t$ on the event's plaquettes. Indeed, an earlier vertex of the running profile has reference weight at least $\theta_t - c_5$, and a later vertex can lose at most $\bar{B}\check{R}_t$ before freezing. At a final preparatory stage the extra vertex is $x_s + b_{s-1}$. Its frame value is $\theta_s + \theta_{s-2} - \theta_{s-1}$, so the adjacent frame comparison gives the same lower bound after allowing the three relative tube errors. The cutoff leaves all these bounds intact on the charged footprint. Set

$$E_{\mathrm{pay}} = a_\sharp \sum_t p_0(g_t)^2 n_t^{\mathrm{cr}} + \sum_t p_0(g_t) n_t^{\mathrm{mk}},$$

where the counts concern the creations and marks paid in this component. A drop-out's own mass omits its failed root test. Charge it in a later waiting window when that component supplies its root witness on the compatible inverse branch. With all the assigned certificates on that branch, the event ledger gives

$$S_{\mathrm{W}} + \sum_j \theta_j G_j + \tfrac{1}{4}\gamma_{\mathrm{p}} \sum_j \|A_j\|^2 \geq E_{\mathrm{pay}}.$$

Use the same real branch for the Wilson action and the witnesses, and the same stored coordinates for the gauge costs and the kept quadratics. The part of the exponent involving these three weights satisfies

$$e^{-S_{\mathrm{W}} - \sum_j \theta_j G_j - \frac{1}{2}\sum_j \operatorname{Re} q_j} \leq e^{-E_{\mathrm{pay}}} e^{-\frac{1}{4}\gamma_{\mathrm{p}} \sum_j \|A_j\|^2}.$$

The bound is pointwise before taking the supremum over admitted evaluations. It leaves $\beta = \gamma_{\mathrm{p}}/4$ in the reference Gaussian majorant above. The normalized shell measure needs no further scalar factor. The old island factor uses its pair-uniform Borel majorant at the admitted inner core. Any reference-law denominator belongs with the corresponding Wilson product and restoration measure.

For the application to an actual later term, use its current background at each factor. On the full carrier of a retained strip, the original-domain comparison gives the coercive bound using the original masks and the two adjacent layer radii. A carried determinant uses the full two blocks of the original elimination row and the small-curvature bound there. Keep this determinant separate from the inverse-density factor of a raw row change. The restriction to each inner island's complete core gives the argument for its majorant.

For the layer estimate at a point of a birth carrier, separate the datum plaquettes of the current background according to their complete test footprints. The retained ones with the prepared-datum support bound have defect at most Ce_q at level q. Use the original positive density bounds on the unchanged exterior tests. Where these tests cover a weighted neighborhood of radius D about the carrier, the profile eq. 3.ccclxxviii–eq. 3.ccclxxix gives

$$Ce_s + C\varepsilon_\star e^{-\delta D}$$

in actual layer s, with $\varepsilon_\star$ the fixed admission ceiling on the rest of the datum. The first term follows by the exponential decay across separated layers and the frame bound on e_q/e_s. When a waiting collar separates the carrier from those other tests, its weighted width of order $M\check{R}$ absorbs the second term. At carriers reaching the exterior halo we must include the positive tests of that halo in the read.

Assign the tests of the current carrying datum before taking any marginal. At an unchanged ordinary place use its original density cube and the full lower blocks for each completed bond. A

passed test supplies a local configuration with the stated averages and a curvature bound. The averaging estimate then bounds the holonomy of the datum plaquette. For a plaquette in a stopped component use its recorded departure place and the full union of its corner blocks. When this union lies in the tested inset, use the last applicable stage guard. On a collar departure include the approximate test on the collar links. A footprint extending outside that inset uses the original density cube on its complete exterior read. The ordinary defect bound is of order ε_q. For a remade shell it has the factor $C_L L_\flat^{2(q-k_0-1)_+}$, and a collar departure has the factor $c_\mathrm{f} L_\flat^{2(q-k_0)_+}$, with k_0 the cutoff between the uncompressed and compressed stages. These powers are bounded by $C(\log \theta_q)^r$ by the frame and the stage widths.

Carry the resulting holonomy bound through the actual later moves. A gauge draw, a frame change or a tree gauge conjugates the holonomy. A late Haar refresh leaves the old determining datum in the inner slot. The fresh field is used by the outgoing rows. A reference-law draw changes the datum itself. At an island its reference has the exterior bounds of the passed extendibility test and of the surrounding density cubes. On the restored box, comparing the four links with the reference and using the retained cutoff gives the bound $C(M)\varepsilon_i$. If a determining plaquette is deleted, the newly made layer uses its own regularity guard. In each case the certificate concerns the data that enter the current background.

In a quiet containing component that heals, the old top test enlarged by four cells covers the outer six cells of the component, since the complement of the top member is inset by two cells. The final positive test on the six-cell inset supplies the interior. Their merger gives the top test of the new domain. The reverse tree gauge preserves the resulting plaquette bounds. The full original localized read of each test is used even where it crosses the two sets of test places.

On a joint inverse branch these tests act on the assembled datum of the current background. Their supports give the input of the weighted profile in its current determining sequence. Restrict that profile to each complete birth carrier before applying the strip, pivot or island bound. In using the upper integral for a later term we must verify the full inverse reads of these tests and the energy inequalities for its recorded event witnesses.

The coordinate count is local. A localized Gaussian marginal with m scalar coordinates has an $\exp(Cm)$ cost from its proved comparison estimate, regardless of the number of exterior auxiliary coordinates used to construct it. Here $m \le C(LM)^4 N_c$, where N_c counts the relevant coarse cubes. If the count already denotes m, the factor $(LM)^4$ is not inserted again. In particular the reference cost does not acquire an outside-volume multiplier.

The analytic and geometric conditions needed for an outer component can now be stated without assuming its desired mass. On every carried support and on every argument in the supremum, require:

(i) the exact exponent identity in eq. 4.cdlxvii, or the evaluated identity in eq. 4.cdlxxi, with the correct retained Wilson weight;
(ii) the complete bound $|V_X| \le C_V N_0$ on the admitted triples, including the actual source and counterterm normalization;
(iii) real admissible reads for the inner factors, whose differences from substituted complex reads have been included in V_X;
(iv) the scalar normalizer estimates just proved and the actual kept-form coercivity and reference-coordinate domination;
(v) a disjoint ownership of the action, gauge and Gaussian pieces used to pay for the event witnesses.

The last requirement has the quantitative meaning

$$A(\upsilon, U) + \sum_j \theta_j G_j(\xi) + \beta_1 \sum_j |A_j|^2 \ge \sum_e \Gamma_e, \qquad \Gamma_e = c_\mathrm{w} \theta_{t(e)} a_e^2, \tag{4.div}$$

leaving the positive reserve β of eq. 4.dii unspent. For ordinary components U is the real inner background; for a drop-out the inequality must hold for every compatible real evaluation in its fibre. A bound only at one preferred background would not justify the supremum in its mass.

These are finite-domain conditions, uniform in the admitted parameters and in the outer index. Each has specific mathematical content. In particular eq. 4.div requires actual witnesses at the stated levels, while eq. 4.dii requires an integral in the actual stored coordinates. We next derive the mass from them; no mass estimate is included in this list of conditions.

4.18.9.7. Which coupling pays for an old event. There is a useful profile check in eq. 4.div. Suppose a plaquette first enters the large-field region at level t. The action rule stops its running weight within $C_R R_t$ further levels. On its owned support the retained weight is a convex combination of inverse couplings with indices no later than $t + C_R R_t$. Earlier couplings are at least $\theta_t - c_5$, and a later coupling in this range is at least $\theta_t - C_6 R_t - c_5$ by the bounded one-step drift. For a sufficiently high floor, $R_t = O(\ell_t^r) = o(\theta_t)$, and hence

$$\upsilon(p) \geq c\theta_t. \tag{4.dv}$$

This argument uses the action supports. Continuing the weight all the way to an arbitrarily later level could make it much smaller, and the same conclusion would not follow from bounded drift alone. The freeze rule is thus a local support statement, not an informal appeal to approximate monotonicity.

4.18.9.8. Elementary witness estimates. For $W \in \mathrm{SU}(2)$ in the operator norm, $1 - \frac{1}{2}\operatorname{tr} W = \frac{1}{2}|W - 1|^2$. A failed kept gauge test $|W - 1| \geq a$ therefore supplies the gain $\theta a^2/2$. A failed physical fluctuation test of size a has $|A^{\mathrm{s}}| \geq \theta^{1/2} a$, and its reserved Gaussian form supplies $c\gamma\theta a^2$.

For a plaquette certificate, suppose the actual tested quantity has the following bound on the failure event, with nonnegative coefficients T_{ep}. Weighted Cauchy–Schwarz then proves

$$\begin{aligned} a \leq \sum_{p \in P_e} T_{ep} |\partial U(p) - 1|, \qquad &\Longrightarrow \\ \sum_{p \in P_e} \upsilon(p)\bigl(1 - \tfrac{1}{2}\operatorname{tr} \partial U(p)\bigr) \geq \frac{a^2}{2\sum_{p \in P_e} T_{ep}^2/\upsilon(p)}&. \end{aligned} \tag{4.dvi}$$

For an ordinary loop identity such a certificate follows by writing the loop as a product of conjugated plaquettes and telescoping the product; all other unitary factors have norm one. For a nonlinear block average the certificate and its uniform weighted row bound must instead be proved for that actual average. A flat linear row estimate alone does not supply it. Similarly, a failed existence or extendibility test needs a quantitative implication saying that all smaller local witnesses would put its data inside the admitted background chart. Its contrapositive then provides a witness. Failure of an unquantified existence assertion is not itself an energy lower bound.

For an outer mass, assign the Wilson part of a mark witness on u to the plaquettes of $C(u)^+$ with no corner in its floor. Use this assignment when the outer Wilson action contains that share. A stopped root can use this halo when it is read in a containing operation. For a mark at level m, $C(u)^+$ adds two layers of *unit cubes of level* m, of total thickness $2L^m$ in bare units. Distinct components at this level are separated by a coarse cell of side $a_m = M\check{R}_m L^m > 4L^m$, so their enlargements are disjoint. For incomparable marks at different levels, follow the earlier enlargement in the ordinary hull to the level of the later mark. It is contained in the earlier mark's successor there. That component and the later mark are separated by a coarse cell of the later level, which exceeds the thickness of the later enlargement.

If a standing mark v of level m lies below a later eligible mark u of floor level h, then $m < h$. The ordinary step into level $m+1$ contains $C(v)^+$ in the one-cell enlargement of the hull of Z_m. If $h = m + 1$, the eight-cell buffer of the ordinary step therefore puts the full h-cell carrier of $C(v)^+$ in the floor. If $h > m + 1$, the neighborhood has already entered Z_{h-1}, whose hull again receives

eight cells before reaching Ω_h. The floor entries on the containing component agree with those of this ordinary step. In both cases the earlier share lies inside the floor. The same argument applies to Wilson paying halos at birth levels $t < h$, which are contained in the ordinary Z_t at birth. For a plaquette or approximate-fluctuation birth at h, the cell lies in P'_h or Q'_h, with the level-zero plaquette births also included in the first step. Its one-cell paying halo leaves at least one coarse cell of the original two-cell buffer to Ω_h. Thus it too is in the floor. A fresh ordinary test outside a live component and its margin has its Wilson share outside the carried halo.

The stored gauge terms are assigned by their original level and contour. Assign the Gaussian payment from the scalar reserve $\frac{1}{4}\gamma_{\mathrm{p}} \sum_b |A_b|^2$ of the complete form, using the actual failed coordinate. Nested mark windows are disjoint by the quarantine at the lower end of the waiting window. A creation at the first level h of a later window uses gauge and fluctuation coordinates of the step from $h-1$ to h, below the coordinates $j \geq h$ used by the mark. Incomparable nodes have disjoint spatial shares in any common layer. Within a one-step share, divide by the bounded multiplicity of its cell witnesses before assigning the gains.

Cut the outer genealogy at its inner islands. Their earlier witnesses have already been used in the inner masses. For a still-standing second-class island Y of level m, the negative density test is on its restored level-m field. Its determining datum includes every top bond meeting Y. The original entries through m on Y survive, and any later eligible window containing this island starts above m. On the full interior carrier of that test, the retained constraints therefore identify the level-m averages of a compatible real evaluation with the restored field.

Choose a density cube C in the six-cell inset of Y where the test fails. The regularity criterion uses C enlarged by four test layers, of side $M_2\check{R}_m$ in level-m units. Completing the averaging blocks of a plaquette on that carrier costs at most one more such unit. Since $4M_2\check{R}_m + 1 < M\check{R}_m$, all these blocks stay in Y. If every level-m plaquette defect on the carrier were less than $c\varepsilon_m$, the local regularity criterion would give the required orbit with regularity radius $B_3 c\varepsilon_m$. Choose $B_3 c < 1$ and the weak-coupling floor so that $c\varepsilon_m \leq a_1$ and $B_3 c\varepsilon_m \leq \varepsilon_{\mathrm{v}} \leq a_0$, with the torus condition of the regularity criterion. The curvature on the tested inset is then strictly within its threshold. Thus a failure, including undefinedness, gives a plaquette defect of size at least $c\varepsilon_m$. The four-block certificate eq. 4.cdlvii gives bare Wilson energy at least $c'\varepsilon_m^2$ in Y. The action gives this region weight x_m at birth and includes a still-standing second-class Y in the level-m action region. The core taper is one on the whole old-core carrier just located. Use the lower stopped-weight comparison eq. 4.dv there and $x_m \asymp \theta_m$. This gives $c_0\theta_m\varepsilon_m^2 = c_0 P_m^2$ in the carrying Wilson action.

The inner core Wilson action is on its prepared inverse field. These are distinct action factors in the exponent identity. If the outer ledger counts the island as b creation cells and also as a mark, both credits come from the fresh-field witness. Here b is uniformly bounded. From an energy $c_0 P_m^2$ reserve $a_\sharp b P_m^2$ for the creation cells, with $a_\sharp b \leq c_0/2$, and use $P_m \leq c_0 P_m^2/2$ for the mark at weak coupling.

For the untouched one-step pieces, the tests and the averaging constraints give the witness estimates for every compatible real evaluation. Each created cell has a witness within two cells, and a plaquette, gauge factor or fluctuation coordinate is used by at most 5^4 of these witnesses. Divide the available energy by this multiplicity. The plaquette witnesses use the Wilson action on $N_{t,D}$; the approximate fluctuation witnesses use that action and the gauge-fixing energy; the remaining fluctuation, collar and rim witnesses use the scalar Gaussian reserve at their actual failed slots. The threshold comparisons therefore give

$$\frac{1}{2}A_{\mathrm{cr}} + \frac{1}{2}\sum_{(t,D)} \theta_{t-1} G_{t,D} + \frac{\gamma_{\mathrm{p}}}{4} \sum_{(t,D)} \sum_{b \in \mathfrak{X}^{\mathrm{s}}_{t,D}} |\mathcal{A}^{\mathrm{s}}_{t-1}(b)|^2 \;\geq\; c \sum_{(t,\Delta)\in \mathrm{Cr}} P_t^2 .$$

Here $\mathfrak{X}^{\mathrm{s}}_{t,D}$ is the stored strip mask of the piece and A_{cr} is the Wilson sum over the disjoint shares. The sums run over the selected untouched pieces, Cr is their set of created cells, and the actual kept-form coercivity and coupling comparisons are those used in the one-step witness estimates.

The unused halves of the Wilson, gauge and Gaussian energies remain available for the reference integral.

The smallest stated mark witnesses can have size $cR_t^{-4}\min_{j\text{ in window}}\delta'_j$. With $\delta'_j \asymp g_j\ell_j^{p_1}$ and the bounded comparison of reference couplings over a window of $O(R_t)$ levels, this gives

$$\Gamma_e \geq c\ell_t^{2p_1-8r} \quad \text{for a mark witness.} \tag{4.dvii}$$

The comparison uses bounded drift over that window, not over the entire history. Assume $2p_1-8r > p$ and $p > 6r$. Then this gain exceeds both a fixed multiple of the later cell costs and $2P_t+1$, after the coupling floor is raised. Creation witnesses of size cg_tP_t have gains bounded below by cP_t^2 and obey the same conclusion. For example the two strict exponent inequalities are compatible with the other hierarchy $p_1 \leq p-4r-1$ once p is sufficiently large. This arithmetic does not establish the witness certificates or their ownership; it proves what those certificates would pay for.

The root witness of a drop-out needs a separate comment. Its certificate can use X^+, whereas that drop-out's own evaluation has a field only on X. Its root gain cannot then be claimed in its own mass. A later containing component can use the gain if its record includes the failed last test and its compatible field supplies the witness on the full paying carrier in X^+. Restricting the earlier mass to this additional test can only decrease it. Comparing the old creation reserve gives the sharper mass bound below without an additional root gain.

4.18.10. *The pointwise envelope and the mass induction.* The reference-coordinate maps used here are fixed by the stored record. They may depend on other stored variables, including inner variables, but not on a parameter still inside the supremum. An argument-dependent translation that makes each separate Gaussian integral small would not bound the integral of the supremum.

Under the conditions stated above, split the positive outer action, gauge and Gaussian energy into two parts. Use the first to pay $\sum_e \Gamma_e$ in eq. 4.div. Use the second to construct the nonnegative Borel reference envelope of eq. 4.dii, or use eq. 4.diii for the completed operation with unmarked core. Bound the scalar normalizers and the complete local energy by $e^{C_7V^\circ}$. For every inner operation replace its actual real admissible read pointwise by its strong real majorant in eq. 4.cdlxxiii. The result is

$$\boxed{m_\omega(\xi) \leq h^{-f(\omega^\circ)}e^{C_7V^\circ-\sum_e\Gamma_e}g_\omega(\xi^\circ;\xi_{\mathrm{in}})\prod_y \frac{m^{\mathbb{R}}_{\omega'_y}(\xi'_y)}{h}, \quad \sup_{\xi_{\mathrm{in}}}\int g_\omega\, d\mu^\circ \leq e^{C_5V^\circ}.} \tag{4.dviii}$$

The same formula is required over the compatible evaluation fibre in a drop-out. The envelope is constructed before that supremum: every evaluation satisfies the same energy certificates, and every complete free form satisfies the same coercivity bound. Its stored coordinates, reference measure and normalizers have been identified as just specified. These facts, not a pointwise gas expansion at each evaluation, prove eq. 4.dviii.

The displayed uniform conditional integral is enough even if the envelope depends on inner variables. When the actual reference construction makes it a function of outer variables alone, this condition follows immediately. In the more general case it follows from the uniform triangular calculation in eq. 4.dii. Its constant must be independent of all inner histories and all their variables. An estimate only after averaging some other exterior law would not be the estimate in eq. 4.dviii.

We prove explicitly the induction step. Fix the outer index ω°. Its inner islands, their levels and their domains are fixed. The remaining histories are the independent local records ω'_y. The retained operations have the corresponding product reference measures, as in eq. 4.cdlxv, and $v^\natural(\omega) = V^\circ(\omega^\circ) + \sum_y v^\natural(\omega'_y)$ exactly. Suppose the earlier strong real masses with coefficient c are at most one. Multiply eq. 4.dviii by the weight and use its Borel envelope. Tonelli allows the outer variables to be integrated first. The bound on that integral is uniform in the inner variables. The remaining nonnegative integrals and sums separate into the earlier masses. Each is at most one.

We obtain

$$\frac{1}{h}\sum_{\omega \text{ over } \omega^\circ} e^{cv^\natural(\omega)} \int^* m_\omega \, d\mu_\omega \le h^{-1-f(\omega^\circ)} e^{(C_5+C_7+c)V^\circ - \sum_e \Gamma_e}. \tag{4.dix}$$

No measurable choice of a maximizing pair or evaluation has entered this calculation. No interchange of supremum and integral was made. The earlier masses include their own frame factors and their own histories, exactly once.

The scalar reserve is applied with $c_1 = C_5 + C_7 + c + c_{\mathrm{e}}$. The counting estimate applies to the outer tree cut at its inner islands. Its cut leaves have their bounded number of boundary seeds. Their last tests lie outside the inner masses and supply the assigned creation gains. Under the witness hierarchy in eq. 4.dvii, or directly under the strengthened scalar conditions, the coefficient of each event can pay its allocated part of $c_1 V^\circ$ and leave the specified reserve. In particular it is sufficient to have

$$\sum_e \Gamma_e - c_1 V^\circ \ge \sum_{e \text{ creation}} (2P_{t(e)} + 1). \tag{4.dx}$$

For the stronger event-by-event form one leaves $2P_{t(e)} + 1$ also at every mark whose witness is available on this outer tree. This stronger form follows from the actual witness powers, not from treating a conservative credit of size P_t as if it were a larger gain. The weaker form in eq. 4.dx already suffices for the mass.

Here is the exact comparison that removes a possible constant loss. For $t \le i$ the bounded-error monotonicity of the reference flow gives, by the mean value theorem,

$$P_t \ge P_i - C_8 \frac{\ell_i^{p-1}}{\theta_i}.$$

The error tends to zero. Raise the common floor so that it is at most $1/4$. The outer tree has a creation leaf, and its reserved $2P_t + 1$ is then at least $2P_i$. Thus, for any fixed $0 < a_\star \le 2$, eq. 4.dix–eq. 4.dx and eq. 4.cdxcvii yield

$$\boxed{\mathsf{M}_c(i, X; v^\natural) \le e^{-a_\star p_0(g_i)}.} \tag{4.dxi}$$

This argument proves the same constants at the new level; it does not produce a factor e at every step. It proves the complex-pair mass from the previous strong real masses. Restricting the pair supremum to the real core recovers that induction hypothesis at the new level. At the first level there are no earlier islands, so the same proof starts with an empty product equal to one.

For a drop-out the same proof holds with every complete form in its evaluated fibre and with its retained Wilson weight. The version including its own failed last test is a restriction and has no larger mass. The reserve argument with the extra unit per old creation also gives the exact e^{-2P_i} bound when that value is desired. Its proof does not use an unavailable root witness on the smaller domain X.

4.18.10.1. The induction has a stronger input than stability. For emphasis, the induction statement is

$$\frac{1}{h}\sum_{\omega} e^{cv^\natural(\omega)} \int^* \sup_{\text{admitted real reads}} e^{\Phi_\omega} \, d\mu_\omega \le 1, \tag{4.dxii}$$

not a bound on an integral at each fixed read. It is also not a bound on a final Gibbs partition function. The real statement is propagated by the pointwise structural envelope, while its complex counterpart is an output of the same step. The proof uses the strong norm exactly where the inner histories are separated in eq. 4.dix. Stating this quantifier prevents an otherwise hidden strengthening in the induction.

4.18.11. *Perturbations paid for by the stored-site reserve.* The same volume weight pays for an explicitly bounded source excess. Suppose, on the full domain used in the supremum,

$$|\Psi_\omega| \le \bar f\, n^\sharp(\omega). \tag{4.dxiii}$$

If $c\ell_j \ge 2\bar f$ for all relevant levels, eq. 4.cdlxxviii gives $|\Psi_\omega| \le c v^\sharp(\omega)$. Therefore, for a bounded insertion F,

$$\frac{1}{h}\sum_\omega \int^* \sup\bigl|F e^{\Phi_\omega+\Psi_\omega}\bigr|\, d\mu_\omega \le e^{-a_\star p_0(g_i)} \sup|F|. \tag{4.dxiv}$$

This is pointwise domination by the already weighted mass. It requires the same normalizers, reference measures, test supports and argument domains on both sides. A source that moves a sharp test or changes the reference measure must first be rewritten in that fixed representation; it is not covered by eq. 4.dxiii by name.

The weight may also be changed. If $0 \le v' \le v^\sharp$, monotonicity gives the mass bound with v'. If an owned window volume satisfies $v^{\mathrm{win}} \le 2v^\sharp$, use the original mass with coefficient $2c$ to bound its weight with coefficient c. This comparison must have a fixed multiplicity. The formula in eq. 4.cdlxxx explains why there is no analogous statement for arbitrary repeated-past volumes.

One can verify eq. 4.dxiii from local carrier information. The following criterion records the constant terms as well as the oscillations. At level j, let $\mathcal{A}_j(\omega)$ be its owned stored sites, with the fixed read collars assigned as in eq. 4.cdlxxviii. Let $\psi_f(z;\cdot)$ have carrier R_f of that level, and let a reference argument p_f^0 in its admitted carrier core be fixed. Suppose

$$|\psi_f(z;p_f^0)| + \sup_{p\ \text{admitted}} |\psi_f(z;p)-\psi_f(z;p_f^0)| \le b_f(z), \qquad \sup_{x\in\mathcal{A}_j}\sum_{f:x\in R_f}\frac{b_f(z)}{|R_f|} \le \bar f. \tag{4.dxv}$$

Every carrier here has a nonempty owned site set R_f; using a coarser root convention instead changes the displayed density bound by its proved local counting constant. Sum first over the sites of R_f, then over the carriers. Absolute convergence or finite sums gives $\sum_f \sup|\psi_f| \le \bar f \sum_j |\mathcal{A}_j|$. The total source excess consequently satisfies eq. 4.dxiii, with its fixed dimensional factors included in $\bar f$.

For a usual rooted decay criterion, assume each carrier has a chosen owned root and tree length $d(R)$, and its total rooted weight is at most $Be^{-\kappa d(R)}$. Assume, at any fixed owned site x, that at most $C_0C_1^m$ carrier/root choices of length m contribute with $x \in R_f$, and that $\kappa > \log C_1$. This is an incidence count at x, not merely a count of carriers whose original root was x. Then the per-site sum is bounded by $BC_0/(1-C_1e^{-\kappa})$. A polynomial root multiplicity is absorbed by a strictly smaller retained exponent: for $\varepsilon > 0$, $m^q e^{-\varepsilon m}$ has a finite maximum, obtained by differentiating $t^q e^{-\varepsilon t}$. This proves the carrier criterion with explicit rate expenditure. It does not verify the amplitudes of the actual formed members.

The constant term in eq. 4.dxv cannot be omitted. A function constant in its field arguments has zero oscillation and can have arbitrarily large parameter-dependent value. In the actual source class its value is fixed by the vacuum, scalar-action and normalizer readouts. Those readouts must be bounded along with the oscillation. Gauge invariance does not bound an arbitrary constant.

For the actual recursion let V_X^{col} be the interaction before re-evaluating the kept inner factors. Write the exponent of an inner source perturbation as its stored-variable part plus its carrier functions ψ_R. The two systems use the same response map for a kept trunk. Its contribution to the difference is

$$T_R^1[\psi_R] = \psi_R(q(\xi)|_R) + \delta_R[\psi_R].$$

The first term rejoins the stored-variable part of that inner exponent at its admitted real pair. Keep the second term in the new excess. The resulting identity is

$$\begin{aligned}\Psi_\omega &= \Psi_\omega^{\mathrm{new}} + \sum_y \Psi_{\omega'_y}(\xi'_y; \mathbf{q}_y(\xi)),\\ \Psi_\omega^{\mathrm{new}} &= A(\zeta''(z)\zeta_1 \mathbf{1}_X, U''(\xi)) + V_X^{\mathrm{col},z} - V_X^{\mathrm{col},0} + \sum_R \delta_R[\psi_R].\end{aligned} \tag{4.dxvi}$$

The reference measures, the bare stored fluctuation slots and the reference quadratic q_X are common to the two systems. The source profile ζ'' multiplies the core cutoff ζ_1. Where that cutoff is nonzero the real inner datum gives curvature $C\check{R}_l^2 \varepsilon_l \eta_l^2$ on layer l. At weak coupling the square of this bound is $O(\eta_l^4)$. The $O(\eta_l^{-4})$ bare plaquettes per site of that layer give a cost $C_W \bar{c} N_0$ when $|\zeta''| \le \bar{c}$. The bare layer uses the uniform Wilson bound.

Apply the formed collar bound to each of $V_X^{\mathrm{col},z}$ and $V_X^{\mathrm{col},0}$. Their absolute bounds include the unpaired plain values at the trivial pair and give $(c_V - 1)(1 + \bar{c})N_0$ for each. This application uses the full common field and stored-slot ranges of the two systems. For $\delta_R[\psi_R]$, subtract the value at $q(\xi)|_R$ and use the same response disc as for the unsourced kept factor. Its bound is the product of the response amplitude and the admitted carrier bound for ψ_R. A term constant in the pair cancels in this difference. The weighted carrier sum for the kept factors therefore applies to these differences with the bound for the source carriers. In particular the resulting sum is at most $2(1+\bar{c})N_0$ once the weak-coupling ceiling is chosen with that carrier bound fixed. The power margin is the one in the kept-trunk estimate, before division by $N_0 \ge 2^{-5} M^4 \ell_t^{5r}$. Hence

$$|\Psi_\omega^{\mathrm{new}}| \le [C_W \bar{c} + 2c_V(1 + \bar{c})]N_0.$$

Add the older complete exponents at their own sites. The additivity of the fresh and older counts takes the maximum of their coefficients. For the source induction we must check the admitted carrier bounds of the actual generated members on the enlarged source lines, including the stored switches. The argument uses these bounds and the full interaction bound on the same domains.

4.18.12. *Complex parameters with the inner Wilson weight fixed.* The preceding proof has a parameter version, but its domain must be specified before taking suprema. Fix the real reference sequence θ and the real physical weight profile x. Freeze all characteristic cutoffs, stored-coordinate charts, reference measures and the inner Wilson weight at those real data. Let the complex parameters y_j satisfy

$$|x_j - \theta_j| \le t_j, \qquad |y_j - x_j| \le \bar{c}, \qquad \tau_j = y_j/\theta_j. \tag{4.dxvii}$$

Here t_j is the radius of the frozen tube at level j. The ordinary strip uses the ratio disc of radius $2(t_j + \bar{c})/\theta_j$ about 1. This radius tends to zero uniformly as the inverse-coupling floor increases. In particular it lies within the half-disc used for the scalar logarithms. The actual ordinary presentation determines where y_j occurs. In particular its complete free-coordinate quadratic form is the one prescribed by eq. 4.d, including a compensation if a normalized $\tau_j K_j$ Gaussian is used. The weight in eq. 4.cdlxix is still the specified real weight x''. Putting a complex weight on a large real Wilson variable and estimating it as if it were the same positive reserve is a different operation.

For a complete matrix on a fixed real free-coordinate space there is a determinant calculation on a half-disc. Under the real hypotheses preceding eq. 4.di, define $B = K^{-1/2} K_A K^{-1/2}$. Since $K_G \ge 0$, one has $B \le I$. Since $K_A \ge -\gamma I$ and $K \ge \gamma I$, one has $B \ge -\gamma K^{-1} \ge -I$. Thus $\|B\| \le 1$ and

$$Q_\tau = K^{1/2}[I + (\tau - 1)B]K^{1/2}, \qquad \mathrm{Re}\, Q_\tau \ge K/2, \qquad \|Q_\tau^{-1}\| \le 2/\gamma. \tag{4.dxviii}$$

The matrix logarithm of $I + (\tau - 1)B$ is its uniformly convergent power series on $|\tau - 1| \le 1/2$. Consequently the determinant and its square root have coherent analytic branches agreeing with the positive branches at one. In d free scalar coordinates, the absolute determinant ratio is between

2^{-d} and $(3/2)^d$. The normalized Gaussian at each fixed real K has total variation at most $3^{d/2}$: its determinant costs $(3/2)^{d/2}$ and replacing the real precision K by $K/2$ costs $2^{d/2}$ on integration.

For a supremum over varying backgrounds, this last fixed-matrix integral is not the argument. If $\gamma I \le K \le \Gamma I$ uniformly on those backgrounds, eq. 4.dxviii and the determinant upper bound instead give the common pointwise envelope $C^d\Gamma^{d/2}e^{-\gamma|b|^2/4}$ in their same stored coordinates. Its integral is at most $(C\Gamma/\gamma)^{d/2}$. Alternatively one uses the proved local comparison with a fixed positive reference matrix. This additional uniformity is precisely what places a parameter supremum inside eq. 4.dii. The classical flat gap is one realized matrix case. A one-step nonflat estimate can verify the same criterion by bounding the negative part of K_A in the actual free coordinates; neither case alone verifies it on every retained layer.

At complex parameters the pair-independent factor of the exponent need no longer be real. The proof uses its modulus, with the real positive energy and the fixed reference envelope just constructed. Suppose the actual local formations and read maps are jointly holomorphic on eq. 4.dxvii, with their cores admitted throughout, and their complete energy bound is $C_V(1+\bar{c})N_0$ there. The scalar gauge branch is supplied by eq. 4.cdxcviii; the pivot branches by eq. 4.cdxcix; the complete Gaussian forms by eq. 4.dxviii where its real matrix hypotheses apply, and by the original-strip estimate for the kept chains on their admitted reads. All their costs are then bounded in modulus by the same type of e^{CV° factor.

Apply the mass proof to the norm with the parameter supremum included from the start. Its real part refers to real *field reads*, while the parameters can be complex:

$$m_\omega^{\mathbb{R},\mathcal{D}}(\xi) = \sup_{y\in\mathcal{D}} \sup_{\mathbf{p}\ \text{real admitted}} |e^{\Phi_\omega(\xi;\mathbf{p},y)}|. \tag{4.dxix}$$

The parameter domains at earlier levels are the corresponding prefix domains of the same reference frame and initial weight. This prefix condition is essential for using the earlier norm in eq. 4.dix. It is not a conclusion of separate holomorphic presentations with different frozen frames.

Uniform primitive estimates give eq. 4.dviii with these parameter suprema, so the same induction proves eq. 4.dxi uniformly in y. The floor is raised for the new local-energy and Gaussian cost constants. If the former is $C_V(1+\bar{c})$, its stated dependence is preserved in the floor. This is a proof from uniform finite domination. It is not analytic continuation of an inequality known only on the real parameter slice.

The positivity used to pay for old failed plaquettes is exactly why the inner Wilson weight was frozen. In a variable-profile source presentation, physical Wilson perturbations are instead carried as specified older potential members. The equality of that presentation with an original numerator and denominator is an exact formation identity with its own counterterm rule. A complex parameter in eq. 4.dxvii cannot be declared a physical source in every factor merely because both families agree at zero.

4.18.12.1. Holomorphy of the actual integrals. Let $\mathcal{D}_0$ be a compact parameter polydisc strictly inside the admitted domain. The pointwise integrands are holomorphic there, all reference measures are parameter independent, and the mass proof supplies one integrable Borel majorant on the full product of stored variables. Integrate the one-variable contour identity of each integrand around a triangle in any coordinate; Fubini is justified by that majorant. The integrated function is continuous by dominated convergence and has zero contour integrals. Morera's theorem gives holomorphy in that coordinate. The same bound and the iterated Cauchy formula give joint holomorphy and its power series. Countable sums of histories are handled by the summable common majorant. It is the reference measure and not just the notation $d\mu$ that must be independent of the parameter in this argument.

For a polydisc with radii $r_1, \dots, r_m$ and a bounded holomorphic numerator insertion F, Cauchy's formula gives

$$|\partial_1^{a_1} \cdots \partial_m^{a_m} I(0)| \le (\prod_{\nu=1}^{m} a_\nu! r_\nu^{-a_\nu}) e^{-a_\star P_i} \sup |F|. \tag{4.dxx}$$

This differentiates the complete numerator with its actual normalizers. A normalized expectation additionally differentiates its denominator. It is not obtained by differentiating only the newly inserted local member.

For example, if an actual one-zone perturbation has the uniform bound

$$|\Psi_\omega(z)| \le C|z| p_n n^\sharp(\omega), \qquad |z| < r_n, \qquad r_n \le \frac{c\ell_{\min}}{2Cp_n}, \tag{4.dxxi}$$

and all its fields remain in the same admitted domains, eq. 4.dxiv and eq. 4.dxx prove the corresponding complex mass and derivative estimate. This specifies a concrete formation estimate to test: the coefficient C must be uniform in the histories, stored fields, levels, zones and allowed reads. A bound for one chosen background or a source function before it is formed is not eq. 4.dxxi.

For several perturbations, a per-site criterion can contain $\sum_\nu |z_\nu| p_\nu$ or a smaller local sum, depending on their supports. The admitted product radii must satisfy that actual criterion. A one-source disc alone does not authorize an equally large product disc for arbitrarily many overlapping sources. Disjoint local supports and a proved local carrier bound can supply such a product disc; its justification is the local bound, not one-variable Cauchy.

4.18.13. *Consequences for stored volume, ages and marked integrals.* Fix $c > 0$ at which the mass bound holds. Any subcollection of histories with $v^\natural \ge T$ has unweighted mass at most

$$e^{-a_\star P_i - cT}. \tag{4.dxxii}$$

This follows pointwise from $e^{cv^\natural} \ge e^{cT}$ and monotonicity of the upper integral. More generally the power series of the exponential gives

$$\frac{1}{h} \sum_\omega \int^* (v^\natural(\omega))^q m_\omega \, d\mu_\omega \le q! c^{-q} e^{-a_\star P_i}, \qquad q = 0, 1, \dots. \tag{4.dxxiii}$$

For $q = 0$ use the unweighted mass directly. For $q > 0$ use $(cv)^q/q! \le e^{cv}$. Combining this with eq. 4.cdlxxviii gives the site-count moments with c^{-1} replaced by $2/(c\ell_{\min})$.

A path of length A in the recorded genealogy contains a node at every one of those levels. Since each such node has at least one cell, $v^\natural \ge \ell_{\min} A$. Therefore its recorded age has exponential tails with exponent $c\ell_{\min}$. For any fixed $b > 0$ the age-weighted sum with factor L^{bA} is finite once $c\ell_{\min} > b \log L$, by summing the geometric series from eq. 4.dxxii. This age is the length inside the recorded genealogy. The number of later levels for which an already formed mark is carried is not part of its unchanged local record; that later duration is controlled by the live-component reserve and the global label comparison, not by silently increasing its local volume at every read.

These bounds control stored counts, not every unbounded function of a stored field. Small mass alone would allow an integrand concentrated at field magnitude T with a second moment of order T^2 times that mass. Field moments need the Gaussian reserve or their own pullback estimate. If the pointwise proof retains $e^{-\beta|A|^2}$, then

$$|A_b|^q e^{-\beta|A|^2} \le \left(\frac{q}{e\beta}\right)^{q/2} e^{-\beta|A|^2/2} \le \beta^{-q/2} \sqrt{q!}\, e^{-\beta|A|^2/2}. \tag{4.dxxiv}$$

The maximum of $t^q e^{-\beta t^2/2}$ occurs at $t^2 = q/\beta$; the factorial estimate follows from $q^q \le e^q q!$. Run the same reference calculation with $\beta/2$. Its extra factor $2^{d/2}$ is another local volume cost, independent of q. With the floor chosen for that unspent reserve, the marked mass has the prefactor in eq. 4.dxxiv. For a physical observable the coefficients and the map from its field to A_b must still

be tracked, including their powers of the scale ratio. A small bad-event probability alone does not give this marked estimate.

These consequences also explain what the volume weight can contribute to a large-field extraction remainder. It supplies arbitrary fixed exponential weights in the recorded age after the corresponding floor is chosen. It supplies polynomial stored-coordinate moments when a spare Gaussian fraction is kept. It does not identify a resummed positive conditional measure, its boundary terms, or its exterior force. Those are different estimates in an interacting covariance calculation.

4.18.14. *Formation, reading and loading at later levels.* We make the quantifiers of transfer explicit. A factor is formed at level i, with a definite local history, stored-coordinate space, support and normalizer. For each later level $k \geq i$ at which its mark stands in a term, let $\mathrm{Read}_{k,i,X}$ denote the actual argument supplied to that same factor. The coverage assertion needed is

$$\begin{cases} \xi_X \in S_{\omega_X}, \quad \mathrm{Read}_{k,i,X} \in \mathcal{U}_i(X^{\sim}) \text{ and is real}, & o = 2, \\ \mathrm{Read}_{k,i,X} \in \mathcal{K}^{\sharp}(\omega_X, \xi_X), & o = \mathsf{d}, \end{cases} \tag{4.dxxv}$$

for every admissible later history and every configuration on its carried support. It is a pointwise statement, before taking an exterior expectation. In the drop-out case it includes every average in eq. 4.cdlxx, every recorded test, the prescribed variant of the last test, the inner-island cores and all one-sided matrix and Jacobian bounds. In the island case its reality is what allows the strong real induction in the new formation.

The finite geometric part can be checked as an invariant of the construction. A later operation outside the component does not change its stored variables. An operation containing it acts above the levels protected by its waiting floor, and its determining entries use the actual re-entry field described after eq. 4.cdlxiv. The action entries keep the tests with their recorded ownership. Restricting a history before that later operation consequently retains the same local history and the same operation. This proves the record statement under the specified local separation and window rules. Admission of the resulting background to the analytic core, and the actual matrix bounds in eq. 4.dxxv, are the remaining analytic part of coverage; the invariant does not prove them by itself.

4.18.14.1. A stop at the prospective regularity test. With n stages completed, let $j = i_\flat + n$. A stop before the collar gauge and the removal keeps the ordinary prefix of index n. Where the preceding guard is already present, it remains a passing test of this prefix. For a datum plaquette of level q, take the union of the endpoint blocks at that level. Read the ordinary density test at its original cube if $q > j$, if the top action region there is untouched, or if this footprint leaves the region covered by the preceding stage test. On the covered footprints use the passing guard $\chi_i^{(n)}$. An untouched prefix reads its original density tests throughout. The old core keeps its own tests and the averaging constraints remain in the original rows.

The ordinary-prefix real admission applies with these tests and with the old determining list. It gives the layer profile of the old background, and the half-radius bounds on the corresponding earlier spaces, including those of carried drop-outs. This uses the tests of the prefix without the newly failed test. The stage has added neither a gauge draw nor a pivot elimination. Its one-step factors remain in their birth coordinates and there is no normalizer from the interrupted stage. For a later evaluation of this stopped fibre, the full footprints of these tests and the same original pivot and walk carriers must occur in the compatible read.

4.18.14.2. The datum at an early prepared seam. A complete test footprint can meet both sides of a prepared face, even when the bare guard uses plaquettes contained in its individual shells. Use the coarse datum at the preceding averaging fibre to control such a footprint. Consider promotion to level $q = j + 1$ in the uncompressed range $q \leq k_0$. In the quiet geometry $G_j \subset H_q$, and the new face is the boundary of $H_q^{[3a_q]}$, with $a_q = M\check{R}_q L^q$. Every new top test based on this promotion has a row outside the new inner box. Its complete blocks extend only $O(L^q)$ inward, so the footprint

remains outside G_j. A footprint meeting the original exterior wall of Ω_q is read on the full halo of the original level-q density test, before that test is removed. The other new footprints lie in the old exterior $\Omega_q^c \setminus Z_j''$. At the first promotion their full carrier is in the region $\Omega_{i_\flat} \setminus \Omega_{i_\flat+1}$ of the stage-zero test. At later promotions the preceding exterior guard reads the whole carrier. The local preceding background reproduces the old determining level-j rows there. Thus the guard bounds the curvature of that background by $C\varepsilon_j L^{-2j}$ on the full carrier. The new coarse rows are its averages by the original constraints. The plaquette estimate gives $C_L\varepsilon_j \le C'_L e_q$, including a plaquette that straddles the new prepared face. The surviving tests of level j use a subset of the previous rows and the same lower completions. The lower tests are unchanged. If level $q+1$ is present, each tested plaquette there has a first-kind edge meeting the original Ω_{q+1}. Its whole carrier is within $O(L^{q+1})$ of that member. The quiet gap of $8a_{q+1}$ keeps this carrier inside the original Ω_q. Its completion therefore uses the same rows as before. Higher tests read neither the changed member nor its immediate completions. Each promotion uses its own positive tests and a single averaging bound. Carry the new coarse holonomy bound as a support condition before marginalizing the old fibre.

4.18.14.3. The datum at a compressed prepared seam. For $q = j+1 > k_0$, take a level-q test whose complete footprint meets $\partial Z_q''$. The footprint extends at most $2L^q$ from this face. The separation from Z_j'' is at least ML^q. The face is at least $5ML^i$ from the old Ω_{k_0+1}, and the original exterior has its clearance from ∂X. Thus the entire footprint lies in

$$X \cap (\Omega_{k_0+1}^c \setminus Z_j''),$$

in the layer of index j before promotion. At the first compressed transition $j = k_0$ this is the single exterior region of the preceding guard. At the other transitions it is its deep exterior region. In both cases its bound is at most $F_j\varepsilon_j L^{-2j}$, with $F_j = L_\flat^{2(j-k_0-1)_+}$.

The local preceding background has the actual old level-j datum on this footprint. Every first-kind link of the new test is promoted there, and every second-kind link uses the same retained level-j blocks. Their common coarse values are exactly the one-step averages. Hence the test holonomy is the level-q plaquette of the averages of this local preceding background. The guard on the full bare carrier and the averaging estimate give a defect at most $C_L F_j \varepsilon_j$. Since $L_\flat < L$ and $L^{i-k_0-1} = \check{R}_{k_0+1}$, this is at most $C_L e_q$. The preceding guard is available before deletion, so the bound can be carried in the coarse support after the integration. This also applies to the last prepared face before the final collar integration.

At a new level-q footprint away from the prepared face, use the same calculation when it is contained in a single preceding exterior region. The factors in those clauses are at most F_j. A remaining new footprint meets an original face $\partial\Omega_l$, with $k_0+1 \le l \le q$. Consecutive original walls of levels $l, l+1$ are separated by at least $8a_{l+1}$, so the footprint meets only one wall level. Use the density test at that face before it is removed.

Put $u = ML^i$ in bare units. Start with a tube of width $3u/2$ about the original face of level l. Its level-l plaquettes are covered by the original density test with its full halo. Before deletion this gives $|\partial V_l - \mathbf{1}| \le C\varepsilon_l$ there. For each subsequent promotion to level $p > l$ reduce the width by $4L^p$ to keep complete backward averaging carriers. The total width lost is less than $8L^i$, so more than u remains. These tubes stay clear of every prepared inner face and every other original face. In a later promotion at level p the tube is outside the original Ω_p and inside the preceding prepared member. Thus its level-p field is the exact average of the retained level-$(p-1)$ field there.

On the joint graph before eliminating these averaging constraints, the level-q field on the remaining tube is the iterated average of the same V_l. Any frame changes act at the block endpoints and preserve its plaquette defect. Apply the full-carrier estimate of Prop. 3.4 once at depth $q-l$. This gives a bound

$$CL^{2(q-l)}\varepsilon_l \le C'\check{R}_q^2\varepsilon_q.$$

The inequality uses $L^{i-k_0-1} = \check{R}_{k_0+1}$ and the frame comparison within the compressed interval. At weak coupling the coarsest scaled input is inside the averaging radius. This bound is a condition on the coarse holonomies in the tube. Insert it on the joint graph and carry it through the exact pushforwards. When $q = l$ the bound follows directly from the original positive density test. In this way the quantitative datum bound uses the original density test at its actual level of formation.

At a final regularity stop, $n = \mathsf{N}_i - 1$. If the broader waiting convention admits the component at the lower endpoint of a later window, it is a partial re-entry. Its level-i density test uses its original action region at that level, which agrees there with the determining region. The top field is the old datum on Γ_i. For an unprescribed level-i bond c with both ends in Ω_i^c, the surviving one-step delta gives

$$V_i(c) = \mathcal{M}(V_{i-1})(c).$$

On a protected footprint containing the two full blocks of c, the later read has the same level-$(i-1)$ rows. Composition of the averages therefore gives this same value of $V_i(c)$ in the later read. The ordinary density tests and the local stage guard are evaluated from the resulting old datum on their own footprints. Deeper remade levels still use their separate determining lists. For a strip operator this argument applies when the later structured address also contains its complete birth carriers. The footprint needed for an energy witness can be smaller than that operator address.

On a fixed incoming prefix and outgoing field, the old and inset versions of the early stop have the same fibre after omitting the root's negative indicator in its own mass. The gauge factors, averaging graphs, retained measure and weight are those of the common prefix. A later read with the new failure imposed restricts this common fibre. Any absolute reference bound on the root-omitted fibre thus also bounds the restricted read. The uniform joint-core bound on the common fibre and the fresh payment for the new failure are separate estimates.

4.18.14.4. A stop between removal and collar integration. Consider a component X of the operation of level i with n completed collar integrations, and put $j = i_\flat + n$. Stage $n+1$ first imposes the localized regularity test $\chi_i^{(n+1)}$, the collar gauge and the approximate closeness test χ'_j at $2\delta'_j$. It completes the fluctuation tests of step $j+1$. The removal uses the retained averaging deltas and the density tests at the top and the old core, together with the lower and higher one-step tests left in the term. The sharper collar radius $CL\delta'_j < \delta_j/2$ supplies the fluctuation implications on the covered exterior bonds. The completed ordinary tests supply the bounds on inherited strip bonds. For the regularity implication the error on a shell of level $l \le j$ is bounded by $C\delta'_j e^{-c(M/M_1)(j-l)}$ in its curvature units, which fits the gap $c\beta_{\mathrm{s}}2^{-(j-l)}\varepsilon_l$ in the ladder. For the missing crossing reads use the comparison of §4.17.1.25. Remove an old indicator only when it equals one on the complete chart used for its removal. Any retained active indicator is part of the real collar integral. The sharp collar split at δ'_j follows the removal.

At the collar gauge insertion, the group is pinned at the next coarse sites, so the coarse row remains fixed. Use Prop. 3.23 on the incoming law before selecting the subsequent gauge-dependent outcomes. The group is supported beyond the reach of the old retained factors. For the prospective regularity test use covariance of the critical orbit. This gives the invariance needed to use the soft gauge factor against the incoming law at this insertion. Its support is in complete blocks inside the component's exterior buffer. A link moved across the prepared inner face belongs to the collar, while the exterior of the component is fixed. The later tests are weights on the resulting variables.

In the row chart this can also be seen directly. At a site x with contour $V_j(y,x)$ from its coarse centre, the draw of a new contour value q_x uses $u(x) = q_x^{-1}V_j(y,x)$. Its input contour lies in a single block and reads no corridor pivot. At fixed nonpivots and gauge draw, each selected pivot changes by fixed group translations preserving Haar, and the averaging row has its original target. Carry the resulting contour values in the branch kernel for the tests that read them. A prescribed contour value would be a graph relation with the gauge draw.

When the component leaves at that split, the retained determining list still has index n. Its tests include the stage-$(n+1)$ regularity test and the approximate collar test at the old level j, together with the failing sharp test. In the local sharp convention this test is formed at the localized next-stage background, so its failure is a condition on the variables of this component. In the global sharp convention use the exact transported test and density of the failed branch. In the variant of the fibre that omits the root's failing test the positive tests are still required. The same list supplies the passing branch up to integration. For comparison one may form the prospective ordinary stage-$(n+1)$ datum with the same variables and the retained averaging constraints. The two determining sequences differ only at $j+1$, by the collar. The prospective read introduces no additional stored variables.

For a datum plaquette use the smallest-level drop-out containing its place. Take its full footprint, the union of the endpoint blocks at its test level. An ordinary density test is read at its original action cube if the footprint leaves the region of the stage test, if its level exceeds $j+1$, or if it belongs to the untouched top action region. The old core also keeps its own tests. Within the covered part use $\chi_i^{(n+1)}$, supplemented by χ'_j for a level-j plaquette touching the collar. The density cube and the footprint are taken in the prescribed partitions of the test. The current mask of an old exponent does not set the place of this guard.

On footprints covered by the literal clauses, the prospective guard gives the curvature bounds used in the block averages. At a prepared or original wall use the coarse holonomy bound from the preceding promotion calculation. The prospective datum has the layer bounds Ce_q on all these reads. The unchanged older rows use the bounds retained in their own prefix. For the old datum on the collar, where the complete double block is in this comparison, the retained deltas give the pivots from the nonpivot values and the prospective coarse row values. The pivot comparison at equal coarse values costs a fixed factor depending on L. Thus the approximate test changes the old level-j holonomy bound by at most $C_L\delta'_j$, by telescoping the plaquette product. The changed lower rows leave their prescribed coarse values fixed. In particular the corresponding level-$(j+1)$ holonomies agree with their prospective values, also when an old edge reads the complete one-step average. For the no-inward determining sets the global and localized next-stage averages differ on the collar by at most

$$C\mathsf{F}e_i e^{-\delta_0 M\check{R}_i} \le \delta'_j/2.$$

Apply this comparison on the complete collar blocks inside the quiet component. The collar lies in O_{j+1}. If $j+1<i$ this is inside G_{i-1}, whose clearance from ∂X is $10a_i$. At $j+1=i$ the clearance of O_i is $2a_i$. The endpoint blocks and the original small test-cube halos together reach less than a_i past this carrier by the cell-size hierarchy. This gives the weighted margin of order $M\check{R}_i$ in the comparison. On a passing sharp branch the two centre comparisons fit $2\delta'_j$. At a sharp stop the retained local approximate test gives $2\delta'_j$ in local coordinates, hence at most $3\delta'_j$ in global coordinates. Use the transported density for the global sharp stop.

For the energy estimates at the approximate and sharp collar stops, consider a bond crossing the old Ω_{j+1} wall. Let y_- and y_+ be the centres of its exterior and interior blocks. The interior block is in the first ordinary strip cell. Both the passed and the failed ordinary cube masks start at least one full cell inside the wall, and their enlarged reads reach at most $2LM_2\check{R}_{j+1}+1$ in level-j units. The complete interior block, including its internal bonds, therefore lies in the plain zone. Its internal bonds are nonpivots and are kept by the original ordinary split. On them the exact plain-zone map gives

$$V_j(e) = \exp\bigl(ig_j\mathcal{A}_j^{\mathrm{s}}(e)\bigr)S_{\mathrm{o,loc}}(e),$$

where $S_{\mathrm{o,loc}}$ is the original localized strip centre. The full block lies in the joined interior, and its fine sites other than y_+ are free for the ordinary axial gauge. Hence the mean contours of $S_{\mathrm{o,loc}}$ from y_+ are the identity. If the kept Gaussian reserve gives $\max_e|g_j\mathcal{A}_j^{\mathrm{s}}(e)|\le\sigma$ on these links, telescoping the contour products and using the derivative bound of the mean gives $\max_{x\in B(y_+)}|V_j(y_+,x)-\mathbf{1}|\le C_L\sigma$.

At the exterior block the retained soft gauge weight gives the same bound if its gauge exponent, divided by its inverse coupling, is at most σ^2.

On the complete double block, the curvature bounds below give defects of size $C\sigma$ for V_j and the prospective local centre. Axialize V_j with the two mean contours, fixing the two block centres. Its coarse row is still $V_{j+1}(\langle y_-, y_+\rangle)$, the target of the original ordinary pivot constraint. The prospective centre is axial on both blocks and has that same target. Double-block rigidity compares each axialized crossing to the common coarse value with error $C_L\sigma$. Undoing the auxiliary gauge costs another $C_L\sigma$, by the two contour estimates. Thus the principal angle on this crossing is bounded by $C'_L\sigma$ in the local chart. On a full history the global angle is at most this bound plus $C\sup_b|H(b)|$, where H is the stage centre shift. Consequently either failure indicator on the full history is bounded above by the local indicator that some tested angle is at least $\delta'_j/2$. Use this upper bound in a local mass, where the evaluation need only give the localized centre. The labelled integral still uses the actual sharp test. The crossing estimate uses the stored ordinary coordinates on the interior block even when the guard itself reads only the crossing.

Write $q = j+1$, and take the one or two full order-q blocks of a tested collar bond together with the backward carriers for their averages. The bond has an endpoint in $(\Omega_q^c \setminus Z''_q)\cap X$. The blocks and their carriers reach only $O(L^q)$ past this set. The gap from Z''_q to Z''_j is at least ML^q, also in the compressed nest. At the first stage use the gap from $G_{i_\flat}$ to the first prepared face and $\Omega^c_{i_\flat}\cap X \subset G_{i_\flat}$. Thus all these carriers have prospective layer at least j. The clearance of O_q from ∂X is at least $2a_i$. After the $O(L^q)$ enlargement this leaves the carriers in the unchanged interior of the join. In particular the old Ω_i wall at the last stage is separated from the outer tower collar.

Every tested datum plaquette whose backward carrier touches the floor is below level $i_\flat$, and its blocks are in the protected core. To reach it from a sharp carrier one must cross the band from $G_{i_\flat}$ to the first prepared face. That band has thickness of order $a_{i_\flat+1}$ in layers at most $i_\flat$, which gives weighted distance at least $cM\check{R}_i$ even at a later compressed stage. The artificial tower collar at ∂X is also this far in the weighted metric. The datum tests inside this weighted neighborhood use the exact old or promoted averages on their complete carriers. Their bare Wilson shares are in the charged enlargement and outside the floor, so small energy gives defect $C\sigma$ there. Use the real admission bound $C\check{R}_i^2\varepsilon_i$ on the other tests. The weighted regularity estimate now gives bare defect

$$C\big(\sigma + \check{R}_i^2\varepsilon_i e^{-cM\check{R}_i}\big)L^{-2j}$$

on the sharp carriers. The averaging estimate gives the same bound without L^{-2j} for the prospective level-j field. The exponential term and the stage centre shift are $o(\sigma)$ for $\sigma = c_*\delta'_j\check{R}_i^{-4}$, uniformly in the waiting window.

For the actual V_j at an old wall crossing, the interior free links belong to the old ordinary fibre. Use the original localized strip centre on the component of $Z_q\cap\Lambda_j$ in X, with the one-part join on Z_1 at the first step. The strip admission uses the original density bounds and exact averaging rows on this domain. Reproduce those rows and the density tests from the retained birth data in the compatible evaluation. This admits the joined centre at the fixed ordinary radius without requiring an extension of the evaluation to the torus.

A tube of width ca_q about ∂O_q lies deep in this join, stays outside G_j, and misses the next original wall. Its layers are j and q. The level-j datum reads on its exterior are old determining values, and the level-q reads are the old coarse targets and the exact averages of the exterior rows. Their full backward carriers lie in the charged enlargement and avoid the floor. The datum away from the tube has the ordinary admission bound, and leaving the tube costs weighted distance $cM\check{R}_q$. The weighted estimate therefore gives level-j plaquette defects of size $C\sigma$ for the localized strip centre on the full double block.

On the interior and crossing nonpivots the exact plain-zone formula and the small retained Gaussian coordinates bound the change from this centre by $C\sigma$. The exterior internal links are

determining and are identical for the two fields. The centre and the actual field have the same coarse target there by the joined row identity. Use the straight-corridor estimate for the actual middle bond with the centre curvature and the nonpivot changes both of order σ. This puts the actual solution in the regular branch, where the one-row inverse gives the bound $C_L\sigma$ for its pivot. If the stopped branch has translated a retained slot, use its original value from the recorded inverse map for the Gaussian reserve. Telescoping each plaquette gives the required bound for the actual field, including plaquettes using the pivot.

If the sharp bond does not cross the old wall, its endpoint blocks are in the old exterior and their fine links are preceding determining rows. The compatible field supplies the full V_j plaquettes directly, so the Wilson share gives their bound. At the inner prepared face the inner block remains in the determining layer. The two fields have identical internal links and hence identical mean contours there. When the two auxiliary axial gauges are undone, this common contour factor cancels in the norm of the relative link. Only the contour errors on the collar side enter. On every collar block the soft weight is either inherited from the old exterior belt or inserted on the remaining blocks of this stage. This covers all its contours. For a bond internal to a single block use the single-block clause of rigidity. The coarse target for a crossing of two blocks is the common retained target.

At the approximate split, use the test in the original coordinates, against $V_X^{(j)}$. At this moment the collar gauge has been inserted and the old ordinary strip still carries the coordinates in the preceding calculation. The complete coarse average is its original constraint. The completion of the ordinary fluctuation tests takes place later. The bound on the two block contours here follows from the small paying energy in the old strip and the collar gauge. Together with the curvature and rigidity estimates it gives

$$|V_j(b)(V_X^{(j)}(b))^{-1} - \mathbf{1}| \le C_L\sigma$$

on the original approximate mask. With $\sigma = c_*\delta_j'\check{R}_i^{-4}$ this lies below $2\delta_j'$. On a sharp stop use the original values recovered from the recorded translation, and apply the angle bound in the chart of its sharp test.

The paying Gaussian and gauge variables in these two estimates are of level $j \ge i_\flat$. Their weights and the Wilson coefficients on the charged enlargement are comparable to the corresponding ones at level i. If the sum of the fresh Wilson, gauge and kept Gaussian shares is at most $c\theta_i\sigma^2$, the individual bounds used above follow after reducing c. Hence a failure at either collar test forces the opposite inequality. In a containing mass these shares use the child's full carriers in its enlargement outside its own floor and its original level-j slots. For a containing operation whose waiting window starts at h, an older standing mark of level $m < h$ is in the retained Z_{h-1} and in the innermost box G_h. Its witness extends only two unit layers of level m beyond the mark. The hull and eight-layer enlargement at step h still contain the witness after removing the cells in contact with Ω_h. Thus the child's bare plaquettes lie in the containing operation's floor. The containing operation spends only plaquettes with no corner in that floor. Its gauge and Gaussian shares start at h, above the corresponding slots used by the child. This separates payments through nested waiting windows.

The newly inserted ordinary completion uses the stored fluctuation coordinate with threshold δ_j. The ordinary change of variables has already been made, and the symbol $\mathcal{A}_j$ in the completion denotes its resulting coordinate. The masks extend from the first strip cell by the two small test-cube layers and fit in the retained two-cell strip. A failed completion therefore has a stored bond with $|g_j\mathcal{A}_j^{\mathrm{s}}| \ge \delta_j$. The kept Gaussian reserve pays for this event on the local fibre. Tests inserted before the ordinary change of variables keep their original pullbacks, as in the ordinary birth payment.

These bounds give regularity on the two stage sequences. On directly guarded old collar reads the layer factor at level j is $O(1)L_\flat^{2(j-k_0(i))_+}$. On the full datum use the bound Ce_l at level l. The real profile estimate then bounds the scaled curvature and current on the retained carriers. The

adjacent-layer conversions and the compression loss are those of the real endpoint comparison, so the bounds fit the half radii of the earlier structures. Local gauges follow from the curvature bounds on their full cubes. The restricted real background is critical over its own averages on subordinate towers, so the tower and core conditions use the same bounds. In particular an inner island leaf is read in its original real core.

The stopped operation keeps the old one-step integrals of levels $l = j + 1, \dots, i$, the bare nest averaging integrals of levels $l = i_\flat + 1, \dots, j$, and the old core. The factors present at departure multiply this product, including the current test and any collar gauge already inserted. At a sharp-test stop in the global convention the first kept one-step integral uses the transported collar coordinates, with the corresponding pivot and Jacobian factors. A sharp failure in the component-local convention keeps the untransformed prefix with its local test. The earlier stops use the original pivot representation. Only completed integrations contribute stage Gaussian normalizers and terms to the stage boundary sum. At each domain D that sum is filed once, with stages up to the maximum completed index of the components meeting D and with already integrated stored fields set to zero. The stopped action keeps the Wilson weight from before the stages. The Wilson differences from completed stages cancel when one returns to that weight and are excluded from this boundary sum.

For its norm separate each completed stage term into its direct normalizer and its localized cluster term. At a fixed carrier, the cluster bounds cost at most $2\mathsf{N}_i\epsilon_{\mathrm{comp}}$ at the final rate. The conversion to pinned norms and the closing of carriers spend $O(1/\mathsf{N}_i)$ in the rate at each stage. The count uses the separation of the stage components. The total loss is therefore bounded independently of N_i. The direct part must use the sum of its pinned normalizer norms, not a single-stage supremum multiplied by N_i. In particular the coefficient for the retained stage entry is bounded by $\bar{D}_1^{\Sigma} + 2\mathsf{N}_i\epsilon_{\mathrm{comp}}$, where $\bar{D}_1^{\Sigma}$ is this summed direct norm. This gives the stage amplitude in the standing-list bound once the direct sum is bounded on the actual graded cells. The identification of each Gaussian determinant with its own stage integral supplies the direct terms for that sum.

For a sourced excess taken at the same evaluated pair, the direct terms cancel before the pinned estimate is used. Keep the stage prefix, masks, stored data and reference Gaussian the same in the two systems. The direct term is then the same function of the pair, including its subtraction at the trivial pair. All system entries occur in the potentials and the resulting closed clusters. Thus the difference of the retained stage sums uses only the cluster majorants on that common chart, including for graded cells. The absolute real bound on the standing term still uses the direct sum.

A later connected coefficient of a stored Gaussian piece also admits a comparison at varying pairs. Suppose the piece has been formed with its local holomorphic majorant ν_e on the larger fixed pair domain. Along the interpolation $t \mapsto p(t)$, let δ be the size of the pair displacement in the local coefficient norms, divided by their admitted radii. Restrict the piece to the complex line of the displacement. On a disc of radius c/δ its supremum is bounded by ν_e, so its change up to $t = 1$ is bounded by $C\nu_e\delta$. For a stored quadratic form $Q_e(y, y)$ read at $y = \mathrm{Ad}_g\, x$, a change from y_1 to y_2 gives the two terms $Q_e(y_2 - y_1, y_2) + Q_e(y_1, y_2 - y_1)$. The bilinear majorant and the bounded adjoint actions give the corresponding linear bound in the size of the relative rotation. When a connected coefficient reads the piece through a mixed derivative in a nonempty set of its switches, that derivative kills the value at the initial pair. Cauchy's estimate then applies to the increment. This argument applies to an arrested Gaussian piece, or a survivor piece meeting its arrested collar, when its formation gives the stated local majorant. The undifferentiated term in the standing sum still requires the absolute bound.

For each completed stage the number of integration bonds is bounded by $C(L)$ times the number of sites of its collar and strip at that stage's scale. Distinct drop-outs sharing a re-made level are disjoint, so this count charges the completed stage numbers once at that level. Changing the departure place within the preparatory stage at fixed n keeps the regions, the integration list and the action carrier. The particular tests and any inserted gauge are recorded in the local history.

There are at most $4\mathsf{N}_i + 6$ possible places for an operation at level i, including the second class, while the marked label uses at most $\mathsf{N}_i + 2$ indices. This is the stage-place part of the count in eq. 4.cdxcvi.

4.18.14.5. A stop at extendibility. At extendibility all preparatory integrations have been completed. Use the prepared datum with the holonomy bounds carried from those integrations and the original exterior and core tests. The real profile estimate therefore applies on the prepared read. The negative extendibility test depends on its exterior argument. At this stop the central integration is still pending. The old top values and the bare averaging chain in the core keep their original places. A later read replays the prepared support from those values and constraints. The frame operation and the new box Haar field enter only at the subsequent stops.

For its failure in a containing mass, use the old exterior top values on the complete carriers in the child's enlarged component. These carriers are outside the central box and its floor. If their Wilson share is E, the averaging energy bound controls the exterior top plaquette defects by $C\sqrt{E/\theta_i}$. The axial extension on the boundary of the central box gives a top field with the same exterior and defects at most $C(M)\sqrt{E/\theta_i}$. In the top inset the localized critical configuration for this extension has bare curvature bounded by this number times CL^{-2i}. The required region $\Omega_i^c \cap X$ lies in that inset by the two-cell clearance. Thus the recorded negative extendibility test forces $E \geq c(M)\theta_i\varepsilon_i^2$. This witness uses the original exterior argument of the test.

4.18.14.6. The tests retained at a late stop. A shell or last-shell failure occurs after the final preparatory guard and the central integration. It retains the positive tests preceding the failure. Use the prepared datum for the regularity comparison and the fresh outgoing field for the later averaging rows that read it. The removal that uses the two passing shell tests takes place only on the continuing branch. In the old prepared estimate the final stage test is used with the original top density tests and the old core tests.

For the inset operation, a level-q tested plaquette of the prepared sequence in X, with $q < i$, has its place in $Z_i'' \subset O_i$ by nesting. Its footprint is the union of the four order-q blocks. From its place this extends by at most $3L^q/2$, so the clearance in eq. 4.cdxliii puts the full footprint inside the spatial inset. On the no-inward list every corner is outside the prepared Ω_i: the first-kind ends are outside Ω_{q+1} and the second-kind ends are outside Ω_q. Thus all four corners are in Z_i''. The final box is a union of aligned level-i blocks, and each order-q block lies in its containing order-i block. The footprint is therefore in Z_i'' in this geometry. The top tests in the original top action region keep their halos, including any reads outside X.

A lower footprint can still meet a seam of an earlier shell. The literal shell bound is on bare plaquettes wholly contained in that shell. The comparison test at the last prepared seam supplies a different set of plaquettes. For real half-radius admission on an inverse branch, use the real endpoint comparison. Before marginalizing the central integral, keep its prepared variables. In the framed integral these are $V'' = V'V_0$ on the changed coordinates, with V_0 formed from the retained exterior. This substitution recovers the same datum in each frame summand. On its admitted incoming fibre the old lower holonomy bounds and the exact top averaging relation give the prepared datum bounds Ce_q of the endpoint comparison. Carry these bounds as a support condition on the prepared datum. For each actual exterior e, the indicator of the bounds depends only on e and the prepared variables. It equals one before the old averaging deltas are integrated, on the admitted entering fibre. The pushforward therefore assigns full mass to the set where this indicator is one. Insert the indicator in the retained kernel to use this density version at each exterior. The real layer estimate and the subordinate tower criterion then give the half-radius membership on its earlier read sets.

On a later read, use the prepared first-kind links directly, including the old top determining values on bonds meeting the box. A second-kind edge is completed from its retained lower double block. This replays each prepared holonomy on the complete read set. The promotion relation on the original fine rows was used to prove its bound before integration. Its consequence on the

prepared datum is the support condition just described. The fresh box field continues to enter the outgoing averaging rows. The original exterior density tests near Ω_i retain their own halo. In the quiet window the central box lies in $\Omega^c_{k_0+1}$, with $k_0+1 \le i-1$, inside the predecessor's hull. The eight-cell growth leaves at least four cells between it and $\Omega_i^{\sim 4}$. A complete density-test read uses less than one more cell. These tests therefore read the retained top exterior even after the central draw. The shell test itself reads the retained framed fluctuation, and the last-shell test reads the prescribed configuration with the retained bottom shell field on the core side of the cut and the identity on the shell side. It keeps the original values on bonds crossing the inner cut, according to the convention in the last-shell comparison.

The first outgoing chart recovers this exterior before it uses the free box pivots. Keep the old tests and support indicator in that joint measure. If a later row change makes an exterior argument a function of its outputs and remaining coordinates, compose each test with that function on the actual inverse branch. An earlier exterior row is read from a fixed coordinate, a retained variable, or an output of its original graph. Take the closure of the test reads under these graphs before taking a marginal. This preserves the support indicator even at a generated exterior. We must check the joint row bound at the resulting read set. A later estimate that uses a sharper threshold at an earlier shell seam must supply that bound on the full footprint.

For the analytic read of the kept one-step factors use X enlarged by one level-i cell layer. The walk carrier of a kept strip from step $l < i$ lies inside X. A strip still carried from step i can have a carrier extending to that full one-cell enlargement. Once all preparatory stages are complete the top strip no longer remains and the one-M-cube collar suffices. In either case the pivot factor uses the two endpoint blocks in its original birth partition. Their regularity follows from the corresponding pointwise bounds and the adjacent-level radius comparison. The walk and pivot bounds are then taken on their original masks. The larger analytic read does not extend the paying Wilson plaquettes or the integration coordinates of the component. The fibre on X receives only the resulting values of the forms and Jacobians, with their uniform one-sided bounds.

4.18.14.7. The same halo at later levels. Include the old top density reads and their first outgoing double blocks in the read set B_{read} of a mark of level i. For a still-carried top strip include its one-cell analytic read as well. The old cells are nested in the new grid and are no wider than the new cells. Thus B_{read} lies within two layers of the level-$(i+1)$ hull of X. This is inside the eight-layer growth and away from the new gauge draw. It lies in the ordinary successor of the mark. At subsequent ordinary steps, a full double block of a row reading the preceding component lies in its hull enlarged by one cell. The same growth includes these rows in the raw region of the successor. Their outputs use the carried lower graph and the current ordinary inputs.

For a later containing preparation let h be its bottom level. The window rule gives $i < h$. If $h = i+1$, the initial two-layer bound puts B_{read} strictly inside the old core of the new operation, even after removing the cells touching Ω_h. If $h > i+1$, apply the eight-layer inclusion at h to the successor at $h-1$, which still contains B_{read}. In both cases the original reads are in the floor. The preparation uses the old outputs in its bottom core and modifies only higher layers. The carried chart and its inverse factors therefore stay at their original levels. A healing that absorbs the component instead supplies the new determining datum on the healed part. The old graphs there remain in the integrated weight of the healing.

4.18.14.8. The next ordinary strip. The larger coarse bounds at the original walls are attached to footprints within the carried components. At the next ordinary step the complement of Ω_t contains the hull of Z_{t-1} and its eight-layer enlargement. The old wall tubes are inside that hull. The ordinary test and strip carriers use the exterior halo of this growth rule. On that halo the ordinary positive tests retain their original thresholds and use their complete averaging footprints. For the one- or two-cell neighborhood of Ω_t, the complete small test and contour carriers cost less than one more cell. The no-inward convention also puts the places of all tests of level below $t-1$ outside

Ω_{t-1}, hence inside Z_{t-1}. The near part of the datum profile uses levels $t-1$ and t, with comparable thresholds.

In the real profile near the ordinary strip, the part of the datum carrying the enlarged wall bound is at weighted distance at least $cM\check{R}_t$. Indeed the path across the guarding cells uses layers of spacing at most L^t, and the fixed read halos leave a cell margin. By eq. 3.ccclxxix its contribution to the normalized curvature and current is at most $C\varepsilon_\star e^{-c\delta M\check{R}_t}$. This is smaller than ε_{t-1} at weak coupling. The ordinary tests in the remaining part of the profile give the usual $C\varepsilon_{t-1}$ bound near the strip. For the localized strip at $t \geq 2$, the join is formed on $Z_t \cap \Lambda_{t-1}$. This domain is disjoint from Z_{t-1}, which contains the carried wall tubes. Use the two-field construction of the joined datum there. Its top values satisfy the retained $\mathcal{M}(V_{t-1}) = V_t$ constraints on the complete blocks, and its lower values use the original positive density cubes meeting the join. Their bounds give the local datum radius of order ε_{t-1} on the full joined test carriers. At $t = 1$ the strip has the one-part join and there are no earlier marks.

One can formulate the transfer without identifying two unnecessarily large sets of physically realizable arguments. Let $\mathcal{W}_k(i, X, o)$ be the admitted reads at level k, obtained by imposing the creation rule and all retained prefix constraints up to that level. Then

$$\mathcal{W}_k(i, X, o) \subset \mathcal{W}_{k'}(i, X, o) \subset \mathcal{W}_i(i, X, o), \qquad i \leq k' \leq k. \tag{4.dxxvi}$$

Actual read images are contained in these sets by eq. 4.dxxv. If one defines $\mathcal{W}_k$ instead as those images themselves, the same nesting additionally needs the exact prefix projection to commute with the local read. Label truncation alone is not a proof of that stronger statement. The admitted-set version already gives the required mass transfer.

Restriction of a supremum and reduction of either its volume or its coefficient can only reduce its upper integral. Hence for $0 \leq c' \leq c$ and $0 \leq v' \leq v^\natural$,

$$\mathsf{M}^\sharp_{c'}(\mathcal{W}_k; v') \leq \mathsf{M}_c(i, X; v^\natural) \leq e^{-a_\star P_i}. \tag{4.dxxvii}$$

There is no new factor for the number of later levels. If an inductive class permits a slack constant, for example $e\, e^{-a_\star P_i}$, that same slack is preserved for its old marks; it is not multiplied once per read. Newly formed marks have the sharper bound proved in eq. 4.dxi. A run started with those formed bounds retains them at all later levels as long as its weights, domains and presentations remain in their admitted tubes.

If a mark is absorbed into a new outer component, its local record occurs inside the new local history. Its weighted mass is then used in eq. 4.dix, not loaded again as a second independent outer mark. This is the operational version of the multiplicity identity in eq. 4.cdlxxvi.

4.18.14.9. Field readings and compensators. Gauge covariance acts on stored variables as well as external triples. Denote that action by $\rho_\omega(u)$. It conjugates the variables rooted in a tree by the transformation at its root and acts on an outside-starting stored bond at its actual starting site. Let R_ω be this finite list of sites. A permitted compensator $c[U]$ is Borel, obeys the actual chart conditions, and is the identity on R_ω. Then $\rho_\omega(c[U])$ is the identity on every stored variable. The compensated tied expression

$$\Phi^\diamond_\omega(\xi; \mathfrak{z}) = \Phi^\circ_\omega(\xi) - \tfrac{1}{2} q_X(\xi; c[U] \star \mathfrak{z}) + V^\diamond_X(\xi; \mathfrak{z}) \tag{4.dxxviii}$$

therefore needs no change of integration variable depending on ξ. Its formation identity must say that the whole tied sum takes the same value for equivalent triples. Separate invariance of the two summands is not required.

On every admitted fixed U chart the dependence on the complex potential and current is holomorphic, and the same envelope bounds the compensated read. Borel dependence on U follows from its Borel compensator and background maps. These claims require the actual compensator with these fixed sites and core admission. Gauge covariance for a fixed global transformation would

not alone construct it. This is why the read rule retains the sites on which the stored-variable action depends.

On the chart of a healed label one can construct this compensator on the ordinary towers and the rooted trees. Let $a(x)$ be the top of the tower of x, or the root of its box if that tower starts in a treated box. For each x, take $c[\mathbf{U}](x)$ to be the product of the averaged transports from $a(x)$ to x. The path first follows the box tree to the top, when present, and then the combs in the successive layers of the tower. The product is empty at a top outside the boxes and at every root. At the real points of the chart the factors are measurable group variables, and on the admitted complex chart they are holomorphic. Endpoint covariance cancels the transformations at the intervening sites, giving

$$c[\mathbf{U}^u](x)u(x) = u(a(x))c[\mathbf{U}](x).$$

The compensator gauges each comb and tree transport to one. For a tree variable the action on the stored coordinate is at the root. For an outside-starting variable whose start is a tower top the action is at that top. Both kinds of coordinates are therefore fixed in this reading. A term that reads another stored site requires that site to be checked separately in R_ω.

Apply $c[U]$ to the real arguments, and $c[\mathbf{U}]$ to the pair $(\mathbf{U}, \mathbf{J})$, with the current conjugated. At fixed U the real change is fixed. The compensated pair depends only on the original pair, so a tied slice expression is still tied on its admitted reads at fixed stored variables. Under a real gauge change the two normalized presentations differ by $u \circ a$. The invariance of the slice expression under these root and top rotations gives the joint invariance of the read expression. For a local term the carrier must contain the full paths just used. In particular a carrier that reads a box tree must contain that tree as well as the affected towers.

The analytic bound applies on the preimage of the original chart. This restriction matters even for flat complex links. Take a constant imaginary potential in one direction on a local order-j tower, with bare spacing L^{-j} in level-j units and with $U = 1$. The real compensator is then one. The complex comb puts the transport across two adjacent tops on the bare bond joining their towers. A logarithmic potential of size α before this change has size $L^j\alpha$ on that bond afterward. Hence the small potential bound in the original chart does not give the same bound on every compensated pair. At a frozen seam we must also check the endpoint constraints on the unchanged lower rows. The rooted product on the healed label supplies the gauge correction only on the admitted chart just described.

4.18.15. *Causal restrictions and the product of healed histories.* We give a finite algebraic statement that explains when a sum of histories is a gas. Spatial separation by itself is not its hypothesis. The determining reads, action reads and reference normalizers must all be included.

An elementary move has a discrete type, a finite list of input slots, a finite list of output slots and an integral kernel for the variables it removes. A test is a move with a finite outcome list and no integral. Every slot has a level, region and type, such as a group field, free Gaussian coordinate, scalar constant or background chart. Slots are versioned. The dependency relation directs an edge from a move producing a slot version to each later move reading it. It also orders every write/write, remove/read and priority conflict consistently with a legal execution. We require every pair left incomparable to be independent in the sense below; producer-to-reader edges alone do not imply this property. The relation includes the discrete reads deciding class membership and the background box in which a critical configuration is formed.

Let $R(\gamma)$ be the closed read support of a group of moves γ: include their written variables, every input they read, every relevant action plaquette and every wall and gauge factor they use. If a move evaluates a background on a whole box, that box is included. A carrier cannot be reduced to a short random-walk segment merely because a displayed kernel term has a short segment. In particular q_X in eq. 4.cdlxvii has carrier $X^\sim$; its separate walk terms use a minimizer on all of X and are not local functions of their short walk supports.

The exact locality hypotheses for the finite statement are as follows. Local functions and reference kernels obey hereditary restriction: forming a move on a larger admitted box and setting outside decoupling parameters to zero gives the move formed on the smaller box. Its normalizers and counterterm readout obey the same identity. Two independent groups have disjoint closed read supports and no common decoupling wall. Their incoming exterior slots agree with the reference carried history, and all parameters stay in the common admitted domains.

Lemma 4.68 (Order and restriction)**.** Under these hypotheses incomparable independent moves commute, and a hereditary subcollection has the same outputs on its slots whether executed alone or inside the larger history. ■

Proof. For two integral moves, the inputs held fixed by one contain no variable written or removed by the other. Their integrands multiply, their reference measures are product measures and their output substitutions concern disjoint slots. Tonelli proves commutation for positive real kernels. For complex kernels the common Borel envelope in eq. 4.dviii supplies the absolute integrability for Fubini. A test has the same value before and after an independent move, since every slot it reads has been included in its closed support. This also proves commutation for a test and an integral move.

Two linear orders of a finite dependency partial order differ by adjacent swaps of incomparable entries. To see this, take the first entry of the second order and move it forward in the first. Every entry passed is incomparable: an ancestor must precede it in both orders, and a descendant cannot precede it in the first. Remove this entry and continue by induction. The commutation just proved makes the operation independent of the chosen linear order.

For restriction, take the first retained move. Every input it needs is either fixed exterior data or produced by a retained move, by heredity. It therefore has the same value as in the larger history. Determinism of its test and formation formula gives the same outcome and output. Induct on the remaining moves. Hereditary consistency identifies their formation on the restricted boxes with their restrictions from the larger boxes. This proves the statement for functions and integral operations. □

A minimizer on a larger domain generally changes with exterior data. Locality of the bare action does not make that minimizer a function of an arbitrarily smaller carrier. The actual localized background functions, interpolation endpoints and hereditary identities must be used in this lemma. Naming a carrier is not such an identity.

Fix the outer history $\bar{H}$ and the real data that the completed operation leaves unintegrated. In a history over $\bar{H}$ the healed components of the current level t form a compatible family $\mathfrak{X}$. Restricting to a subfamily deletes the entire ancestral cluster of each omitted component. Conversely, disjoint admissible component histories that do not touch the standing region can be united with $\bar{H}$. This follows from the history restriction and union rules in §4.17.1.1. The output label and marks are common to the resulting histories. The sums over the histories and frames of $C \in \mathfrak{X}$ are part of the same local integral operation $\mathbf{T}'_t(C)$ in every family that contains C.

These are statements about the records. In the integral, each record uses its actual test support. In particular, on the first-class support $\chi_t(C^{\sim -6}) = 1$ the two reference-law cutoffs in C are one. For the cutoff of the reference fluctuation this uses the bound by a fixed multiple of $M^6\varepsilon_t$ and the choice of its radius $M_0\varepsilon_t$ above that bound. The exterior small-field test incorporates $\chi_t(C^{\sim -6})$, and the reverse gauge-fixing identity removes the reference tree factor relative to the variables of C. The second-class support retains the complementary test, both cutoffs and the tree factor. The operations for the standing components thus act on the following sum, with their variables kept fixed while summing over the healed components.

Write $\mathcal{Y}(\mathfrak{X})$ for the domains, other than single collars, that contain at least one collar of a healed or second-class component and contain every collar that they meet in a cube. Here the collar is the whole enlargement $C^{\sim}$. Write $V_{\mathfrak{X}}(Y)$ for the interaction on such a domain. The single-collar terms

are included in the component operations. The completed action is common to the families over $\bar{H}$. To compare the interactions, take the local lists before assigning terms to slots. Localisation is linear within each of the pointed, unpointed and Wilson classes. The Wilson pieces with profile-dependent weights first use one common cover, on which the level-t filing profile φ_t cancels by the Wilson identity. The terms made by $\mathbf{T}$ and the stages are compared before filing.

For a complete localized carrier missing the enlarged collars of the deleted first-class components, use the comparison obtained by erasing their histories. It preserves the local comparison before filing. The input members on the domain must correspond, the strip shifts must be determined by the zone and label, and the standard rules for the levels must apply. Under these conditions the local operators, fluctuation potentials and stage terms agree as partial maps. In particular the stage region is read on the enlarged domain and its preparatory entries and nests are read in their declared level windows. The Wilson pieces using the final filing profile were combined above. The comparison keeps the common functions even when the final mask changes their slots.

The same argument applies to a deleted second-class component when the formal history space permits reassigning its class for this comparison. The ordinary and stage functions are formed before the final class test. Give the component the first-class designation in the comparison of those unfiled functions, apply the erasure identity, then file under the actual output mask. This uses the order of formation and the formal admissibility of the reassigned history. The real histories in the integral retain their actual tests.

More generally, suppose $\mathfrak{X} \subset \mathfrak{X}'$ and Y is admitted for both families and meets none of the added collars. Every entry with base in Y then has the same carrier, domain and value: the earlier entries agree by coherence, the response evaluations use the same components and pinned sites in Y, and the kept factors have carriers inside the collars of the components that remain. Thus $V_{\mathfrak{X}'}(Y) = V_{\mathfrak{X}}(Y)$ on its common domain. The requirement that Y be admitted for both families is used here. Adding a component can change the admissible resummation domains.

For $Y \in \mathcal{Y}(\emptyset)$ let $Y^{\mathfrak{X}}$ be Y together with each healed collar sharing a cube with Y. The collars are disjoint, so this is a domain in $\mathcal{Y}(\mathfrak{X})$. Set

$$W_{\mathfrak{X}}(Y') = V_{\mathfrak{X}}(Y') - \sum_{Y \in \mathcal{Y}(\emptyset)\colon Y^{\mathfrak{X}} = Y'} V_{\emptyset}(Y).$$

If Y' contains no healed collar, the only preimage is Y' and the difference vanishes by the preceding comparison. Each other difference depends on the family only through the healed components in Y' and their local histories. The subtracted terms are independent of the variables integrated by the healed operations. Grouping by $Y^{\mathfrak{X}}$ and taking their common exponential outside these operations gives

$$\begin{aligned} &\sum_{\mathfrak{X}} \prod_{C \in \mathfrak{X}} \mathbf{T}'_t(C) \exp\left(\sum_{Y \in \mathcal{Y}(\mathfrak{X})} V_{\mathfrak{X}}(Y) \right) \\ &\quad = \exp\left(\sum_{Y \in \mathcal{Y}(\emptyset)} V_{\emptyset}(Y) \right) \left[1 + \sum_{\mathfrak{X} \neq \emptyset} \prod_{C \in \mathfrak{X}} \mathbf{T}'_t(C) \exp\left(\sum_{Y' \in \mathcal{Y}(\mathfrak{X})} W_{\mathfrak{X}}(Y') \right) \right]. \end{aligned} \tag{4.dxxix}$$

The component operations act on the exponentials following them, including the dependence on their histories and integration variables. This identity requires no division by a history density.

Expand the exponential inside the square bracket as a product of $1 + (e^{W_{\mathfrak{X}}(Y')} - 1)$. Make a graph with one vertex for each healed collar and each selected interaction domain. Two vertices are joined when their supports have coinciding or adjacent cubes outside the hulls of the fixed outer label. Each healed collar lies outside those hulls. The restriction and union rule for the histories and the agreement of the differences on retained domains give the product of the activities for the different connected components of this graph. The standing variables remain parameters during this factorisation. Each activity contains a healed component, since every selected nonzero

difference has a healed collar in its domain. The local terms $V_\emptyset$ remain in the boundary exponent, since their domains contain a second-class collar.

The identity is for the complete operation on its physical data. Local activity formulas can also be estimated on their admitted complex cores, including independent currents. Their estimates do not extend the global physical identity to independently varied currents. To take the logarithm of the square bracket and file its terms by their unions, use the polymer criterion after the integrable kernel majorants and the activity bounds have been established.

4.18.15.1. A kernel norm for composition. For a local kernel $K(\xi;p)$ define

$$\|K\|_c = \int^* e^{cv(\xi)} \sup_p |K(\xi;p)|\, d\mu$$

including its discrete sums and frame factors. It gives

$$\|\mathbf{T}_K F\|_\infty \le \|K\|_0 \|F\|_\infty$$

for bounded insertions on the full read space. If a second kernel is evaluated at an admitted read $q = q(\xi,p)$ and has stored variables η, then the additive weight and a common Borel envelope give

$$\int^* e^{c(v_1+v_2)} \sup_p |K_1(\xi;p)K_2(\eta;q(\xi,p))|\, d\mu(\xi)d\nu(\eta) \le \|K_1\|_c \|K_2\|_c. \tag{4.dxxx}$$

Bound the factors by their strong majorants and use Tonelli. The read must lie in the core of the second norm at every point of the first support. A real read needs only the strong real version of that norm. This is the kernel mechanism of eq. 4.dix, and shows why a fixed-read integral estimate is not the right norm for general composition.

4.18.16. *The loaded label sum and its analytic price.* At final level k let N_k be the number of lattice sites. In the site load put $D_m = \Omega_m \setminus \Omega_{m+1}$ for $m \ge 1$. At level zero use $D_0 = T_\ell \setminus \Omega_1$, counted on the bare lattice. This counts all bare sites of that layer, including the sites outside the collared first member. The determining sets of eq. 4.cdlxx still use their own first member. Put $Z_j^+ = ((\Lambda_j^{\mathsf{a}})^c)^\sim$. The required load is

$$\mathscr{L}_c(\mathcal{S}) = c\sum_{m=0}^{k} |D_m| + \sum_{j=1}^{k} (C_{\log}\ell_{j-1} + C_{\mathrm{loc}} + c)\#_j(Z_j^+), \qquad C_{\log}, C_{\mathrm{loc}} \ge 0. \tag{4.dxxxi}$$

Every count is at its indicated level. At the last level the outer remaining layer has at most N_k sites. Older layers may have been redone; their counts are not a single present-day volume.

The scalar site load has a direct estimate. Since Ω_{m+1} is aligned at level $m+1$, for $m < k$ one has

$$|D_m| \le \#_m(\Omega_{m+1}^c) = L^4 \#_{m+1}(\Omega_{m+1}^c) \le L^4 \#_{m+1}(Z_{m+1}^{\mathsf{a}}).$$

This uses inclusion of the action members in the determining members and applies also to the full bare count at $m = 0$. The last layer costs at most N_k. For the source share charge each dilated cell of Z_j^+ to a cell of Z_j^{a}; the one-layer enlargement costs a fixed multiplicity. The bounded drift gives $\log\theta_{j-1} \le C\log\theta_j$. Thus the total scalar load is bounded by $cN_k + B(c)\sum_{j\le k}\log\theta_j\, \#_j(Z_j^{\mathsf{a}})$ for a fixed coefficient $B(c)$. To use it in the product over histories, retain the ownership of each local action load. The geometric load comparison is checked by ownership of level-site addresses. Charge an unaltered layer site to its action cell, with one-step fine-to-coarse multiplicity at most L^4. Charge a site in a redone determining layer to the local history of the mark that remade it, retaining its original level. Prepared means are charged to their owned level cells, not to an integrated-out variable at a different level. The re-entry rule after eq. 4.cdlxiv specifies the actual datum read there. With nested marks, use the latest operation owning the remade slot; its inner record already accounts for the earlier history.

The precise finite geometric assertion is that each such read belongs to its owning cell collar, with a bounded covering multiplicity C_{d}. It involves the actual determining entries, action entries

and retained nests together. Once this assertion holds, summing the assigned addresses and using eq. 4.cdlxxvi–eq. 4.cdlxxviii bounds the load by current-level sites, live action-cell volume and marked volumes. No factor counts the number of later reads of a mark. In particular a coefficient of the following form suffices to pay the redone load:

$$b(c) = L^4(c + C_{\mathrm{sf}}) + C + c, \qquad c^\sharp(c) = c + CC_{\mathrm{d}}(b(c) + c_{\mathrm{e}}). \tag{4.dxxxii}$$

The fixed C includes the proved collar, scalar-number and normalizer prices, and C_{sf} bounds final unmarked local energy per site. Both expressions are affine in c. The terms $C_{\log}\ell_{j-1}$ and C_{loc} in eq. 4.dxxxi enter the cell price before the reserve is applied. Another price in an actual presentation must be inserted with its actual sign and magnitude, not omitted by this notation.

Separate the surviving real coarse Wilson factor. The unmarked localized energy costs $C_{\mathrm{sf}}N_k$ plus the assigned defect-site prices. Rescaling and the remaining Gaussian and chart factors have the local prices proved above. The vacuum subtraction uses the following count.

4.18.16.1. Subtracting the label vacuum number. The label density carries $e^{-\mathcal{E}_k(\mathcal{S})}$. Let $E_{(k)} = -\mathcal{E}_k(\mathcal{S}_\emptyset)$ be the vacuum number of the all-small-field prefix. Its subtraction leaves the scalar $-[E_{(k)} + \mathcal{E}_k(\mathcal{S})]$. Use the same one-step constants for the label and the all-small-field term, with the actual ranges in each.

For a region Y made up of level-j blocks, put

$$n_{j-1}(Y) = |Y^{(j-1)*}| - (L^4 - 1)\#_j(Y).$$

The first count consists of the incident free bonds after pivot removal. The second counts the sites of the normalized block gauge factors. In bare gauge dimension three, the Gaussian scale contributes $-\frac{3}{2}\log\theta_{j-1}$ per free bond and the gauge denominator returns the same amount per gauge site. The remaining normalizer terms, including the bounded ratio x_{j-1}/θ_{j-1}, are the regular part of the count. On the full torus $n_{j-1}(T_\ell) = 3(L^4 - 1)N_j$.

To compare a region with the torus, let $b_j(Y)$ count the bonds of level j with one end in Y. Counting bond endpoints outside Y shows that the number of bonds with both ends outside is $4\#_j(Y^c) - b_j(Y)/2$. The corresponding fine count uses $L^4\#_j(Y^c)$ sites and $L^3 b_j(Y)$ crossing bonds. Subtract the coarse pivots and then the gauge sites. This gives

$$n_{j-1}(T_\ell) - n_{j-1}(Y) = 3(L^4 - 1)\#_j(Y^c) - \tfrac{1}{2}(L^3 - 1)b_j(Y).$$

Since $b_j(Y) \le 8\#_j(Y^c)$, this difference is nonnegative and is at most $3(L^4 - 1)\#_j(Y^c)$. For $Y = \Omega_j$ the logarithmic term in $\mathcal{E}_k(\mathcal{S}) - \mathcal{E}_k(\mathcal{S}_\emptyset)$ is $-\frac{3}{2}\log\theta_{j-1}$ times that difference. Thus its sign in the density after vacuum subtraction is positive.

For the bounded activity terms, charge a missing base point in Z_j^+ by the rooted domain sum. Every other missing pointing lies in a domain meeting Z_j. Root there and sum the at most $CM^4(1 + d_j(X))$ pointings with the spare exponential decay. A missing remainder meets Z_j^+ because its range excludes the inner boundary layer. These sums cost $C\#_j(Z_j^+)$. The analogous source difference uses the same ranges, and the Gaussian and gauge counting factors cancel in that difference.

For the stage scalars, sum by the remade level j. At a fixed remade level the drop-out windows have disjoint spatial pieces. Their strip and collar bonds are counted in Z_j, at most $CL^4\#_j(Z_j)$ fine bonds in total. The normalized Gaussian spectrum at the trivial pair gives a bounded log contribution per integration coordinate. Each pivot contributes its fixed flat Jacobian, and the change of scale costs $C\log\theta_{j-1}$ per bond. This gives the stage price $(C\log\theta_{j-1} + C)\#_j(Z_j)$. Together these counts give the local price in eq. 4.dxxxi, including its logarithmic share.

For a later normalization $E_{(n)}$ of the same run, the full-lattice count gives

$$E_{(n)} - E_{(k)} = -\tfrac{9}{2}(L^4 - 1)\sum_{j=k}^{n-1}(\log\theta_j)N_{j+1} + \mathfrak{r}_k, \qquad |\mathfrak{r}_k| \le CN_k.$$

Here the bounded one-step costs sum geometrically because $N_{j+1} = L^{-4(j+1-k)}N_k$. The logarithmic sum is nonnegative before its minus sign, and is bounded by $C(1+\log\theta_k)N_k$ using bounded adjacent frame drift. In particular the prefix floor expressed with $E_{(n)}$ loses at most e^{-CN_k} compared with its expression using $E_{(k)}$.

Under these local prices, the modulus of each literal label term is bounded, before its last Haar integration, by its positive history envelopes, defect-site prices and $e^{C_{\mathrm{sf}}N_k}$. The remaining real Wilson factor is at most one. Normalized Haar integration is at most one after positive restrictions are dropped. For a drop-out restrict the sum to inner histories compatible with its marked label. The volume bound on these histories is $\mathsf{v} \geq V_{\mathrm{in}}$, where V_{in} is the inner volume of that label. If $c' = c^\sharp(c)$, then on these histories

$$e^{c\mathsf{v}} \leq e^{c'\mathsf{v}}e^{-(c'-c)V_{\mathrm{in}}}.$$

The restricted mass with weight c' is bounded by the full mass with that weight. The extra factor pays the redone load of the label. The full mass at weight c includes other histories with smaller inner volume, so the restriction precedes this estimate. For a second-class mark use its full estimate at c' by monotonicity. Unfinished live lineages use eq. 4.cdxciii, not an additional fictional marked mass.

Here is the final field-free summation. Root each connected carried component at a cell of the fixed M partition at level k. There are N_k/M^4 root addresses. Earlier healed components have already been resummed into local energies and are not independent roots in this carried forest. Counting them again would incorrectly introduce a bare-volume root factor.

At each root the connected histories have the bounded-degree address encoding of eq. 4.cdxcv and the local code in eq. 4.cdxcvi. Increase the cell price by a fixed amount and use the reserve at the correspondingly raised floor. The residual positive weights a_γ of carried components then have

$$\sum_{\gamma \text{ at } r} a_\gamma \leq 1. \tag{4.dxxxiii}$$

This is the connected-set sum in eq. 4.cdxcvii, with the specified load in the price and the marked masses already integrated. Histories leading to the same label are retained; the code pays for them. No one-to-one identification of labels with histories has been assumed.

More explicitly, let a_γ be the integrated positive envelope of the particular component record, after its marked operations have been dominated and its owned defect prices assigned. The per-record bound used here is $a_\gamma \leq h^{-f_\gamma}e^{-\sigma V_\gamma}$, with σ larger than its ancillary code constant plus $2\log D + \log 2$. It follows from the event reserve with this additional cell price only when the complete kept forms and stored coordinates of that literal term have the uniform domination already stated. They give a product envelope in the disjoint owned coordinates; bounded reads are first replaced by their strong majorants. Counting that bound by eq. 4.cdxcv–eq. 4.cdxcvii proves eq. 4.dxxxiii. Thus eq. 4.dxxxiii and eq. 4.dxxxv require the product-coordinate and analytic price estimates for each component record. Positivity of the final gas alone does not give these estimates.

Allowed collections are a subset of all finite collections of distinct component records. Dropping compatibility in a nonnegative sum proves

$$\sum_{\Gamma \text{ allowed}} \prod_{\gamma\in\Gamma} a_\gamma \leq \prod_\gamma (1+a_\gamma) \leq \exp\Big(\sum_\gamma a_\gamma\Big) \leq e^{N_k/M^4}. \tag{4.dxxxiv}$$

For countably many records first prove the finite inequality, then take the increasing limit. The loaded integral and label sum consequently satisfy

$$\sum_{\mathcal{S}} e^{\mathrm{Re}\,\mathcal{E}_k(\mathcal{S})}\tau^{\mathrm{abs}}_{\mathcal{S},c}(\mathcal{V}_k)e^{\mathscr{L}_c(\mathcal{S})} \leq e^{(c+C_{\mathrm{sf}}+M^{-4})N_k}. \tag{4.dxxxv}$$

Here $\tau^{\mathrm{abs}}_{\mathcal{S},c}$ is the literal measure with moduli and $e^{cv^{\natural}}$ at its outer marks. The term cN_k is the current-level part of eq. 4.dxxxi; older loads have been paid by the action-cell reserve or the excess marked weight.

Thus eq. 4.dxxxv is a conditional deduction from the exact normalized label representation, local analytic prices, read ownership and mass bounds. It is not a consequence of a final coarse gas alone. History summation forms the local energies and carried measures to which the prices apply. Their formation and common vacuum normalization must first be matched. Complex sources need uniform modulus prices on their admitted domains. For a real system, positivity of the remaining Wilson term is used exactly in the final Haar comparison.

4.18.17. *A weighted analytic extension from a prepaid real norm.* There is a second way to extend a parameter family. It does not require the pointwise excess estimate in eq. 4.dxxi. Its hypotheses are instead an ordinary complex bound in the actual kernel norm and a more strongly weighted bound along a real interval. We prove the statement, including its norm and domain requirements.

Fix the stored-variable spaces and allowed argument fibres $D_\omega(\xi)$. They may be ordinary cores or compatible evaluation fibres. They do not change with the parameter being continued. For a complex kernel family $F = (F_\omega)$ put

$$\|F\|_{\mathfrak{E}_c} = \frac{1}{h}\sum_{\omega}\int^{*} e^{cv(\omega,\xi)} \sup_{p\in D_\omega(\xi)} |F_\omega(\xi;p)|\, d\mu_\omega, \qquad c \ge 0. \tag{4.dxxxvi}$$

The weight is a fixed finite nonnegative Borel function. The history volume is its principal example; the proof does not require it to be integer valued. Reference measures, fibres and weight are fixed throughout the argument. Kernels with zero norm are identified. No measurable maximizing argument is required by the definition.

Lemma 4.69 (Completeness and truncation)**.** The finite-norm quotient in eq. 4.dxxxvi is a complex Banach space. Multiplication by a Borel scalar of modulus one is an isometry. Multiplication by $1_{\{v\le N\}}$, denoted P_N, has norm at most one, and $P_N : \mathfrak{E}_0 \to \mathfrak{E}_c$ has norm at most e^{cN}. ■

Proof. Homogeneity and the triangle inequality follow from their pointwise supremum versions and eq. 4.cdlxxii. Zero norm has a concrete meaning. If its supremum is f, choose Borel majorants $g_n \ge f$ with weighted integrals at most 2^{-n}. Fatou gives $\liminf g_n = 0$ almost everywhere, so $f = 0$ outside a Borel null set. Conversely, zero outside such a set has zero upper integral. The null set is common to every argument in the fibre. Thus the quotient is a normed space with one common equivalence relation for all arguments.

For completeness take a Cauchy sequence and a subsequence F_{n_j} whose consecutive norm differences are at most 2^{-2j}. On the countable disjoint union of the stored spaces choose Borel majorants b_j for the fibre suprema of these differences, with total weighted integrals at most 2^{-j}. Countably many errors in the separate history integrals can be allocated a further summable amount when choosing these majorants. Tonelli gives $\sum_j b_j < \infty$ outside one Borel null set. Remove also the null sets on which one of the countably many finite-norm kernels is unbounded on its fibre. On the complement the subsequence is uniformly Cauchy on every fibre, so it has a uniform pointwise limit $F_\omega(\xi;\cdot)$. Define it to be zero on the removed null set. Its difference from F_{n_j} is majorized by $\sum_{l\ge j} b_l$, whose weighted integral tends to zero. Thus the subsequence, and then the original Cauchy sequence, converges in norm. Uniform limits preserve continuous field dependence or holomorphy on fixed field cores when those properties are imposed. These give closed subspaces if desired. The multiplier and projection claims follow pointwise from their absolute values. □

We will also use continuity from below of this upper integral when the integrals have a finite bound. If $0 \le f_n \uparrow f$ and $\int^* f_n \le M$, choose Borel majorants $g_n \ge f_n$ with integrals at most $M + 1/n$. The functions $h_n = \inf_{k\ge n} g_k$ are Borel, increase, and satisfy $h_n \ge f_n$. Each has integral at most M, since it is bounded by every g_k with $k \ge n$. Measurable monotone convergence shows

that $h = \lim h_n$ majorizes f and has integral at most M. Monotonicity gives the reverse inequality needed for equality of the increasing upper integral limit. This applies on the disjoint union as well.

4.18.17.1. A criterion for ordinary Banach holomorphy. Suppose the actual representatives $K_\omega(z;\xi;p)$ are holomorphic in $z \in D_R$ at each fixed (ξ,p), and their $\mathfrak{E}_0$ norms are at most M for every z. This is a kernel bound, not just a bound on an integrated scalar partition function. Assume on each interior source circle $|z| = R_0 < R$ that

$$a_\omega(\xi,t) = \sup_{p\in D_\omega(\xi)} |K_\omega(R_0e^{it};\xi;p)| \tag{4.dxxxvii}$$

is jointly Borel. The reference measure and fibres are independent of z.

For a fixed separable field core the usual Carathéodory hypotheses give this measurability. For each fixed field argument, Borel dependence on ξ and continuous dependence on the source circle give joint measurability by piecewise-constant circle approximations. A countable dense set in the field core then makes its supremum a countable supremum of these jointly Borel functions. A fibre depending on ξ need not have a fixed dense set; in that case eq. 4.dxxxvii, or a direct common Borel envelope, must be checked on the actual evaluation rule.

Tonelli and the uniform ordinary norm give

$$\frac{1}{h}\sum_\omega \int \frac{1}{2\pi}\int_0^{2\pi} a_\omega(\xi,t)\,dt\,d\mu_\omega \le M.$$

Outside a Borel null set the circle average is finite. Cauchy's formula at each field argument therefore gives, simultaneously for every argument and $|z| \le r < R_0$,

$$\sup_{|z|\le r}\sup_p |K_\omega(z;\xi;p)| \le \frac{R_0}{R_0-r}\frac{1}{2\pi}\int_0^{2\pi} a_\omega(\xi,t)\,dt. \tag{4.dxxxviii}$$

The right side is a common Borel majorant with total integral at most $MR_0/(R_0-r)$. It was obtained first from the Cauchy kernel, and then from Tonelli; no uncontrolled supremum was interchanged with the stored-variable integral.

The coefficient formula $A_m = (2\pi)^{-1}\int K(R_0e^{it})R_0^{-m}e^{-imt}\,dt$ has fibre supremum at most R_0^{-m} times the same circle average. Thus $\|A_m\|_{\mathfrak{E}_0} \le MR_0^{-m}$. The Taylor remainder on $|z| \le r$ has norm at most $M(r/R_0)^{n+1}/(1-r/R_0)$ after degree n, by the geometric series in Cauchy's formula. It proves actual norm holomorphy and identifies its coefficients with the differentiated kernels outside one common Borel null set. The centre can be any point with an interior source circle, so the proof works throughout the domain.

This criterion applies when the ordinary complex mass is available before the weighted one. The ordinary complex kernel bound, pointwise kernel holomorphy and the stated measurability then supply the Banach premise of the following theorem. Scalar integral holomorphy alone supplies none of these kernel assertions.

4.18.17.2. An explicit harmonic barrier. Let $0 < a < R$, remove the segment $[-a,a]$ from the disc $D_R = \{|z| < R\}$, and for z outside the segment let $w(z)$ be the root of $w + w^{-1} = 2z/a$ with $|w| > 1$. There is exactly one such root: the two roots have product one, and a root on the unit circle would put z on the segment. The roots are simple off its endpoints. The unique choice is therefore holomorphic there by its local simple-root formula, and these choices agree on overlaps. Put

$$g(z) = \log|w(z)|, \qquad H = \operatorname{arcosh}(R/a), \qquad h_*(z) = 1 - g(z)/H. \tag{4.dxxxix}$$

The function g is positive and harmonic, locally the real part of a logarithm of its nonzero holomorphic root. It tends to zero on the segment. The identity for w and the triangle inequalities give

$$a\sinh g(z) \le |z| \le a\cosh g(z). \tag{4.dxl}$$

Thus $g \geq \operatorname{arcosh}(R/a)$ on the outer circle and $g \leq \operatorname{arsinh}(r/a)$ on $|z| \leq r$. In particular $h_* \leq 0$ on the outer boundary, $h_* = 1$ on the slit, and

$$h_*(z) \geq h_0 := 1 - \frac{\operatorname{arsinh}(r/a)}{\operatorname{arcosh}(R/a)} \quad (|z| \leq r). \tag{4.dxli}$$

Take $a = R/2$ and $r = R/4$. Then $h_0 > 1/2$: indeed $\cosh(2\operatorname{arsinh}(1/2)) = 3/2 < 2$. No assertion about a general harmonic-measure theorem is needed for these explicit bounds.

4.18.17.3. The weighted extension theorem. Suppose $F : D_R \to \mathfrak{E}_0$ is holomorphic in the Banach norm and $\|F(z)\|_{\mathfrak{E}_0} \leq M$ there. The case $M = 0$ is immediate; take $M > 0$ in the proof. Suppose also that, on the real segment $[-a, a]$, its same kernel classes belong to $\mathfrak{E}_C$ and obey $\|F(x)\|_{\mathfrak{E}_C} \leq M$. If $Ch_0 > c$, then

$$F : D_r \longrightarrow \mathfrak{E}_c \text{ is holomorphic}, \qquad \sup_{D_r} \|F(z)\|_{\mathfrak{E}_c} \leq M. \tag{4.dxlii}$$

The same M is retained. In particular, the choices $a = R/2$, $r = R/4$, $C = 2(c + 1)$ give the conclusion with an additional positive weight margin. If the two hypotheses have different constants, their maximum is a valid M.

Proof. First truncate to $v \leq N$. On any simply connected patch off the slit choose a holomorphic function b with $\operatorname{Re} b = h_*$. Then $e^{Cb(z)v} P_N F(z)$ is a holomorphic $\mathfrak{E}_0$ vector. To check the multiplier analyticity, its power series and all derivatives converge in operator norm on the truncation, since $v \leq N$. Its norm is

$$u_N(z) = \left\| e^{Ch_*(z)v} P_N F(z) \right\|_{\mathfrak{E}_0}. \tag{4.dxliii}$$

Different local harmonic conjugates differ by imaginary constants. Their multipliers differ by diagonal phases of modulus one. The norm in eq. 4.dxliii is consequently single valued even though a global harmonic conjugate around the slit need not exist.

The logarithm of the norm of a holomorphic Banach vector is subharmonic. A direct proof at a nonzero value chooses a norm-one complex linear functional attaining the norm there by Hahn–Banach, applies the scalar logarithmic submean inequality, and bounds its values on the circle by the vector norm. At a zero, use the value minus infinity and the same upper semicontinuity argument. Thus $\log u_N$ is globally subharmonic off the slit, because its local definitions agree.

On the slit the fixed truncation is continuous in the $\mathfrak{E}_0$ norm and h_* tends to one. Its boundary norm is at most the assumed real $\mathfrak{E}_C$ norm, hence at most M. On the outer circle $h_* \leq 0$; the ordinary bound and $v \geq 0$ give boundary upper limit at most M. For this fixed N the function is bounded above throughout the punctured disc, and the subharmonic maximum principle gives $u_N(z) \leq M$. This proof uses the norm-continuous extension of F across the real interval in $\mathfrak{E}_0$. Scalar partition holomorphy would not supply it.

At any point of D_r off the slit, $Ch_*(z) \geq Ch_0$. Monotonicity of the weight gives $\|P_N F(z)\|_{\mathfrak{E}_{Ch_0}} \leq M$. The continuity-from-below argument proves that $F(z)$ belongs to that weighted space, with the same bound. On $D_r \cap [-a, a]$ it follows directly from the assumed $\mathfrak{E}_C$ bound. The identification with the original $\mathfrak{E}_0$ class is exact, since these spaces have the same common-null-set identification and P_N exhausts the fixed finite weight.

Choose $\delta > 0$ with $c + \delta \leq Ch_0$. Uniformly on D_r one now has

$$\|(1 - P_N)F(z)\|_{\mathfrak{E}_c} \leq e^{-\delta N} \|F(z)\|_{\mathfrak{E}_{c+\delta}} \leq M e^{-\delta N}. \tag{4.dxliv}$$

Each $P_N F$ is holomorphic into $\mathfrak{E}_c$, because $P_N : \mathfrak{E}_0 \to \mathfrak{E}_c$ is bounded. Their uniform convergence on the smaller disc proves holomorphy of the limit there. One can see this directly by taking their Banach-valued Cauchy integrals on any interior circle: uniform norm convergence permits the limit in that formula and its differentiated formula. This proves eq. 4.dxlii. □

It follows in particular that

$$\|F^{(m)}(0)\|_{\mathfrak{E}_c} \leq m! M (4/R)^m, \qquad m = 0, 1, \ldots, \tag{4.dxlv}$$

for the quarter-disc choice. There is no factor growing with the number of histories, no reciprocal survival probability in the radius, and no extra constant in front of M. The cost is the explicitly larger prepaid real weight and a fixed radius loss. The coupling floor for the real mass remains affine in the requested final coefficient c.

When the formed kernels have their pointwise holomorphic representatives, these norm derivatives are their actual kernel derivatives. Here is a way to avoid separate exceptional sets at uncountably many parameters. The norm Taylor coefficients on an interior circle satisfy a summable geometric bound on any smaller circle. Choose Borel majorants for their fibre suprema with a summable total integral. Outside one Borel null set, the resulting power series converges uniformly on every smaller parameter disc and every fibre. At a countable dense set of parameters it agrees with the original kernel classes outside a further countable union of Borel null sets. Pointwise holomorphic uniqueness then makes it agree for all parameters there. Differentiating this series gives the actual differentiated kernels on that same full set. No point evaluation is asserted to be a bounded functional on $\mathfrak{E}_0$.

4.18.17.4. What would make this an actual source extension. For a fixed cutoff, use exactly its admitted field or evaluation fibres and the fixed history volume. The required ordinary family is the complete kernel, including its normalizers, not just the scalar integral of that kernel. Its $\mathfrak{E}_0$ holomorphy can be established from jointly measurable, pointwise holomorphic kernels with a common integrable fibre-supremum envelope on each compact parameter disc. The dominated Cauchy argument used before eq. 4.dxx, now in this complete normed space, proves that assertion. A proved norm power series is another sufficient verification. Pointwise holomorphy without this norm control is not the premise of eq. 4.dxlii.

The other premise is the strongly weighted real family over the same field core, uniformly for every real parameter in the stated interval. Real field values only on the physical-current graph would not be that premise. The theorem neither enlarges the current core nor proves admission of a noncovariant source array to the ordinary complex source class. A moving domain must first be replaced by a single common admitted domain with the two stated bounds. Here "real" concerns the source parameter. If the desired norm takes its supremum over a complex field core, the real-source premise already takes its supremum over that same complex field core.

If these checks hold with $M = e^{-a_\star P_i}$, the theorem proves the same weighted complex mass and its Cauchy bounds on the smaller source disc. It is thus an alternative to proving the pointwise one-zone estimate in eq. 4.dxxi. Each route has a finite, testable analytic input. The local-excess route uses actual carrier and read bounds. The interpolation route uses an ordinary complex kernel bound and arbitrarily prepaid strong real weights on the same admitted core. Neither route follows from compactness of source parameters or scalar partition holomorphy.

4.18.17.5. A dimension-free real-form corollary. Let $\mathcal{B}$ be a complex Banach source space with an isometric conjugation κ. Its real form is $\mathcal{B}_{\mathbb{R}} = \{u : \kappa u = u\}$. Thus every h has $h = h_1 + ih_2$ with real h_1, h_2 and $\|h_j\| \le \|h\|$. Finite coordinate arrays with their usual real-form supremum or sum norms have this property, with constants independent of the number of coordinates.

Suppose F is Fréchet-holomorphic from $\{\|h\| < R\}$ into $\mathfrak{E}_0$, bounded by M, and for every real u with $\|u\| < R$ it obeys the $\mathfrak{E}_C$ bound M on the same field fibres. For any $c \ge 0$ the prepaid coefficient $C = 2(c+2)$ suffices to give

$$\sup_{\|h\|<R/8} \|F(h)\|_{\mathfrak{E}_{c+1}} \le M, \qquad F : \{\|h\| < R/8\} \longrightarrow \mathfrak{E}_c \text{ is Fréchet-holomorphic.} \tag{4.dxlvi}$$

The number of source coordinates does not enter the constant.

Proof. Fix h in that smaller ball. If $h_2 = 0$, the asserted weighted bound is part of the real premise. Otherwise put $v = h_2/\|h_2\|$ and consider the single translated complex line $f(z) = F(h_1 + zv)$. For $|z| < R/2$ its source norm is less than $5R/8$, so its ordinary bound is M. For real $|z| \le R/4$ it is a real source of norm less than $3R/8$, and has the prepaid weighted bound. Apply eq. 4.dxlii with

ordinary radius $R/2$, real half-segment $R/4$ and target radius $R/8$. Since $h_0 > 1/2$, the chosen C is strictly more than sufficient for weight $c+1$. Evaluation at $z = i\|h_2\|$ gives the first assertion.

This estimate is uniform on the whole smaller source ball, not just on one line. Therefore $\|(1-P_N)F(h)\|_{\mathfrak{E}_c} \le Me^{-N}$ uniformly there. Each $P_N F$ is Fréchet-holomorphic into $\mathfrak{E}_c$ by its bounded linear projection from $\mathfrak{E}_0$. Their uniform norm limit is Fréchet-holomorphic. One direct verification uses the Cauchy formula on every complex line in an interior source ball and polarizes its homogeneous Taylor coefficients. Uniform convergence gives convergence of those coefficients; polarization gives convergence in each multilinear norm, and the Cauchy bounds make their Taylor series converge uniformly in a smaller ball. Its sum is the asserted limit. □

The derivative constants in this assertion can be made explicit as well. Write $\rho = R/8$. The m-th homogeneous Taylor polynomial at zero is bounded by $M\rho^{-m}$ on the unit source ball, by scalar Cauchy on each line. For its symmetric m-linear form, the coefficient of $z_1 \cdots z_m$ in its value at $\sum z_j h_j$ is $m!$ times that form. Cauchy's formula on m unit circles bounds this coefficient by m^m times the polynomial bound, since $\|\sum z_j h_j\| \le m$ when $\|h_j\| \le 1$. Consequently

$$\|D^m F(0)\|_{\mathcal{B}^m \to \mathfrak{E}_c} \le m^m M(8/R)^m \le m! M(8e/R)^m. \tag{4.dxlvii}$$

These are multilinear operator norms. No coordinatewise entropy or factor equal to the dimension of the source space has been introduced.

For a normalized excess with $F(0) = 0$, scalar Schwarz on every source line and Hahn–Banach scalarization give $\|F(h)\|_{\mathfrak{E}_c} \le (8M/R)\|h\|$ in the smaller ball. For a general kernel family the difference $F(h) - F(0)$ has the corresponding bound with $2M$. This is a weighted estimate on the complete kernel, not a bound on a chosen logarithm of that kernel. A logarithm requires its own zero-free normalization.

The corollary is useful precisely because its premises say which source arrays are allowed. If the real source bound is known only on a gauge-covariant subspace, the translated real point h_1 and direction v must both lie in that subspace. The theorem then extends its complexification, not the whole ambient array space. It does not create a noncovariant extension from data on the physical-current graph. If the ordinary complex family is available on a radius depending on an order parameter p_n, that same radius, with the fixed factor eight, appears in eq. 4.dxlvii; no larger radius has been supplied by interpolation.

For a genuine array extension one must verify all three statements: the ordinary kernel map is Fréchet-holomorphic and bounded in $\mathfrak{E}_0$ on its actual complex source ball; the real weighted bound holds on the full real ball used in the argument; and all those families use the same field/read fibres and fixed reference data. These are formation and domain assertions. Once they hold, the weighted extension, its source-dimension independence and its derivative bounds follow from eq. 4.dxxxvi–eq. 4.dxlvii.

4.18.18. *The finite estimates to be matched.* The weighted-history assertion requires the following estimates for finite operations. Their quantifiers are uniform in the height, compatible torus, component, local history, stored variables on its support, and the full joint argument domain. Compactness at a single cutoff is not that uniform statement.

First, every stored-coordinate formula must be the literal operation in eq. 4.cdlxv or eq. 4.cdlxxi, with its fixed measures, normalizers, tests and frame factors. Later reads must satisfy eq. 4.dxxv. The five region lists and retained seam prescriptions determine this check. Full re-entry must use the current datum on its remade shell, not an earlier field already integrated there.

Second, every prepared, localized and substituted datum must belong to its joint background/current core. Its complete kept forms must have the lower bound and reference domination in eq. 4.dii or eq. 4.diii on their respective coordinate domains, with local dimension counted once. Independent-current completion needs its projected gauge and other current terms. It does not follow from setting a coarse averaging constraint equal to the identity. The flat precision and one-step perturbation results verify restricted cases, not the whole all-layer assertion.

Third, the sum assigned to V_X needs eq. 4.cdlxviii on those cores for all supported stored fields. Its counterterm, vacuum and boundary conventions belong to this bound. Oscillation of isolated terms does not bound their constants. A pointwise KP logarithm does not supply the integrable supremum without its common envelope. The local formation and Gaussian theorems address parts of this check under their primitive matrix and background hypotheses.

Fourth, failed tests need their certificates and owned energy sets in eq. 4.div. The core Wilson term keeps its stopped real weight, and every compatible drop-out evaluation must preserve the certificates used under its supremum. A last test requiring an extra collar supplies its renewed gain only in a later read with that collar present.

For parameters these checks hold on one fixed-frame domain. The finite gauge-normalizer extension and the complete Gaussian half-disc criterion have been proved here. For a second-class component formed by the island kit, the pair reader gives the exact source excess on the admitted output core. The bound following eq. 4.dxvi uses the formed carrier estimates there. At other weighted source lines or drop-out fibres we must check eq. 4.dxiii on the actual read, for example by the carrier criterion eq. 4.dxv. eq. 4.dxxi is a precise one-zone test for a finer weighted source extension. Ordinary source compactness and holomorphy alone do not prove that test.

Alternatively the full kernel family can meet the explicit same-core ordinary complex and prepaid real norm hypotheses of eq. 4.dxlii or eq. 4.dxlvi. Those theorems then prove its weighted extension without the pointwise excess test. They do not assert those formation or domain premises for a source-array class outside the stated hypotheses.

The loaded global comparison also needs the literal label representation, common vacuum price, local unmarked energy price and finite read-ownership map. These are more specific identifications than the claim that a density is a sum of labels. Once matched, eq. 4.cdlxxv–eq. 4.dxxxv give the counting, reserve, integration and summation with constants uniform in height and volume. They retain the field, current and history types needed to apply those scalar consequences.

4.19. **Complex stage integrals with retained tests.** Preparatory integrations of the large-field operation integrate a stored fluctuation on a strip and a new fluctuation on the adjacent collar; see [B89a, B89b]. The earlier stage terms enter later integrals. The estimates below control this accumulation on one component. They also give a branch of the logarithm when the actual tested integral is close, pointwise in its density, to a positive reference integral. All coordinate maps and all retained factors are specified before this comparison is applied.

4.19.1. *The tested local integral.* Let $b \in \mathbb{R}^m$ be the actual free real coordinates of a finite stage chart. A parameter σ includes its geometry, real background, real stored spectators and retained tests. Fix

$$S_\sigma \subset [-T,T]^m, \qquad T \geq 1, \qquad Q_{0,\sigma} = Q_{0,\sigma}^{\mathsf{T}} > 0.$$

The set S_σ is Borel. It can be disconnected and can contain arbitrary carried sharp tests. On each complex parameter domain used below it is fixed. Put

$$I_{0,\sigma} = c_{0,\sigma} \int_{S_\sigma} e^{-b^{\mathsf{T}} Q_{0,\sigma} b/2 + V_{0,\sigma}(b)}\, db, \qquad 0 < I_{0,\sigma} < \infty, \tag{4.dxlviii}$$

where $c_{0,\sigma} > 0$ and $V_{0,\sigma}$ is real. No uniform lower bound on $I_{0,\sigma}$ is assumed.

For z in a complex polydisc $\mathcal{D}$, suppose the actual integral has the exact representation

$$I_\sigma(z) = c_{0,\sigma} \int_{S_\sigma} e^{-b^{\mathsf{T}} Q_{0,\sigma} b/2 + V_{0,\sigma}(b)} e^{H_\sigma(z,b)}\, db. \tag{4.dxlix}$$

Here H is Borel in the real variables and holomorphic in z, with a uniform bound on the polydisc. In an application it contains

$$H = \ell - \tfrac{1}{2} b^{\mathsf{T}} (Q - Q_0) b + (V - V_0) + \log(J/J_0). \tag{4.dl}$$

The term ℓ includes every change of a Gaussian normalizer. The factor J/J_0 includes the nonlinear constraint determinant, Haar densities and other chart Jacobians. These terms are retained even when the quadratic exponent alone is small. An analytic reciprocal determinant is used at complex arguments; an absolute determinant is used only at real arguments.

Proposition 4.70 (A tested integral in a disc about its reference)**.** If $\sup_{\sigma,z,b\in S_\sigma}|H_\sigma(z,b)|\le\delta\le 1/8$, then

$$\left|\frac{I_\sigma(z)}{I_{0,\sigma}}-1\right|\le e^{\delta}-1<1,\qquad \left|\log\frac{I_\sigma(z)}{I_{0,\sigma}}\right|\le 4\delta. \tag{4.dli}$$

The logarithm is the analytic branch defined by the power series about 1. For a polydisc with coordinate radii R_i, centred at z_*, and a multi-index $\alpha\neq 0$,

$$|\partial_z^\alpha \log I_\sigma(z_*)|\le 4\delta\,\alpha!\prod_i R_i^{-\alpha_i}. \tag{4.dlii}$$

Let $\nu_{0,\sigma}$ be the probability measure obtained by dividing the integrand in eq. 4.dxlviii by $I_{0,\sigma}$, and let $\nu_{z,\sigma}$ be its complex reweighting by e^H. Then

$$\int|d\nu_{z,\sigma}-d\nu_{0,\sigma}|\le 8\delta. \tag{4.dliii}$$

These bounds are uniform when the positive reference masses tend to zero. ■

Proof. By eq. 4.dxlix, the ratio is $w=\int e^H\,d\nu_0$. Thus $|w-1|\le r:=e^\delta-1$. For $\delta\le 1/8$, one has $r<1/4$, and $|\log w|\le r/(1-r)\le 4\delta$. Dominated integration gives holomorphy of the ratio. Its values remain in the simply connected disc $|w-1|<1$; hence this logarithm is coherent throughout $\mathcal{D}$. Apply the several-variable Cauchy formula on smaller concentric polydiscs, then increase their radii to R_i. The reference mass is independent of z, so its logarithm has no derivative in eq. 4.dlii.

The complex density relative to ν_0 is e^H/w. Therefore

$$\int\left|\frac{e^H}{w}-1\right|d\nu_0\le\frac{\int|e^H-1|d\nu_0+|w-1|}{|w|}\le\frac{2r}{1-r}\le 8\delta.$$

No inverse bound on the unnormalized mass has entered this proof. □

4.19.2. *The complete Gaussian and coarea factors.* The comparison can be verified using local matrices before taking any absolute values in an auxiliary Gaussian. In the notation of Prop. 4.7, the exact marginal has covariance $D=C+C\Gamma\Gamma^{\mathsf T}C$. Its auxiliary dimension need not be local. The following bound uses only the number m of free coordinates remaining in the marginal.

Lemma 4.71 (The Gaussian density ratio on a tested box)**.** Suppose

$$\|C_0\|+\|C_0^{-1}\|+\|\Gamma_0\|\le K,\qquad \|C-C_0\|+\|\Gamma-\Gamma_0\|\le\epsilon,$$

where C_0 is real symmetric positive definite and Γ_0 is real, and take $\epsilon\le\epsilon_*(K)$. Let $D_0=C_0+C_0\Gamma_0\Gamma_0^{\mathsf T}C_0$. The normalized marginal density ratio has an analytic logarithm

$$L_D(b)=-\tfrac12\log\frac{\det D}{\det D_0}-\tfrac12 b^{\mathsf T}(D^{-1}-D_0^{-1})b,\qquad \sup_{|b|_\infty\le T}|L_D(b)|\le C_K\epsilon m(1+T^2). \tag{4.dliv}$$

The bound is independent of the auxiliary dimension. ■

Proof. Expanding the products that define D gives $\|D-D_0\|\le C_K\epsilon$, since all rectangular factors are bounded in operator norm. The real matrix D_0 has $D_0\ge C_0\ge K^{-1}I$. For $E=D_0^{-1/2}(D-D_0)D_0^{-1/2}$, decrease ϵ_* so that $\|E\|\le 1/2$. The convergent matrix logarithm gives

$$\left|\log\frac{\det D}{\det D_0}\right|=|\operatorname{Tr}\log(I+E)|\le m\sum_{q\ge1}\frac{\|E\|^q}{q}\le C_K m\epsilon.$$

The resolvent identity gives $\|D^{-1} - D_0^{-1}\| \le C_K\epsilon$. Finally $|b|^2 \le mT^2$. The marginal identity in Prop. 4.7 must be applied before this calculation; a total-variation estimate on the unreduced joint Gaussian would charge its auxiliary dimension. □

Here is the corresponding finite coarea calculation. Suppose the actual constraints in a chart are solved for three-component pivot coordinates, and their real derivative matrices are $M_{0,a}(b)$, $1 \le a \le k$, with positive determinant. Suppose their complex continuations satisfy

$$E_a = M_a M_{0,a}^{-1} - I, \qquad \sup_{z,b} \|E_a\| \le \epsilon_a < 1/2. \tag{4.dlv}$$

Then the logarithm of the ratio of the inverse pivot determinants is

$$L_{\mathrm{piv}}(z,b) = -\sum_{a=1}^{k} \operatorname{Tr}\log(I + E_a), \qquad |L_{\mathrm{piv}}| \le 6\sum_{a=1}^{k} \epsilon_a. \tag{4.dlvi}$$

Indeed the power series used in the preceding proof applies to each three-by-three matrix. The identity powers of L in the per-length pivot convention cancel in the ratio. Their real normalization remains in I_0. Equation eq. 4.dlv requires the actual nonlinear pivot chart on the tested domain.

For SU(2), write $a \in \mathbb{C}^3$ in the orthonormal Pauli basis, using the bilinear square $a \cdot a$. Apart from its fixed normalizing constant, the analytic Haar density in exponential coordinates is

$$j(a) = \left(\frac{\sin\sqrt{a\cdot a}}{\sqrt{a\cdot a}}\right)^2.$$

The quotient at zero is defined by its power series. On $\|a\|_2, \|a_0\|_2 \le 1/4$, it has a nonzero analytic logarithm and

$$|\log j(a) - \log j(a_0)| \le C(\|a\|_2 + \|a_0\|_2)\|a - a_0\|_2. \tag{4.dlvii}$$

To see this, put $f(s) = \sum_{q\ge 0}(-1)^q s^q/(2q+1)!$. For $|s| \le 1/16$, its power series bounds $|f-1|$ away from one and bounds $|f'|$ by an absolute constant. Thus $2\log f(s)$ has bounded derivative. Integrate that derivative along the segment between $a_0 \cdot a_0$ and $a \cdot a$. Summing eq. 4.dlvii over the chart bonds accounts for all Haar density ratios. If the coupling is fixed, the rescaling $a = gb$ has the same Jacobian in the two integrals. A change of g contributes an additional explicit scalar factor.

For comparison, the bare Wilson Taylor remainder also has a direct local bound. For unitary background factors V_i and complex Lie algebra elements B_i, put

$$F(t) = g^{-2}\left(1 - \tfrac{1}{2}\operatorname{Tr}\prod_{i=1}^{4} e^{itgB_i}V_i\right), \qquad S_B = \sum_i \|B_i\|_{\mathrm{op}}.$$

Three differentiations and the multinomial theorem give $|F'''(t)| \le CgS_B^3 e^{gS_B}$ for $0 \le t \le 1$. The integral Taylor formula therefore yields

$$|F(1) - F(0) - F'(0) - \tfrac{1}{2}F''(0)| \le CgS_B^3 e^{gS_B}. \tag{4.dlviii}$$

On a bounded stage box its sum costs at most $Cg\,mT^3 e^{CgT}$ when each coordinate meets a bounded number of plaquettes. Composition with a nonlinear constrained response requires the first three derivatives of that actual response.

Proposition 4.72 (Response of the constrained density)**.** Let the actual constraint chart solve $F(z,b,y(z,b)) = 0$, where F is holomorphic and $M = \partial_y F$ is invertible throughout the admitted domain. Suppose the complete stage density on its fixed tested set is

$$a(z,b)\exp[-S(z,b,y(z,b))]\,(\det M(z,b))^{-1}.$$

All factors are holomorphic and have the uniform bounds needed to differentiate under the finite integral; a includes the Haar densities and numerical normalizers. A local analytic determinant

branch agrees with the positive coarea density at the real reference. With dots denoting differentiation at fixed b,

$$\dot y = -M^{-1}F_z,$$
$$\ddot y = -M^{-1}(F_{zz} + 2F_{zy}\dot y + F_{yy}[\dot y,\dot y]), \tag{4.dlix}$$
$$L = \partial_z \log a - S_z - S_y\dot y - \mathrm{Tr}(M^{-1}\dot M). \tag{4.dlx}$$

On a nonzero domain supplied by Prop. 4.70, the normalized complex stage expectation satisfies

$$\partial_z \log I = \langle L\rangle_z,$$
$$\partial_z^2 \log I = \langle \dot L\rangle_z + \langle L^2\rangle_z - \langle L\rangle_z^2, \tag{4.dlxi}$$
$$\partial_z\langle A\rangle_z = \langle \dot A\rangle_z + \langle AL\rangle_z - \langle A\rangle_z\langle L\rangle_z. \tag{4.dlxii}$$

The second determinant contribution in $\dot L$ is

$$\mathrm{Tr}(M^{-1}\dot M M^{-1}\dot M - M^{-1}\ddot M). \tag{4.dlxiii}$$

For successive triangular eliminations the traces in these formulas are summed over their pivot blocks. ■

Proof. Differentiate the exact constraint at fixed free coordinates. Its first derivative is $F_z + M\dot y = 0$; differentiating again gives eq. 4.dlix. Differentiate the complete logarithmic density, including the reciprocal determinant, to obtain eq. 4.dlx. Jacobi's formula and $\partial_z M^{-1} = -M^{-1}\dot M M^{-1}$ give eq. 4.dlxiii. The quotient rule after differentiation under the integral gives eq. 4.dlxi and eq. 4.dlxii. The tests do not produce a boundary term because they have not been varied. □

For example, suppose $\|M^{-1}\| \le K_M$, $\|F_z\| \le a$, $\|F_{zz}\| \le b$, $\|F_{zy}\| \le c$ and $\|F_{yy}\| \le d$, in the specified Euclidean and multilinear operator norms. Then

$$\|\dot y\| \le K_M a, \qquad \|\ddot y\| \le K_M(b + 2cK_M a + dK_M^2 a^2).$$

For a pivot block of dimension d_p, $|\mathrm{Tr}(M^{-1}\dot M)| \le d_p K_M \|\dot M\|$. These estimates identify which constraint derivatives a quantitative source bound needs. In particular the term $S_y\dot y$ is retained unless the actual stationarity equations cancel it. A derivative of a Gaussian potential at fixed chart alone would omit these contributions.

4.19.3. *Resetting the stored fields.* A near stored field is a real variable under a sharp test. Its reset is represented by a complex switch. Let a_v be such a field, and let μ_v range over $|\mu_v| < \Lambda_v$, where $\Lambda_v > 1$. The term at $\mu_v = 0$ is required to be independent of a_v; at $a_v = 0$ it is independent of μ_v. At a far stored field the same notation represents the radial parameter in the holomorphic substitution $a_v \mapsto \mu_v a_v$. The carried tests are kept at their real arguments in both cases.

Lemma 4.73 (Block differences)**.** Let f be holomorphic and bounded by B on $\prod_{v\in T}\{|\mu_v| < \Lambda_v\}$, together with its other holomorphic arguments. For $A \subset T$, set

$$f_A = \sum_{E\subset A} (-1)^{|A|-|E|} f(\mathbf{1}_E, \mathbf{0}_{T\setminus E}), \qquad q_v = (\Lambda_v - 1)^{-1}.$$

Then

$$f(\mathbf{1}_T) = \sum_{A\subset T} f_A, \qquad |f_A| \le B\prod_{v\in A} q_v, \qquad \sum_{A\neq\emptyset} |f_A| \le B\left(\exp\sum_{v\in T} q_v - 1\right). \tag{4.dlxiv}$$

If f is independent of a_v, μ_v, then $f_A = 0$ whenever $v \in A$. The differences preserve the full declared radii of the remaining stored fields and switches. ■

Proof. The finite inclusion-exclusion identity gives the first equality. For one variable and $1 < r < \Lambda_v$, Cauchy's formula gives

$$f(1) - f(0) = \frac{1}{2\pi i} \int_{|w|=r} \frac{f(w)}{w(w-1)}\, dw.$$

Apply this identity in each variable of A, with all other variables in T set to zero. The bound is $B \prod_{v\in A}(r_v - 1)^{-1}$; increase r_v to Λ_v. Summing this bound gives $B[\prod_v(1+q_v)-1]$, which is bounded by the last expression in eq. 4.dlxiv. Variables absent from the function have zero difference. The proof fixes the other arguments at arbitrary points of their full domains, so it spends none of their radii. □

For a family (f_e), let T_e be its set of read blocks and B_e its analytic bound. Its incidence norm on the integrated blocks is

$$J = \sup_{v\in T} \sum_{e: v\in T_e} B_e. \tag{4.dlxv}$$

If $\sum_{v\in T_e} q_v \le 1$ for every e, then

$$\sum_e \sum_{A\neq\emptyset} |(f_e)_A| \le 2 \sum_{v\in T} q_v \sum_{e: v\in T_e} B_e \le 2J \sum_{v\in T} q_v. \tag{4.dlxvi}$$

This counts blocks actually read by a term. It introduces no Gaussian coordinates on the rest of that term's domain.

A background displacement has the same estimate in an auxiliary parameter. If $f_e(P_e(\lambda))$ is holomorphic and bounded by B_e on $|\lambda| < a_e^{-1}$, with $a_e \le 1/2$, then

$$|f_e(P_e(1)) - f_e(P_e(0))| \le 2a_e B_e. \tag{4.dlxvii}$$

Consequently, if $P_e(1)$ is the old background read and $P_e(0)$ is the new one, the exact split is

$$\begin{aligned} f_e(P_e(1);a) - f_e(P_e(0);0) = {} & f_e(P_e(1);a) - f_e(P_e(0);a) \\ & + f_e(P_e(0);a) - f_e(P_e(0);0). \end{aligned} \tag{4.dlxviii}$$

The first line is bounded with eq. 4.dlxvii; the second uses eq. 4.dlxvi. A displacement that fixes the stored data at their carrying sites is needed for this identity to be the split of the actual operation.

4.19.4. *Uniform accumulation in a finite sequence of stages.* We give the quantitative conclusion in a form that can be applied to a fixed chain of actual tested charts. This is a local assertion for one component. Let $\theta > e$, $\ell = \log\theta$, and $r \ge 1$. Fix constants independent of the stage number, and assume

$$N \le C_N \ell^r, \qquad K_s \le C_s \ell^{4r}, \qquad m_n \le C_m \ell^{4r}, \qquad T_n \le C_T \ell^p. \tag{4.dlxix}$$

At most K_s stored blocks are reset at a stage. Put $\Lambda = \ell^{6r+1}$, and suppose every such block has this switch radius. The bounds hold on the full domains of the switches that remain after integration.

For each remaining stored datum, assume that setting its switch to zero makes both the complete reference kernel and the inserted integrand independent of that datum. Setting the datum to zero makes them independent of its switch. This includes the retained tests and any normalization of the reference kernel. Thus integration preserves the two independence properties defining a switch.

Let J_0 bound the incidence norm of the earlier terms. Suppose that each earlier stage contributes at most one function at each block, with norm at most one; its incidence norm before stage n is then at most $J_0 + n$. The admitted background displacement satisfies the separate budget

$$\sum_e a_{n,e} B_{n,e} \le C_a \ell^{4r-e}(J_0 + n), \qquad e \ge 6r + 1. \tag{4.dlxx}$$

This budget concerns the individual old functions and their response amplitudes. It does not assume a logarithm of the stage integral.

Assume that the sum of the Gaussian density ratio, the coarea and Haar ratios, and the intrinsic interaction remainder is bounded by

$$G_n \le C_g \theta^{-1/2} \ell^A \tag{4.dlxxi}$$

on the tested box. Here A is fixed. For example, eq. 4.dliv gives this form when $\epsilon_n \le C\theta^{-1/2}\ell^a$; then its contribution has $A = a + 4r + 2p$. Equations eq. 4.dlvi, eq. 4.dlvii and eq. 4.dlviii give the same form under the corresponding chart bounds. All these estimates must hold on the full remaining switch domains.

Proposition 4.74 (The logarithmic balance of the stages)**.** Suppose each stage has eq. 4.dxlix, with the old terms split by eq. 4.dlxviii, and the preceding bounds hold. There is a floor θ_*, depending only on the displayed constants, r, p, A and J_0, such that all the normalized stage integrals are nonzero for $\theta \ge \theta_*$. Their logarithms $C_n = \log(I_n/I_{0,n})$ satisfy

$$\sum_{n=0}^{N-1} \|C_n\|_\infty \le C\left[\theta^{-1/2}\ell^{A+r} + \ell^{-1} + J_0\ell^{-r-1}\right]. \tag{4.dlxxii}$$

In particular each $\|C_n\|_\infty \le 1$, so the stated incidence bound closes by induction whenever the next tested chart admits the preceding functions on their declared switch domains. The norm in eq. 4.dlxxii is a supremum over those domains, at fixed real spectators. ■

Proof. Increase the floor so that $q = (\Lambda - 1)^{-1} \le 2\ell^{-(6r+1)}$ and $K_s q \le 1$. The exact exponent change at stage n is bounded, by eq. 4.dlxvi and eq. 4.dlxvii, by

$$\delta_n = C_g\theta^{-1/2}\ell^A + 4C_s\ell^{-2r-1}(J_0 + n) + 2C_a\ell^{4r-e}(J_0 + n). \tag{4.dlxxiii}$$

For $n < N$, this tends to zero uniformly as $\theta \to \infty$. Choose the floor so that every $\delta_n \le 1/8$ and $4\delta_n \le 1$. Prop. 4.70 proves existence and the bound $\|C_n\| \le 4\delta_n$. This supplies the bound one required at the next stage, rather than using the final sum as an inductive assumption.

Sum eq. 4.dlxxiii. The stored-field term is at most

$$C\ell^{-2r-1}(NJ_0 + N^2) \le C\big[J_0\ell^{-r-1} + \ell^{-1}\big].$$

The response term is at most

$$C\ell^{4r-e}(NJ_0 + N^2) \le C\big[J_0\ell^{5r-e} + \ell^{6r-e}\big],$$

which has the same bound since $e \ge 6r + 1$. The intrinsic term sums to $C\theta^{-1/2}\ell^{A+r}$. These are eq. 4.dlxxii. The reference factors remain in the exact equality $\prod_n I_n = (\prod_n I_{0,n}) \exp(\sum_n C_n)$. They can be absorbed into vacuum constants only when they are independent of the retained pair. □

The power $6r + 1$ pays for two stage counts and one block count:

$$N\,\Lambda^{-1}\,K_s\,N \le C\ell^{r-(6r+1)+4r+r} = C\ell^{-1}.$$

This is the role of the enlarged stored-field domain. Its admission is a condition on the actual nonlinear averaging and background maps. Since $g = \theta^{-1/2}$, a fixed power of ℓ times g still tends to zero. This arithmetic alone does not prove that an asserted enlarged chart exists.

4.19.5. *Preservation of switches under integration.* For the induction just used, holomorphy is preserved by the integral and the logarithm under a common integrable bound. Independence at a zero switch requires a further condition on the actual kernel. For a remaining stored datum a_v, suppose that, when $\mu_v = 0$, the integration domain and the complete normalized reference kernel are independent of a_v, and that the non-reference integrand has the same independence. Then the normalized ratio I/I_0 and its logarithm are independent of a_v there. The unnormalized integral has this independence when its reference mass I_0 does as well. If $a_v = 0$ removes μ_v from the integration domain, the normalized reference kernel and the inserted integrand, the ratio and its logarithm are

independent of that switch. No smaller switch disc is needed: dominated holomorphic integration and the fixed logarithm branch apply at arbitrary points of the original disc.

This condition cannot be inferred from freezing the tests only in the complex variable. For example, on $0 < b < 1$, let $S_a = (0, a)$, $0 < a < 1$, and use normalized Lebesgue measure on S_a. The function $F(b) = b$ does not read a, but its expectation is $a/2$. Thus a spectator-dependent test can create dependence on that spectator even when the inserted function has none. In the stage application, any such dependence must either stay outside the integral as a retained factor or be included in the declared switch structure of the kernel.

4.19.6. *A common envelope and the scope of the local result.* The preceding non-vanishing proof is relative to a positive reference integral. A mass estimate for an upper integral of a supremum is a different consequence. Fix the geometry, the number m of free coordinates and its site count N_0. Here is a sufficient condition in these same coordinates. Suppose, uniformly in all real read parameters,

$$Q_{0,\sigma} \geq \gamma I, \qquad c_{0,\sigma} \leq C_0^m, \qquad V_{0,\sigma}(b) \leq B_0 N_0 + \tfrac{1}{4}\gamma |b|^2, \qquad m \leq c_0 N_0. \tag{4.dlxxiv}$$

The complete unnormalized density then has the Borel envelope

$$\sup_{\sigma, z} \left| \mathbf{1}_{S_\sigma} c_{0,\sigma} e^{-b^{\mathsf{T}} Q_{0,\sigma} b/2 + V_{0,\sigma}(b) + H_\sigma(z,b)} \right| \leq C_0^m e^{B_0 N_0 + \delta} e^{-\gamma |b|^2/4}. \tag{4.dlxxv}$$

Its integral is at most $\exp(CN_0 + \delta)$, by the Euclidean Gaussian integral. The supremum need not itself be measurable: the displayed Borel function bounds its upper integral. The common coordinates, the coercive bound and the determinant bound in eq. 4.dlxxiv must hold before the supremum is taken. Separate parameter-dependent changes of variables do not establish this envelope.

The local conclusions require the exact stage chart, the Gaussian marginal identity, the enlarged switch and displacement domains, and the stated kernel condition at zero switches. For simultaneous components, their interaction and the spatial filing of logarithmic terms require the local Gaussian and connected expansion estimates of § 4.5. The finite-component bound here supplies neither their decoupling matrix estimates nor a common chart for an arbitrary history.

Proposition 4.75 (Sharp tests can force a zero without switches)**.** Let w_0 be integrable on a real measure space, let $W = \int w_0 \neq 0$, and let $x \geq 0$ have an atomless push-forward of $|w_0|\, d\mu$. Then there are $c > 0$ and $\lambda \in [-\pi, \pi]$ such that

$$\int w_0 e^{i\lambda \mathbf{1}_{\{x > c\}}}\, d\mu = 0. \tag{4.dlxxvi}$$

■

Proof. Set $A(c) = \int_{x \leq c} w_0$ and $B(c) = W - A(c)$. Atomlessness makes both continuous in c, with $A(0) = 0$, and $A(c) \to W$ as $c \to \infty$. The continuous function $|A(c)| - |B(c)|$ is negative at zero and positive for sufficiently large c. At a zero it has $|A(c)| = |B(c)| > 0$, since $W \neq 0$. Choose $e^{i\lambda} = -A(c)/B(c)$. This gives eq. 4.dlxxvi. □

For a free three-color strip coordinate, $x = |\mathcal{A}^{\mathrm{s}}(b)|$ is atomless under an integrable Lebesgue density. Its norm is invariant under the adjoint action. The phase in eq. 4.dlxxvi can therefore be split among four local terms, each of modulus at most $\pi/4$, without changing analyticity in the background pair. The switch hypothesis rules out precisely this uncontrolled dependence on a tested stored field.

4.20. **Source formation and volume bounds.** A source bound requires three estimates: formation of local interactions, convergence of the polymer logarithm, and a bound on the resulting integral. A convergent polymer expansion supplies the second estimate. To apply it to a renormalisation construction one must first verify its activity bounds for the interactions that the construction

actually forms. The elementary implications below specify the ordinary source estimates needed for that verification.

Site-dependent members and the summation over old levels. Fix an odd integer $L \geq 3$. Let $(\theta_j)_{0\leq j\leq n}$ satisfy

$$\theta_j \geq Y, \qquad \lambda(n-j) - c_5 \leq \theta_j - \theta_n \leq B(n-j), \qquad Y \geq 2(c_5+1), \tag{4.dlxxvii}$$

where $\lambda > 0$ and $c_5 \geq 0$. A pointed family at level j is a collection $G(X,P,z)$, where X is a localisation domain, $z \in X$ is a base point and P belongs to a specified complex field domain. Its norm is

$$\|G\|_{j,\kappa} = \sup_{X,z,P} e^{\kappa d_j(X)} |G(X,P,z)|. \tag{4.dlxxviii}$$

Any companion families used to define its quadratic coefficient are included in this supremum. The field domains and restrictions are part of the data; holomorphy does not assert that a function extends beyond these domains.

At every site z, permit a different family $G_{j,z}$. Each such family comes with its own quadratic coefficient $b(G_{j,z})$. The hypothesis on an individual member is covariance of its *pointed* total, so that subtracting its coefficient times the tent action cancels the marginal quadratic term at that base point. No covariance relating the chosen members at different sites is required. This distinction permits a scalar source to be frozen at the value belonging to each site.

Here is a precise quantitative formulation of the input used in this argument. Put $\epsilon_{jn} = L^{-(n-j)}$, and let ρ_{jn} be the ratio between the field radius required at level n and the radius on which the member of level j is given, enlarged to be at least one. Suppose $\rho_{jn}^2 \leq C_\rho(1+n-j)$. Assume a linear localisation rule with the following estimates, including summability over its rooted domains. For one base point of level j, a normalised regular member contributes at most

$$C\,\|G_{j,z}\|_{j,\kappa}\,\rho_{jn}^3 \epsilon_{jn}^{4+\alpha} \qquad (0<\alpha<1) \tag{4.dlxxix}$$

to a window of level n, after its vacuum and quadratic subtractions. A member with its vacuum value alone subtracted contributes at most

$$C\,\|F_{j,z}\|_{j,\kappa}\,\rho_{jn}^2 \epsilon_{jn}^4. \tag{4.dlxxx}$$

The constants include the permitted loss of spatial decay and the count of domains through the base point. The rule must evaluate every member within its stated field domain for every allowed decoupling and window parameter. This domain inclusion is a separate hypothesis of eq. 4.dlxxix–eq. 4.dlxxx.

The factor ϵ_{jn}^4 has a direct dimensional meaning. A window of level n contains at most $C\epsilon_{jn}^{-4}$ base points of level j. Thus vacuum subtraction balances the number of base points in four dimensions, whereas the quadratic subtraction must supply the additional ϵ_{jn}^{α} to make old regular members summable.

Proposition 4.76 (Uniform ordinary input)**.** Suppose the regular members obey

$$\sup_z \|G_{j,z}\|_{j,\kappa} \leq G_\star.$$

Suppose defects and remainders obey, respectively,

$$\|D_j\|_{j,\kappa} \leq L^{-(n+1-j)}, \qquad \|H_j\|_{j,\kappa} \leq C_H \theta_j^{-p}, \qquad p>2. \tag{4.dlxxxi}$$

Under eq. 4.dlxxix–eq. 4.dlxxx, their combined ordinary input at level n is bounded by

$$CG_\star + C\sum_{a=0}^{n}(1+a)L^{-(a+1)} + CC_H\sum_{a=0}^{n}(1+a)(\theta_n+\lambda a - c_5)^{-p} \leq CG_\star + C + CC_H\theta_n^{2-p}. \tag{4.dlxxxii}$$

The constant is independent of n, the number of sites and the choice of the member at each site. ∎

Proof. The sum in eq. 4.dlxxix over the base points in a window. The inverse volume factor cancels ϵ_{jn}^4, leaving

$$CG_\star \sum_{a\ge 0} (1+a)^{3/2} L^{-\alpha a} < \infty.$$

This uses only the supremum of the member norms, so choosing a different covariant member at each site has no effect on the bound. The same cancellation in eq. 4.dlxxx gives the second sum in eq. 4.dlxxxii for defects. That sum is bounded by a convergent geometric series and its first derivative.

For remainders use eq. 4.dlxxvii and put $y = \theta_n - c_5 \ge \theta_n/2$. For $a \ge 0$, $1 + a \le C(y + \lambda a)$, since $y \ge 1$. Comparison with the integral of the decreasing function $(y + \lambda t)^{1-p}$ gives

$$\sum_{a\ge 0} (1+a)(y+\lambda a)^{-p} \le C\left(y^{1-p} + \int_0^\infty (y+\lambda t)^{1-p}\, dt \right) \le C y^{2-p}. \tag{4.dlxxxiii}$$

This proves the stated, deliberately nonoptimal, bound. □

For SU(2), a bounded scalar action weight supplies another admissible ordinary input. If $W \in SL(2,\mathbb{C})$, then

$$1 - \tfrac{1}{2} \operatorname{tr} W = \tfrac{1}{2} \det(1 - W). \tag{4.dlxxxiv}$$

On a field domain where each plaquette satisfies $|W_p - 1| \le \alpha_n \eta_n^2$, its $\operatorname{tr}(F^2)$ is bounded by $C\alpha_n^2 \eta_n^4$. A local cube contains at most $CM^4 \eta_n^{-4}$ plaquettes. Filing each plaquette in a domain containing its corners therefore gives a weight member of norm at most $CM^4 \alpha_n^2 \sup |u|$. This proof uses the determinant identity and the count of plaquettes; it does not use covariance of u. With $\alpha_n = O(\theta_n^{-1/2} (\log \theta_n)^q)$, any fixed bound on $\sup |u|$ is eventually admissible.

These summations do not prove eq. 4.dlxxix. That estimate contains the renormalisation assertion: covariance of the pointed Hessian, the correct counterterm, regularity of the background within the window and uniform membership after substitution must be proved for the actual formation rule. They cannot be replaced by a bound on the full total or by holomorphy in the source alone.

Exponential reserves and generated local perturbations. Let a local history ω have a positive measure μ_ω on S_ω, a reference exponent $\Phi_\omega(\xi; P)$, and a site count N_ω. Suppose its reserve volume V_ω is additive over the older histories swallowed by this history and satisfies

$$V_\omega \ge A N_\omega, \qquad \sum_\omega \int_{S_\omega} e^{c_\star V_\omega} \sup_P |e^{\Phi_\omega(\xi;P)}|\, d\mu_\omega(\xi) \le \varepsilon, \qquad c_\star \ge 1. \tag{4.dlxxxv}$$

The supremum in eq. 4.dlxxxv is assumed measurable, or is replaced by a measurable majorant throughout. If a holomorphic perturbation satisfies $|\Psi_\omega| \le f N_\omega$ and $A \ge f$, then for bounded F

$$\left| \sum_\omega \int F e^{\Phi_\omega + \Psi_\omega}\, d\mu_\omega \right| \le \varepsilon \|F\|_\infty. \tag{4.dlxxxvi}$$

Indeed, $|e^{\Psi_\omega}| \le e^{V_\omega}$, so take absolute values inside every integral and apply eq. 4.dlxxxv. If each integrand is holomorphic in the parameter and all reference measures and integration sets are parameter independent, a common integrable majorant on compact parameter sets also proves holomorphy by Fubini and Morera. This is an ordinary complex mass estimate. It requires no derivative with respect to the number of source zones.

Suppose a formation rule produces a new excess exponent in the explicit form

$$\Psi_\omega^{\mathrm{new}} = A(\widehat{c}\, \upsilon 1_X, U''(\xi)) + V^{\mathrm{col}}(X^\sim; \mathfrak{L}) - V^{\mathrm{col}}(X^\sim; \mathfrak{L}^0) + \sum_R \delta_R[\psi_R], \tag{4.dlxxxvii}$$

where $U''(\xi)$ is real, $0 \le \upsilon \le 1$ and $\sup|\widehat{c}| \le \bar{c}$. To apply eq. 4.dlxxxvi it is sufficient to prove the actual formation bounds

$$|A(\widehat{c}\,\upsilon 1_X, U''(\xi))| \le C_W \bar{c}\, N_\omega^0, \qquad |V^{\mathrm{col}}(X^\sim;\mathfrak{L})| + |V^{\mathrm{col}}(X^\sim;\mathfrak{L}^0)| + \sum_R \sup|\delta_R[\psi_R]| \le 2c_{\mathrm{int}}(1+\bar{c})N_\omega^0. \tag{4.dlxxxviii}$$

If $\Psi_\omega = \Psi_\omega^{\mathrm{new}} + \sum_{\omega'} \Psi_{\omega'}$ and $N_\omega = N_\omega^0 + \sum_{\omega'} N_{\omega'}$, these inequalities give

$$|\Psi_\omega| \le \max\{C_W\bar{c} + 2c_{\mathrm{int}}(1+\bar{c}), f\}\, N_\omega. \tag{4.dlxxxix}$$

The maximum, rather than a sum of the old and new constants, is what permits unbounded nesting. Preserving the carrier oscillation norm needed in the next formation step is an additional estimate; it does not follow from eq. 4.dlxxxix.

There is a genuine reason to generate local perturbations through this formation rule. A bound on an exponent and on the oscillation of each carrier does not bound arbitrary partial sums of carrier factors. On a one-point integration space, write $\Psi^\circ(\lambda) = -N\lambda$ and $\psi_1(\lambda; P) = N\lambda$, with a second, unused carrier if desired. Then $\Psi^\circ + \psi_1 = 0$, both carrier oscillations in P are zero, and the full mass is unchanged for every λ. Interpolating only ψ_1, while leaving Ψ° at its value at zero, instead gives the mass $e^{N\lambda}$. No bound uniform in N survives on a fixed complex disc. This example refutes that partial-interpolation argument, not a construction which defines its localized exponents recursively by eq. 4.dlxxxvii and proves eq. 4.dlxxxviii on the whole complex data box.

Local data lines in the source induction. Use the fixed real step and its source radius r. Construct the constant-source data first. If the radial increment bounds through level k sum to at most $1/3$, the running constant shift satisfies $|\zeta_k(\zeta)| \le 4|\zeta|/3$. The reserve $2r$ puts the shifts with $|\zeta| < r$ in the real weight tube. The doubled disc $|\zeta| < 2r$ instead uses the larger analytic range of the increment maps. The frame bound $\theta_{i+1} \le \theta_i + C$ carries the upper bound on the tube width at the next scale back to $C'\theta_i(\log\theta_i)^{-C_1}$ at scale i. Choose the tube constant smaller than the constant in the analytic range. The fixed extra reserve $2r/3$ is then available at weak coupling. Thus the previously formed shifts and remainders are admitted when computing $b_{k+1}(\zeta)$ on the doubled disc. The summable increment bound keeps the same $1/3$ bound for the enlarged list. The regular constant-source step supplies the covariant member with this coefficient, before the position-dependent source is introduced.

At level $k+1$ let W be a region containing the complete input reads of the output under consideration. For a source w and a constant comparison value ζ_0 in $D(0,r)$, let m be the source deviation on W, including the scaled Lipschitz bound at level $k+1$. Form the data line at ζ_0 by adding t times the difference from w. Move the site values and the entries with their complete one-layer enlargements inside W. For a boundary sum make this choice at each of its summands. Keep the reference entries outside W. The linear consistency rules are checked at these same indices.

The inherited slope bounds put the line in the enlarged data box for $|t|\mathsf{m} < r$. In detail, the site source has modulus at most $2r$. If $\mathsf{d}_{2r}[b_i]$ is the bound for $(b_i(\zeta) - b_i(0))/\zeta$ on $D(0,2r)$, the increment has Lipschitz constant at most $2\mathsf{d}_{2r}[b_i]$ on $D(0,r)$, by Cauchy's estimate for $b_i - b_i(0)$ on the doubled disc. Thus on the line its deviation is at most $3r\mathsf{d}_{2r}[b_i]$. The sum of the $\mathsf{d}_{2r}[b_i]$ is at most $1/3$, so the site source and the accumulated shifts fit the $3r$ bound. For an earlier defect at level i, the gradient scale is smaller by $L^{-(k+1-i)}$. The product $|t|\mathsf{m}/r$ is at most one. The other rooted entries use their bound at the constant source and $|t|$ times their inherited slope, on the same carrier.

Define the excess exponents on this line by applying the formation operations to the line. At the bare level there are no excess exponents. A region for the new grid is a region for the preceding grid, the new source class is contained in the preceding one, and the deviation at the earlier scale is at most m. Thus the earlier line is available on the same disc. The still-standing exponents are carried from it. At a new operation apply eq. 4.dlxxxvii and eq. 4.dlxxxviii to the data on the line.

The fresh count and inherited counts add, so the maximum in eq. 4.dlxxxix keeps the same total bound at every depth. This defines the line also when W cuts a large-field component. At $t = 0$ it gives the constant-source output. When the disc contains $t = 1$, the line there gives the sourced output on complete reads in W, by locality of the actual operations and of the lines at the inherited operations.

The carrier oscillation has its own bound on the data box. At a new island the common quadratic factors contribute zero to the source difference. The remaining factors are differences of the formed interaction pieces, with the whole island carrier $C^{\sim}$. Its length after exempting the island hull is zero. Normalize the sum of oscillations by $\ell_t^{2\mathfrak{p}_0}$, with the length weight of the carrier. The local pieces on $C^{\sim}$ cost $C(1+\bar{c})\check{R}_t^4$ before normalization, and the source-dependent Wilson pieces have a uniform bound. These contributions give a fixed $b_V^{\times}(\bar{c})$. The difference of an inherited factor is evaluated by the kept response at fixed stored variables. Subtract its value at the common real pair before taking the response difference. The weighted sum of these oscillations contributes at most $C_V^{\times}\vartheta(\theta_t)s$, where s is the admitted normalized bound of the old carriers and

$$\vartheta(\theta_t) = (A_1/C_0)(\log\theta_t)^{-(q-\mathfrak{p}_0)}.$$

This estimate sums over the individual pieces and therefore also bounds their grouped oscillations. Standing factors retain their carriers and restrict their old functions.

Choose $c_\times \geq 2b_V^{\times}(\bar{c})$. On the enlarged data line admit $s \leq 4c_\times$. With $8C_V^{\times}\vartheta(\theta_t) \leq 1$, the new normalized bound is at most $c_\times$. Thus the new carriers have the same room on the next data line. This argument concerns the oscillation at fixed stored variables. For the full source excess use the absolute estimate of eq. 4.dxvi, including the parts constant in the pair.

For a holomorphic output bounded by B on the line disc, Schwarz applied after subtracting its value at zero bounds the difference of the endpoint values by $2B\mathsf{m}/r$. If $\mathsf{m} \geq r$, the separate bounds at the two endpoints give the same inequality. If $\mathsf{m} = 0$, the two reads coincide. For carrier oscillations first subtract the common reference value in each factor. Suppose their sum of suprema on one carrier is bounded by B throughout the line. For any finite collection choose evaluation points and phases to make the endpoint differences nonnegative and arbitrarily close to their individual suprema. The corresponding phased sum is a single holomorphic function bounded by B on the line. Apply the same Schwarz estimate to it and take the suprema and then the increasing sums. This preserves the carrier oscillation slope separately from the slope of the total exponent.

For the regular pointed coefficient the defect needs the bound with unit slope and a spare unit of spatial decay. The Gaussian normalizer is common to the line and the constant source. After removing it, the cluster contribution and the correction for the real weight relative to the frozen one have combined bound

$$\left(C_V\vartheta_k^{\sharp} + C_{\mathbf{M}}\frac{\mathsf{t}_k}{\theta_k}\right)e^{-(\kappa+1)d_{k+1}(X)}.$$

Here $\vartheta_k^{\sharp}$ includes the small fluctuation-radius ratio, and t_k is the real weight tube radius. The ordinary absolute estimate gives this bound on the direct regular windows. For an interior pointing the hulls of the input vertices and the complete Gaussian guards are in the small-field region, so the bracket uses its ordinary legs without a stored exterior mean. The normalizer and the free ratio term use the same real reference in both members of the comparison. The constant source chosen first at each base supplies its own pointed subtraction. The local line uses the direct estimates on its complete bases. Any other origin entering the regular rule must satisfy its own carrier and admission bounds on this line. Taking the parenthesis at most $1/2$ gives the unit slope by the preceding Schwarz estimate. Compare with the constant $\zeta_0 = w(p_z)$ at the pointing z. The spare unit of decay pays for the diameter of the source read, leaving the factor $L^{-(k+1-i)}$ in a defect of level i when it is read at level $k+1$. The uniform box bound supplies the output slope. The input slopes only supply admission to that box.

Form the torus regular output of $\mathbf{T}$ before choosing its new extension. At each pointing z choose the Euclidean member at the constant value $w(p_z)$, with marginal coefficient $b_{k+1}(w(p_z))$. The pointed slope bounds the difference between the actual regular output and this member, admitting the defect of the extension. For estimates along the complex data line, interpolate the extension members and their coefficients affinely between the constant and sourced endpoints. On $|t|\mathsf{m} < r$ the member norm is at most $E_0 + |t|\mathsf{m}/r \le E_0 + 1$, and the summed coefficient deviation and site source obey the same $3r$ scalar bound. For the extension defect use the two regular outputs with the common normalizer removed and the affine change of the member. The first two terms are bounded by $\frac{1}{2}e^{-\kappa d}$ each and the affine change by $e^{-\kappa d}$. The defect therefore fits the enlarged box on the entire line. Applying $\mathbf{R}$ there returns the slope bounds for the new boundary and remainder terms by the same Schwarz estimate. Carried terms keep their previous slopes on their native reads.

For the actual sourced endpoint set

$$c_{k+1}(p; w) = \varphi_{k+1}(p) \sum_{y} h_y^{(k+1)}(p) b_{k+1}(w(p_y)).$$

Use the real-center update $x_{k+1}^{\natural} = x_k^{\natural} - b_{k+1}(0)\varphi_{k+1}$ for the position-dependent weight, and update the running shift by $\zeta_{k+1} = \zeta_k + c_{k+1} - b_{k+1}(0)\varphi_{k+1}$. Then at every plaquette

$$x_k^{\natural} - \zeta_k = x_{k+1}^{\natural} - \zeta_{k+1} + c_{k+1}.$$

Thus the pointed subtraction $-A(c_{k+1}, U)$ pays exactly for the change of the Wilson coefficient. The profiles, tests and integration kernels come from the frozen step throughout. On the admitted formation domains the exactness of $\mathbf{RT}$ with this extension gives the sourced output in the resummed standing classes with their retained variables, on the same source class for the next step.

What a pointwise polymer logarithm proves. Consider a finite hard-core polymer gas Ξ_y, depending on an exterior field y. Suppose its activities $h_y(C)$ satisfy a uniform Kotecký–Preiss criterion, including absolute convergence of the logarithmic series and the bound

$$|\log \Xi_y| \le \sum_{C} |h_y(C)| e^{a(C)} \le c\, N. \tag{4.dxc}$$

If the activities are real for real y, then $\Xi_y > 0$. One proof is that the absolutely convergent logarithmic series is real. Equivalently, replace every activity by $t h_y(C)$, $0 \le t \le 1$. The same criterion applies, so $\Xi_y(t)$ is real, continuous and nonzero. Its value at zero is one, proving positivity at one. Individual activities need not be positive. Moreover $e^{-cN} \le \Xi_y \le e^{cN}$.

If a final representation really has the form $Z = \int q(y)\Xi_y \, d\nu(y)$, with $q \ge 0$, then

$$e^{-cN} \int q \, d\nu \le Z \le e^{cN} \int q \, d\nu. \tag{4.dxci}$$

Thus even a pointwise polymer logarithm requires control of the remaining integral. It does not turn a restricted Haar integral into a probability integral. For example, take the empty gas and let q be the indicator of a Haar set of measure e^{-N^2}. The polymer criterion is automatic, but a lower bound e^{-CN} for Z is false.

In a representation that sums over standing labels, the useful upper estimate instead has the form

$$\sum_{\mathcal{S}} |e^{\mathcal{E}_{\mathcal{S}}(w)} \tau_{\mathcal{S}}^{w}|(\mathcal{V}_n) e^{W(\mathcal{S})} \le e^{cN_n}. \tag{4.dxcii}$$

Here the absolute value is total variation, W pays for missing vacuum contributions and the measures inside the retained integral operations are also majorised before they are integrated. A pointwise bound for one gas does not supply this sum: arbitrarily many positive labels can have the same individually bounded gas. The counting of labels and the exponential reserve in their operations are essential.

For the lower bound at zero source, positivity permits retaining the all-small-field label. Suppose its density, after vacuum normalisation, is at least $\chi(y)\exp[-xA(U(y)) - CN_n]$. Assume the ball in which every one of the $4N_n$ link variables has distance less than s from the identity is contained in $\{\chi = 1\}$, and that $A(U(y)) \le Cs^2N_n$ there. Normalized Haar measure on SU(2) assigns this link ball mass at least $(cs^3)^{4N_n}$. It follows directly that

$$e^{-E}Z(0) \ge \exp[-(C + 4\log(1/(cs^3)) + Cxs^2)N_n].$$

Taking $s = c_0x^{-1/2}$ gives $e^{-E}Z(0) \ge \exp[-(C + 6\log x)N_n]$. The terminal background estimates needed here are proved in the calculation on a product of link balls. No zero-free statement for the sourced full partition function is needed.

4.21. **Weighted domains and scale forgetting.** A multiscale argument needs several analyticity statements with different meanings. Holomorphy of a finite-dimensional partition function is the weakest of them. Holomorphy of a renormalization step on a class of effective interactions is stronger. Geometric forgetting of old interactions is stronger still. The latter can follow from an analytic extension with appropriate domains and bounds, but the weights in that extension must themselves be justified.

There is an additional distinction for large-field regions. A small probability of retaining an old region can appear as a small factor in the bound on an analytic function. It does not in general permit the analytic input radius to grow by the reciprocal of that probability. This section defines a suitable input space and states the local inequalities needed for continuum reconstruction. Their validity for the Yang–Mills step remains to be proved.

4.21.1. *The ordinary input space.* Fix a cutoff, a reference sequence of inverse couplings $\theta_0, \dots, \theta_k$, a complete set of labels and tests, and hereditary complex domains $\mathcal{U}_j(X; r_{0,j}, r_{1,j})$. A point of such a domain is a pair $(\mathbf{U}, \mathbf{J})$; the current $\mathbf{J}$ is an independent complex variable. A regular background gives the special pair $(U, J(U))$. An identity verified at these special pairs is not automatically an identity at all pairs in the complex domain.

One convenient Banach space of pointed local families has the norm

$$\|E\|_{j,\kappa} = \sup_{X,z} e^{\kappa d_j(X)} \sup_{\mathbf{p}\in\mathcal{U}_j(X;r_{0,j},r_{1,j})} |E(X,\mathbf{p},z)|.$$

When families have infinite-lattice companions, include their norms in the maximum. Gauge invariance, the prescribed translation covariance, and compatibility with restriction are closed linear conditions. Holomorphy is preserved under convergence in this supremum norm on the declared domains. These facts specify a closed space of analytic families once the domains themselves have been fixed. The existence and uniform size of those domains remain analytic inputs.

A regular Euclidean member comprises a family G, its companion, and its scalar quadratic coefficient $b(G)$. It has covariant pointed totals on the prescribed regular backgrounds and carries its own counterterm. A spatially varying input can assign a different such member $G_z^{(j)}$ to every base point z. This does not require the array $z \mapsto G_z^{(j)}$ to be translation invariant. Its norm is $\sup_z \|G_z^{(j)}\|_{j,\kappa}$. Each assigned member must retain its own coefficient and the required pointed covariance; covariance of the sum of all base points is a weaker condition.

The complete input also contains a bare plaquette weight u, defect families $D^{(j)}$, remainders $H^{(j)}$, boundary terms B, and excess exponents Ψ in stored large-field operations. A useful product box has inequalities of the following form:

$$\|u\|_\infty + \sum_{j\le k} \sup_z |b(G_z^{(j)}) - b_j^{\mathrm{ctr}}| \le C_u, \qquad \sup_z \|G_z^{(j)}\|_{j,\kappa} \le E_0,$$
$$\|D^{(j)}\|_{j,\kappa} \le L^{-(m-j)}, \qquad \|H^{(j)}\|_{j,\kappa} \le C_H \theta_j^{-\kappa_0/2}, \qquad m \in \{k, k+1\}.$$

Here b_j^{ctr} denotes the coefficient of the chosen real centre. Boundary terms are measured against specified positive majorants $\overline{B}_{j,h}(X)$:

$$\|B\|_{\mathrm{bdry}} = \sup_{j,h,X} |B_{j,h}(X)|/\overline{B}_{j,h}(X).$$

For a stored history ω let $N(\omega)$ count its stored sites, each at its own scale. Excess exponents require both a bound on $|\Psi_\omega|/N(\omega)$ and a carrier-by-carrier oscillation bound. If $\Psi_\omega = \Psi_\omega^0 + \sum_f \psi_f$, the latter can be expressed as

$$\sup_{\omega,R} \overline{M}_\omega(R)^{-1} \sum_{f: R_f = R} \operatorname{osc} \psi_f < \infty.$$

The carrier majorant and the history size are part of the definition, not consequences of holomorphy.

A source trajectory fits this format by freezing the source separately at each base point. Schematically,

$$G_z^{(j)} = E^{(j),\zeta}\big|_{\zeta = w(p_z)},$$
$$D^{(j)}(X,\cdot,z) = E^{(j),w}(X,\cdot,z) - E^{(j),w(p_z)}(X,\cdot,z).$$

For a Lipschitz source, a local freezing estimate can give $\|D^{(j)}\| \le CL^{-(K-j)}\|w\|_{\mathrm{Lip}}$. This smallness is a property of the source trajectory. An arbitrary defect in an ordinary box has only the size stipulated by that box.

This organization resolves a possible misconception. Global noncovariance does not by itself invalidate a construction with sources: Euclidean members can be frozen site by site. The remaining task is to prove the asserted bounds for the full array, including its noncovariant defects, its variable Wilson weight, and its stored-history operations. Scalar marginal cancellation for a globally covariant list alone does not complete that task.

4.21.2. *Three kinds of weights.* Let e_j measure a difference of regular families and let r_j measure a difference of remainders. The regular irrelevance weights have the form

$$\omega_\nu \le C\nu^4 L^{-\sigma(\nu-1)},$$
$$\sigma > 0.$$

They represent decay after the vacuum and the applicable marginal quadratic terms have been removed. In contrast, an unrenormalized remainder can enter with a squared ratio of analyticity radii,

$$w_{n,j} = \left(\frac{r_{0,n}}{r_{0,j}}\right)^2 \asymp \frac{\theta_j}{\theta_n}\left(\frac{\log\theta_n}{\log\theta_j}\right)^{2q}.$$

These weights account for the small size of the remainder. Geometric forgetting and any further symmetry cancellation require separate estimates.

A typed tangent list may also have a marginal amplitude z_j and an increment b_j. Define

$$z_n^\sharp = \sum_{j\le n} L^{-(n-j)}(z_j + z_{j-1}),$$

$$z_{-1} = 0,$$

and a load

$$p_n(\delta) = \sum_{j\le n} \omega_{n+1-j} e_j + \sum_{j\in\mathcal{J}_n} w_{n,j} r_j + \gamma_n \left(z_n^\sharp + \sum_{j\le n} L^{-c(n-j)} b_j \right),$$

$$\gamma_n \asymp \theta_n^{-1} (\log \theta_n)^C.$$

The set $\mathcal{J}_n$ consists of remainder slots still present at level n in the chosen filing convention. If a remainder is re-filed into a regular family, it must be removed from this set and counted in that family instead. A recent-level window can have a separate term without geometric age decay. This bookkeeping cannot be suppressed by changing notation.

The survival age of a large-field zone has a different role. For $0 < q_a < 1$ the desired integrated bound involves

$$\Sigma_k(\delta) = \sum_{n\le k} (k-n+1) q_a^{(k-n-1)_+} p_n(\delta).$$

The factor $k-n+1$ counts the steps at which the zone can be used. The survival factor $q_a^{(k-n-1)_+}$ belongs to an output estimate on the relevant histories. It need not, and generally cannot, be put into a single enlarged analytic input radius.

4.21.3. *What weighted holomorphy actually proves.*

Proposition 4.77 (A segment estimate)**.** Let X, Y be complex Banach spaces, let $C \subset X$ be convex, and let p be a continuous seminorm. Suppose F is holomorphic on

$$\mathcal{T} = \{a + h : a \in C,\, p(h) < \epsilon\},$$

$$\epsilon > 0,$$

and, for every $a \in C$ and $p(h) < \epsilon$, one has $\|F(a+h) - F(a)\|_Y \le B$. Then, for $a, b \in C$,

$$\|F(b) - F(a)\|_Y \le (B/\epsilon) p(b-a). \qquad \blacksquare$$

Proof. Put $h = b - a$. At every $a_t = a + th$, $0 \le t \le 1$, the map $z \mapsto F(a_t + zh) - F(a_t)$ is holomorphic on $|z| < \epsilon/p(h)$ and has norm at most B. The Banach-valued Cauchy formula gives $\|DF(a_t)h\| \le Bp(h)/\epsilon$. Integrating over t proves the inequality. If $p(h) = 0$, the line is entire and bounded in oscillation. Every bounded linear functional on Y makes it a bounded scalar entire function, so Liouville's theorem and separation by the dual imply that it is constant. □

The seminorm in this proposition is an assumption. Applying it with $p(h) = \sum_j \omega_{k+1-j} \|h_j\|$ produces the displayed weights because they already occur in the domain. It does not derive them from an ordinary product box.

A differential bound is a weaker sufficient input. If $\|DF(a)h\| \le Cp(h)$ holds on the segment joining two actual trajectories, integrating this inequality proves the same comparison without constructing a full weighted tube around every off-trajectory point. Thus a derivative estimate along these segments suffices.

Proposition 4.78 (A marked slot)**.** Suppose $F(a,m)$ is jointly holomorphic when $p(a-a_0)<r_a$ and $\|m\|<r_m$, is bounded there by B, and satisfies $F(a,0)=0$. For $p(a-a_0)\le r_a/2$ and $\|m\|\le r_m/2$,

$$\|D_aF(a,m)h\|\le\frac{CB}{r_ar_m}\,p(h)\|m\|.$$ ■

Proof. Cauchy's formula first in the complex line $a+zh$, and then in the line tm, bounds the mixed derivative by $CBp(h)\|m\|/(r_ar_m)$ on the reduced domains. Integrate that derivative from $m=0$ to m. The derivative in a vanishes at $m=0$ because $F(a,0)$ is identically zero. The argument uses two complex lines and introduces no factor equal to the dimension of either input space. □

This explains how a small marked-slot size can multiply the sensitivity to other data. It does not establish the required radii, the marked-slot vanishing identity, or a uniform bound on the enlarged domain.

4.21.4. *Exact examples separating the assertions.*

Proposition 4.79 (Ordinary analyticity does not imply forgetting)**.** Fix $0<q<1$ and any positive numbers s_k. There are entire scalar functions F_k bounded by s_k on the unit polydisc of $\mathbb{C}^{k+1}$ for which no constant C independent of k satisfies

$$|F_k(x)-F_k(y)|\le Cs_k\sum_{j=0}^{k}q^{k-j}|x_j-y_j|$$

on the polydisc of radius $1/4$. ■

Proof. Take $F_k(x)=s_kx_0$, $x=0$, and $y=(1/4,0,\dots,0)$. The inequality would give $1\le Cq^k$. This is impossible as $k\to\infty$. The same example is holomorphic on every weighted tube, but its supremum on a tube of fixed weighted radius grows like s_kq^{-k}. Thus the missing issue can be a uniform bound, even when the extension itself is entire. □

This example is a logical separation, not a model satisfying the gauge-theory power-counting identities. It shows exactly why analyticity and a small one-step factor alone do not establish those identities.

Proposition 4.80 (Rarity does not enlarge the complex radius)**.** Let $0<q<1$, let a be a nonnegative integer, and let an event have probability q^a. For $\delta>0$ its excess generating function can be

$$R_a(\lambda)=q^a(e^{\lambda\delta}-1).$$

On $|\lambda|\delta<c$ it has a bound C_cq^a, and $R_a'(0)=q^a\delta$. There is no age-independent bound C_cq^a on the larger disc $|\lambda|q^a\delta<c$. ■

Proof. The first bound follows from $|e^z-1|\le e^{|z|}+1$. At the positive point $\lambda=cq^{-a}/(2\delta)$ the ratio $R_a(\lambda)/q^a$ equals $e^{cq^{-a}/2}-1$, which tends to infinity. The event model is a genuine two-point probability space, and its generating function is entire. □

The correct large-field strategy is therefore a bounded per-zone radius together with a rare-history factor in the bound. A demand for a bounded extension on a single tube measured only by the aged load would be stronger than what the argument needs and can fail even in this elementary example.

There is a separate reason for the Euclidean-member and marginal-slot conditions. Let

$$H = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$

$$M_\varepsilon = I + \varepsilon H.$$

For real $|\varepsilon| < 1$, take independent centered Gaussian vectors $X_1, \dots, X_m$ with precision matrix M_ε. The normalized block average $m^{-1/2} \sum_i X_i$ has exactly the same covariance M_ε^{-1}, hence exactly the same precision matrix. The traceless quadratic perturbation $\varepsilon x_1 x_2$ survives this blocking unchanged, although its scalar trace coefficient is zero. The Gaussian integrals are holomorphic and uniformly coercive on each fixed complex disc $|\varepsilon| < r < 1$.

This example explains why a scalar counterterm cannot remove an arbitrary anisotropic quadratic perturbation. It does not contradict the use of a scalar counterterm in the Euclidean class. It also explains why a typed extension must supply all of its prescribed tensor counter-insertions before claiming that the remaining part is irrelevant.

Finally, identities on backgrounds do not determine an arbitrary extension to independent currents. The polynomial $P(z, j) = j - z^2$ vanishes on every pair (z, z^2) and is nonzero elsewhere. An analogous cancellation known only on a graph of background pairs needs an additional argument before it can be used throughout a domain where the current is independent.

4.21.5. *Two local inequalities to establish.* The first test concerns the small-field potentials before exponentiation. Let $\dot{V}_{k,j}$ be the variation of the actual localized fluctuation potential caused by one regular family at level j. Include its own scalar counterterm, or the complete tensor counter-insertions for a typed family. A suitable test is

$$\|\dot{V}_{k,j}[\delta E]\|_{\mathrm{pot}} \le C \varkappa_k \omega_{k+1-j} \|\delta E\|_{j,\kappa}. \tag{4.dxciii}$$

The supremum in the potential norm must range over the complex pairs and decoupling parameters actually used inside the fluctuation integral, not just real backgrounds. One possible norm is the least M such that

$$|\dot{V}(Y; \mathbf{p}, B)| \le M e^{-\lambda d_k(Y)} \left(1 + M_0^{-4} \sum_{b \subset Y} |B(b)|^2 \right).$$

Here M_0 is the fixed block-size parameter. The complex field domains, the allowed fluctuation cut, and the enlarged decoupling discs must be specified. Defects and remainders have their own test with squared-radius weights in place of ω. A variable Wilson weight is a marginal slot; it does not receive an irrelevance weight merely by being written as a local family.

For ordinary site-frozen Euclidean members, a regular-output dependence estimate already has this intended structure after the cluster expansion. The additional typed claim requires the same cancellation at the complex pairs in the integrand, with the full tensor removed. A background extraction formula alone is insufficient for that extension. Proving eq. 4.dxciii for these typed inputs is a concrete local task.

The second test concerns a single zone in a large-field operation. Fix a zone n and a step k' at which it is used, where $n \le k' \le k$. Let $\lambda_{n,k'}$ multiply only that use of a direction of load $p_n(\delta)$. Isolate the normally convergent subseries of histories affected by this dial, and denote the resulting output by $R_{k;n,k'}(\lambda)$. The required axis estimate has the form

$$\sup_{|\lambda| p_n(\delta) < c} \|R_{k;n,k'}(\lambda)\|_{k,\kappa} \le C \epsilon_k q_a^{(k-n-1)_+}. \tag{4.dxciv}$$

The constants c, C are independent of the levels, the history, and the positions of the sources. The source is allowed to be complex on the declared source ball. The factor ϵ_k is the small mass assigned to the output under consideration. For an unintegrated boundary term it must be replaced by that

term's actual majorant; its residual dependence is subsequently paid under the relevant mass, rather than being assigned a false termwise survival bound.

Cauchy's formula applied to eq. 4.dxciv gives

$$\|\partial_\lambda R_{k;n,k'}(0)\|_{k,\kappa} \le (C/c)\epsilon_k q_a^{(k-n-1)_+} p_n(\delta).$$

Summing over the $k-n+1$ uses of that zone, and then over n, gives $(C/c)\epsilon_k \Sigma_k(\delta)$. This proves the differentiated age estimate from a precise bounded complex-mass statement. The proof needs no age-dependent increase of the analytic radius.

A complete verification must establish eq. 4.dxciv under the moduli and suprema used by the operation, including its reserve weights. Undifferentiated rarity at the unperturbed source alone does not establish it: the dial changes the integrand on the rare histories. Conversely, a full off-trajectory analytic tube is not necessary if these axis estimates and the needed first and mixed derivatives have been proved directly on the actual trajectories.

4.21.6. *What remains conditional and what can proceed separately.* The ordinary product-box theorem, a weighted dependence estimate for its regular output, and the finer marked and zone-wise statements are different inputs. Coefficient readout uses the physical radii of the chain, as proved in § 4.23: fixed radii give a uniform norm, and running radii carry the inverse-square factor already recorded by the radius weights. Near-zero core inclusion is supplied by the stated tower bounds. The remaining finer assertions concern actual marked and typed evaluations in complex windows, with their proper radius normalization. When a linearized class includes these properties among its hypotheses, contraction rows derived from that class remain conditional on the class hypothesis. Such a deduction does not turn an ordinary complex-box bound into the weighted or zone-wise estimates.

For a prescribed whole-sequence continuum limit, the smallest useful replacement is an actual comparison of the two tuned trajectories: a step inequality, domination of the observable evaluations by the comparison distance, and a terminal-integral inequality with summable defects. These three estimates can be proved directly. Establishing a large weighted analytic class is one route to them, not a logical necessity.

Finite-cutoff source identities do not require this finer statement. Fixed-spacing DLR compactness and closedness of reflection positivity do not require it either. Subsequential separated-correlation compactness follows from its own cutoff- and volume-uniform source bounds. Those bounds remain substantial analytic requirements; their volume-free proof can use undifferentiated age-resolved rarity without proving the differentiated zone estimates above. Similarly, tuning at one fixed cutoff can follow from its own holomorphic slope and target-crossing estimates without establishing a comparison of consecutive cutoffs.

The proposed summable matched-cutoff comparison and the resulting whole-sequence tuned convergence use the stronger comparison route. The typed tangent contractions, scale-uniform memory estimates, and differentiated anisotropy method for rotations also require their corresponding finer inputs. Estimates for several insertions at nonzero source require joint bounds beyond a single first derivative at zero. An independent vanishing-flux theorem would provide a different route to rotations and should be assessed on its own hypotheses.

Thus the unresolved point is a specific family of uniform estimates on the declared inputs, not a general objection to sources or a proof that the construction fails. The potential test and the one-zone complex-mass test locate two places where a proof can be supplied, sharpened, or tested by an explicit counterexample.

4.22. **A reserve estimate for one large-field zone.** The one-zone estimate must bound a complexly perturbed integral; rarity at a real centre alone does not suffice. This section proves a reserve lemma, verifies the direct Wilson-weight channel on regular zones, and tests whether carrier oscillation and a prepaid end mark supply the remaining perturbation bound. The result is partial. The missing statement can be expressed as a norm bound for an explicit local evaluation map. The reserve argument alone does not prove that statement for every formed copy of a direction.

4.22.1. *The integral before taking a logarithm.* Keep the reference sequence, tests, history labels, changes of variables and reference kernels fixed. A local operation is then represented on a disjoint union of stored-variable spaces by

$$I(\lambda, p) = \sum_{\omega} \int_{S_\omega} e^{\Phi_\omega(\lambda, \xi; p)}\, \mu_\omega(d\xi),$$

where each μ_ω is positive and independent of λ. A harmless finite frame average can be included in these measures. The parameter p ranges over the external complex-pair domain. A single zone-use parameter has an index (n, k'): it multiplies the chosen direction where the stored zone n is used at step k'. Only histories containing that use are affected.

Before re-exponentiation, the substitution of an input list by a line of lists is affine in the exponent when its evaluation maps have been frozen. Its perturbation has the concrete form

$$L_{\omega,n,k'}[\delta](\xi, p) = \sum_{e \in \mathcal{E}(\omega,n,k')} \epsilon_e\, \delta F_e\big(\kappa_{\omega,e}(\xi, p)\big) + \delta c_\omega(\xi). \tag{4.dxcv}$$

The index e records the entry, its counter-insertions, its carrier, and its particular occurrence. The signs or fixed coefficients are ϵ_e. The formed argument $\kappa_{\omega,e}$ must lie in that entry's original analytic domain. The last term records scalar parts, including the values subtracted at the trivial field and their contributions to the vacuum bookkeeping. Constants cannot be omitted from this map merely because the observable ultimately uses a connected derivative.

For this affine use one has $\Phi_\omega(\lambda) = \Phi_\omega(0) + \lambda L_{\omega,n,k'}[\delta]$. After local histories or polymer clusters have been summed, the resulting effective families are generally nonlinear in λ. Their control requires a convergent marked expansion; their logarithms need not remain affine. If the formed arguments themselves are changed with the input, their derivatives are additional terms in eq. 4.dxcv; they require their own domain and norm bounds.

4.22.2. *What an exponential reserve proves.*

Proposition 4.81 (A one-zone reserve lemma)**.** Let the fixed affected event E_a consist of histories of age at least a in a measurable disjoint union of history spaces with positive reference measure. Assume that the integrands are measurable in the stored variables and holomorphic in λ for almost every stored configuration. Suppose $W_\omega(\xi) \geq 0$ is measurable, and assume a measurable majorant M_ω satisfies

$$\sup_p e^{\operatorname{Re}\Phi_\omega(0,\xi;p)} \le M_\omega(\xi),$$

$$\sum_\omega \int_{E_a} M_\omega e^{cW_\omega}\, d\mu_\omega \le B\varepsilon q^a,$$

where $c, C > 0$ and $0 < q < 1$. Put $R = c/(2Cp_n)$, interpreted as infinity when $p_n = 0$. Suppose the perturbation is defined and holomorphic on $|\lambda| < R$, and throughout that disc

$$\sup_p |\Phi_\omega(\lambda,\xi;p) - \Phi_\omega(0,\xi;p)| \le C|\lambda| p_n W_\omega(\xi). \tag{4.dxcvi}$$

Then on $|\lambda| p_n < c/(2C)$ the integral over E_a is bounded in modulus by $B\varepsilon q^a$, and is holomorphic. Its difference from its value at zero is bounded by $2B\varepsilon q^a$. Its first derivative at zero is at most

$$(2CB/c)\varepsilon q^a p_n.$$

The same conclusions hold with an additional insertion which is measurable in the stored variables, holomorphic in λ on the same disc, and uniformly bounded there, multiplied by that uniform bound. A fixed bounded insertion is a special case. ■

Proof. The modulus of the perturbed integrand is at most $M_\omega e^{cW_\omega/2}$. The assumed positive majorant is integrable over the disjoint union of histories. Dominated integration, or Morera's theorem and Fubini, proves holomorphy on the open disc. The mass estimate follows from the same domination. The difference is bounded by the sum of the two masses. Cauchy's formula on circles of radius approaching $c/(2Cp_n)$ gives the derivative bound. If $p_n = 0$, the hypothesis makes the perturbation independent of λ, and the derivative is zero. □

Finite upper integrals can replace the measurable majorants in this proposition: choose measurable majorants with integrals arbitrarily close to their upper integrals, apply the argument, and take the infimum. The supremum over external pairs must remain inside the history integral.

A reserve can also produce the age factor. If $W \ge a$ on E_a and

$$\sum_\omega \int M_\omega e^{(c_{\mathrm{pert}}+c_{\mathrm{age}})W}\, d\mu_\omega \le B\varepsilon,$$

then a perturbation paid by $c_{\mathrm{pert}}W$ leaves the estimate $B\varepsilon e^{-c_{\mathrm{age}}a}$. Thus a per-zone radius independent of the age is compatible with geometric forgetting. The perturbation budget and age budget must be allocated before the coupling ceiling is selected.

This argument is effective only after eq. 4.dxcvi has been proved. An oscillation bound for the unperturbed factors does not establish it.

4.22.2.1. The ordinary boundary terms in the zone allowance. Fix a history and time. Count each live first-group boundary term once at its stored level e, with one term per formation domain at that level. Its assigned anchor is a level-e cube in the native anchor region. For a term whose domain misses the live strips, the dial majorant is

$$C_{99} e^{-p_0(g_e)} e^{-(1+\beta/2)\kappa d_e(X)}.$$

At a fixed anchor Q the ordinary rooted domain sum is bounded by K_0 at rate $\kappa - 1$. Since each domain X contains Q, the summed majorant there is at most $C_{99}K_0 e^{-p_0(g_e)}$.

Write $\Gamma_l^\natural$ for the native level-l strata, and use $N_l(S) = \ell_l^{-4}\,\mathrm{vol}(S \cap \Gamma_l^\natural)$ for the volume in units of one native lattice cell. The anchor geometry puts Q entirely in strata with $l \le e$. Since its side is $M\ell_e$, its contribution to the anchor count is

$$1 = M^{-4} \sum_{l \le e} L^{-4(e-l)} N_l(Q).$$

The level-e anchor cubes are disjoint. Thus for anchors contained in S, the summed majorant is at most

$$C_{99}K_0M^{-4}e^{-p_0(g_e)}\sum_{l\le e}L^{-4(e-l)}N_l(S).$$

This uses the native stratum of each cell even when it is finer than the anchor. In a convention counting native M-cubes, absorb their volume factor into the fixed coefficient.

The lower flow window gives $x_e=g_e^{-2}\ge X-2c_2+\lambda(K-e)$ for a run with $x_K\ge X$, including $e=K$. For $p_0(g_e)=A_0(\log x_e)^{p_0}$ with $p_0>1$ we obtain the history-independent bound

$$\sum_{e\le k}e^{-p_0(g_e)}\le\sum_{t\ge0}\exp(-A_0[\log(X-2c_2+\lambda t)]^{p_0}).$$

For large X the series is dominated by the summable inverse squares of $X-2c_2+\lambda t$, so it tends to zero with the coupling ceiling. This gives the all-level allowance for ordinary first-group terms. On domains meeting live strips the size estimate and the counting norm are different. To use a small sum over the levels we must sum the relative estimates over the actual levels of storage. The age estimate below also has a version using a uniform level bound.

4.22.2.2. The relative count in the strip allowance. For the relative comparison family the formation estimate supplies a size $c_1^\flat(g_e)\le Cg_e^{\kappa_0}$, $\kappa_0\ge7$, after removing the relative length weight. Its level sum is bounded by

$$C\sum_{t\ge0}(X-2c_2+\lambda t)^{-\kappa_0/2},$$

which tends to zero with the ceiling. This is a sum of weighted suprema over production domains, before rooting. At an exterior anchor, the rooted relative count converts each supremum to a sum of values. For an activity bound the native site expansion must also supply the rate margin converting those values to activities. The site anchor must stay outside the excused islands with the prescribed separation.

There is a different count for the volume bound in a region Y. When the filed domain is contained in Y and contains an excused island, assign it to the first whole island I it contains. The relative rooted sum at I is at most $1+3^dC_{\mathrm{fib}}N_e(I)$, with $N_e(I)$ the number of its level-e cubes. Thus at each level its cost is proportional to the number of native determining cells of I. Summing over islands of that level uses their disjointness, and summing the size coefficients then uses the level sum. This pays the volume bound on the admitted whole-island reads. A single interior anchor for an activity would lack this whole-island volume.

For the admitted one-run strip terms filed on their tree domains, use the unweighted rooted sum for terms formed by $\mathbf{R}$, after subtracting their declared reference values. Their formation decay $(1+\beta/2)\kappa$ pays the count of domains over each tree at rate λ_θ and leaves at least c_d+1 for the tree count. The resulting bound at a tree root is $Cc_1^\flat(g_e)$. This gives a true-read bound at the formation level e. A direct read at a level-e cube uses a tree root within one layer. A pocket read uses a root within two cells of its strip. There are a bounded number of possible roots for pockets of side at most one. The disjoint larger pockets contribute at most 909^d choices, each with at most $(s_e+7)^d$ roots for side s_e. For a pocket born at $m\le e$, $s_e\le101\check R_mL^{-(e-m)}\le101\check R_e$, by the lower bound on the radius after each step. Thus the reading-cube sum for this class of $\mathbf{R}$-formed terms is at most $C(1+\check R_e)^dc_1^\flat(g_e)$. Since $\check R_e$ is polylogarithmic in inverse coupling and $\kappa_0\ge7$, the bound is at most Cx_e^{-2} at large x_e. The lower flow window therefore also sums it over levels.

For the uniform bound at a fixed level there is a direct count for the dialled family. Use the individual first-group strip domains X before combining their values. At birth such an X contains a union of whole excused strips and has a nonempty part outside them. Its filed skeleton $A(X)$ is chosen from a shortest relative tree. It contains X outside the strips, and each included strip touches it. The term reads $A(X)$ and the attached strips, including the older strips read through a touching cube. The separation of the new strips puts one of these off-strip cubes in the regular

part. The filing rule keeps a cube of the skeleton in $(Z_e^{\boxplus})^{(1)}$ of the current label for a term still stored at level e.

On the admitted age bidisc use the first-group strip majorant $C_{99}\alpha^{1/3}e^{-(1+\beta/2)\kappa d_{\mathrm{rel}}(X)}$. The strip amplitude α is fixed. The skeleton has $d_e(A) \le d_{\mathrm{rel}}(X)$, and there are at most $e^{\lambda_\theta(d_e(A)+1)}$ constituents over one A. Summing the individual majorants over that fibre leaves

$$C_{99}e^{\lambda_\theta}\alpha^{1/3}e^{-(1+\beta/4)\kappa d_e(A)}$$

when $\beta\kappa/4 \ge \lambda_\theta$. This bound also applies to any selected subfamily, so the witness marks may be kept on the individual terms. At a filed cube, the rooted ordinary tree sum gives a pile bounded by $C\alpha^{1/3}$. On the admitted relative-format reads of $\mathbf{T}$, the preparatory move, and the large-field move, the same filed skeleton and attached strips are used for marked and dialled terms. The native cube-to-cell attribution charges this pile to the volume and activity bounds. This gives the uniform part of the age estimate without a summable strip amplitude.

To use the count on every actual mixed history we must admit its fluctuation and preparatory readers on the enlarged age bidisc with the increased history weight. For an inherited crossing in the prepared sharp mask, the quiet-crossing calculation gives the real domains on the approximate pass. On a broader reader we must still account for each pulled-back indicator, and show that the densities on the fixed domains have the required holomorphic majorants. The skeleton sum applies once those readers and majorants have been identified.

4.22.2.3. Carrying the age bound through earlier terms. Compare two lists on the same lattice and scaffold. Give each use of a list entry in a production formula its own parameter. A parameter of class $z = (n, k')$ is bounded using the load of zone n. The diagonal holomorphy proof extends to these separate parameters when it charges each direct use by its absolute size, and reads a previously produced object only through its value and size bound. Indeed the size allowance of every direct input is the same on its own disc. In the order of formation, the earlier inputs retain their admitted suprema, so the same composition estimate gives the next holomorphic object. In this product of discs one may turn off a set of uses without moving the other parameters.

An occurrence means a stored object or a copy of its formula inside an object that read it. The outer domain contains the domain of the copy. For a boundary term of level e its witnessing components are those of Z_e whose enlarged sets meet that domain. A frozen term uses its arrested component. A use with $n < k'$ starts with the geometric witness containing its anchor in $\Omega_n \backslash \Omega_{n+1} \subset Z_{n+1}$. A top-zone use starts in the own set of the object that created it. A fluctuation or an arrest deletes no witness. At healing, a carrier of a use with a deleted geometric witness meets the operated set at its anchor. If an object loses its last witnessing component, the carrier meets the operated set through the domain of that object. The absorption rule places these uses in the newly produced terms. All other uses keep their live witnesses, including those read through copies. This gives a unique current assignment along each occurrence, with witness level $n + 1$ for a surviving geometric witness and level e for a surviving owner of level e. An occurrence carrying a copy need not have the same level as its witness.

In a healed component X_i, the histories that contain a direct old use of zone n must have $Z_{n+1} \cap X_i \neq \varnothing$. For a non-top use this follows from the zone read in the enlarged component and the filling rule for its older cells. An inner top use at level $k' = n$ is supported on $Z_{k'+1} \cap X_i$. A deleted geometric witness must itself be present in Z_{n+1} of the component history. In all these cases the first index of that history is at most $n + 1$. For an absorbed leaf with witness at level e, the component history must contain the witness in Z_e. This also applies if the leaf occurs inside a carrier, because that carrier's formation history includes the leaf's. At operation j these facts give ages at least $j - n - 1$ and $j - e$, respectively.

For a first-group boundary term or a second-group remainder φ formed by $\mathbf{R}_j$, fix a class $z = (n, k')$ of the source uses, and compare the value of φ before and after turning off its own uses. These are the direct old uses of the healed histories, the direct top uses at formation, and the uses

whose witnesses are lost at the operation. Let $\mathfrak{B}_\varphi$ be its holomorphic majorant and $0 < q \le 1/2$ the age rate. The history decomposition partitions the uses into one group of direct and low-level uses and groups of nested leaves of levels $n+2 \le e < j$. A nested leaf in such a group loses its last witness inside a healed component of this operation. The history-absorption rule is needed also for occurrences inside another stored term: a carrier containing such a leaf contains its witnessing anchor and is absorbed with that component.

Turn off the level groups one at a time. For a group of level e, replace a leaf value by its value with the selected uses off plus ν times its change. If the carried bound at level e is $C_*\mathfrak{B}_\psi q^{(e-n-1)_+}$ for each such leaf ψ, take

$$|\nu| \le R_e = [C_*\varepsilon_e^{\mathrm{all}} q^{(e-n-1)_+}]^{-1},$$

where $\varepsilon_e^{\mathrm{all}}$ is the per-cell pile for all such leaves. A zero pile requires no interpolation. This choice makes the changed part at most $\mathfrak{B}_\psi/\varepsilon_e^{\mathrm{all}}$. The summed changed parts therefore cost one additional unit of the per-cell allowance at a direct read with the stored-family count. An intermediate term, once formed, enters subsequent steps by its own majorant.

At the same time, multiply the sub-sums of healed histories of age at least $j-e$ by μ, leaving the younger histories unchanged. The bound on the age tail permits $|\mu| \le q^{-(j-e)}$ at the price of doubling the component input. At $\mu = 0$ the level-e leaves in this group cannot occur: the last-witness condition requires age at least $j-e$ in the component that absorbs the leaf. The term on this face is therefore independent of ν. At $\mu = 1$ the difference between $\nu = 1$ and $\nu = 0$ is the required change for this group. On an admitted bidisc with bound $\mathfrak{B}_\varphi$, subtract both axis values and add the value at the origin. The resulting function vanishes on both axes and has supremum at most $4\mathfrak{B}_\varphi$. Schwarz's estimate in the two variables therefore bounds the group change by

$$4\mathfrak{B}_\varphi\, q^{j-e}/R_e = 4C_*\varepsilon_e^{\mathrm{all}}\mathfrak{B}_\varphi q^{j-n-1}.$$

Here the native formation estimate admits both parameters by two separate charges. First use the enlarged constant in the exponential volume bound for stored values and in the site activity, allowing one more unit of the per-cell stored-value bound at each direct read. The history tail estimate is taken at this enlarged constant, so it is uniform in ν. Then split the sequence sum in each healed component. At $|\mu| \le q^{-(j-e)}$ the two pieces together cost at most twice the unsplit component majorant. This factor is paid in the product over components. At a component formed at step j, the native geometric factor is at most $e^{2\kappa(100\check{R}_j)^4}$. For the native growth number $\beta_0^{\mathrm{pr}} \le 1/7$, the component history bound is at most $e^{1-7p_0(g_j)/4}$ before the split. Thus the doubled bound leaves $e^{-3p_0(g_j)/2}$ by the native coupling ceiling, which implies

$$-p_0(g_j)/4 + 2 + 2\kappa(100\check{R}_j)^4 \le 0.$$

The next formation sum costs a factor $e^{p_0(g_j)/2}$ and retains the original $e^{-p_0(g_j)}$ coefficient per component. This proves the budget on one age disc and one leaf-level disc in the same receiving cluster, with the other interpolations at their endpoints. It uses the admitted per-use formation and the history tail bound at the larger volume and activity allowances.

After the level groups have been turned off, the remaining uses require a healed history of age at least $a = (j-n-1)_+$, except for direct top-level uses when $a = 0$. The single age split at a gives $2\mathfrak{B}_\varphi q^a$ by the same zero-face argument, or by the trivial difference bound at $a = 0$. Summing the levels gives the factor $2 + 4C_*\varepsilon_{\mathrm{tot}}^{\mathrm{all}}$ in front of $\mathfrak{B}_\varphi q^a$. Here $\varepsilon_{\mathrm{tot}}^{\mathrm{all}}$ bounds the sum of the level piles uniformly. Thus $C_* = 4/(1 - 4\varepsilon_{\mathrm{tot}}^{\mathrm{all}})$ closes the induction when the total pile is at most $1/16$.

4.22.2.4. The carry with a uniform bound at each level. There is a second way to close the age estimate. Suppose the actual leaf families have level piles $\varepsilon_e^{\mathrm{all}} \le B$ on the enlarged formation and history domains. Put $A = 1 + 4B$. Choose $0 < q_0 \le q$ with $2Bq_0 \le 1/3$, and set $q' = q_0/A$. Use the history weight increased by $\log(q/q')$. A history of age at least s has volume at least s, so the weighted mass bound gives the share $(q')^s$. The weight is fixed before the coupling ceiling. We must have the formation bounds and the same level-pile bound B at this weight.

With $a = (j-n-1)_+$ use the inductive bound $D_a \mathfrak{B}_\varphi(q')^a$, $D_a = 2A^a$. At a nested leaf of age $b = e-n-1 \geq 1$, the inverse leaf radius is $\varepsilon_e^{\mathrm{all}} D_b(q')^b$, at most $2Bq_0^b \leq 1/3$. The same two-parameter estimate bounds its level group by $4\varepsilon_e^{\mathrm{all}} D_b \mathfrak{B}_\varphi(q')^a$. The direct contribution is at most $2\mathfrak{B}_\varphi(q')^a$. The geometric sum gives

$$2 + 4B \sum_{b=1}^{a-1} D_b \leq D_a$$

with the sum empty for $a \leq 1$. This closes the induction, since $D_a(q')^a = 2q_0^a \leq 2q^a$.

For a term of the second group, its domain is disjoint from the surviving large-field regions and the enlargements that would make the domain first-group. A class use with a surviving geometric witness would put its anchor in one of those regions. A copied occurrence with a surviving witness would put its anchor in the surviving region or its prescribed enlargement, which is excluded for a second-group domain. Thus every class use of a second-group term belongs to its own set, and the carried bound controls the full change of that class. At a native zero-index cluster containing a live strip Y_h and no healed constituent, the only own uses are the direct top uses at formation. There is then no age loss in bounding their change by twice the strip majorant. Uses copied from a surviving witness are still assigned to that witness level. This special case gives a leaf difference bound and still requires the strip count for summation.

4.22.2.5. Reading the transported uses at the later component. Let X be a component of Z_k on which the operation acts, and put $G = \mathbf{T}'_k(X)F$ for a fixed bounded insertion F. In each history summand of G, the filling property takes an older anchor in $X^\sim \cap Z_{n+1}$ into X. A surviving geometric witness at that anchor therefore requires the summand's Z_{n+1} to meet X. An earlier owned use of witness level $e < k$ instead has an anchor of its owner in $Z_{e+1} \cap X^\sim$. The same filling property puts that anchor in X, and its live witnessing component lies in the same surviving component as the anchor. The history containing the occurrence must contain its witness already at e. Hence a use of witness level e requires age at least $k-e$ in the summand. Direct inner top uses and constants attached to a zone satisfy the direct bound $b = (k-n-1)_+$ by the index of the region at which they occur.

To turn off class $z = (n, k')$, first telescope over the own sets of live leaves of levels $n+2 \leq e < k$. These sets are disjoint as sets of uses, and the surviving witness assignment is made in each summand's own history. For a fixed level use the disc of radius R_e above. Its change is supported on histories of age at least $k-e$. The absolute tail majorant for this subfamily, with the extra stored-value unit included, is $\mathrm{e}\,\mathfrak{E}_k q^{k-e} \sup|F|$, where $\mathfrak{E}_k = \exp[-2p_0(g_k)/(1+\beta_0^{\mathrm{pr}})]$. It applies even though different summands use different points of the product of discs, since the tail bound sums the individual majorants. Schwarz's estimate in the single leaf parameter gives $2\mathrm{e}\,\mathfrak{E}_k q^{k-e} \sup|F|/R_e$. The powers $q^{k-e}q^{e-n-1}$ combine to q^{k-n-1}.

The remaining direct uses, geometric uses, and own sets of carriers or leaves at levels at most $n+1$ require age at least b. Their difference costs at most twice the age-b tail bound. Adding the telescope therefore bounds the change of class z by

$$2\mathrm{e}\,\mathfrak{E}_k q^b \sup|F|\,(1 + C_* \varepsilon_{\mathrm{tot}}^{\mathrm{all}}).$$

For the uniform level bound, repeat the telescope with q' and the age-dependent leaf radii. Writing $a = (k-n-1)_+$, it gives

$$2\mathrm{e}\,\mathfrak{E}_k (q')^a \sup|F| \left(1 + B \sum_{d=1}^{a-1} D_d\right) \leq 2\mathrm{e}\,\mathfrak{E}_k q^a \sup|F|,$$

because $1 + B\sum_{d=1}^{a-1} D_d \leq A^a$. On the diagonal of the product of discs this is the difference from setting the class parameter to zero. Apply the one-variable disc estimate in each class in succession. At zone n there are $k-n+1$ classes (n, k'), each with the inverse disc radius given by the zone

load divided by the fixed load allowance. Thus the change between the endpoints is controlled by the load sum with weights $(k-n+1)q^{(k-n-1)_+}$.

4.22.3. *A common reserve for many zone uses.* One-zone bounds do not by themselves give a common polydisc for an arbitrarily large number of zone uses. The reserve also needs a capacity bound. The following precise version distinguishes the two issues.

Proposition 4.82 (A capacity criterion for joint parameters)**.** Let $\mathcal{Z}$ be a finite set of zone-use indices and let i label finitely many directions at each index. Their nonnegative loads are $p_{z,i}$. Use the measurable stored spaces and fixed reference measures of the preceding proposition, and assume that all phase coefficients are measurable in the stored variables. Fix nonnegative measurable history charges $W_{\omega,z}$, a finite family of nonnegative measurable action pieces $S_{\omega,b}$, and nonnegative coefficients $a_{\omega,z,b}$, with

$$\sum_{z\in\mathcal{Z}} W_{\omega,z} \le W_\omega,$$

$$\sum_{z\in\mathcal{Z}} a_{\omega,z,b} \le 1$$

for every b.

Suppose the affine perturbation is

$$\Phi_\omega(\vec{\lambda}) - \Phi_\omega(0) = \sum_{z,i} \lambda_{z,i} L_{\omega,z,i},$$

$$|L_{\omega,z,i}| \le p_{z,i}\left(CW_{\omega,z} + \sum_b a_{\omega,z,b} S_{\omega,b}\right).$$

Assume a majorant at zero obeys, on a fixed event E,

$$\sum_\omega \int_E M_\omega \exp\left(cW_\omega + \sigma \sum_b S_{\omega,b}\right) d\mu_\omega \le B_E,$$

$$\sup_p e^{\operatorname{Re}\Phi_\omega(0,\xi;p)} \le M_\omega,$$

where $c,\sigma>0$. Choose $0<r<\min\{c/(2C),\sigma/2\}$. Then the integral over E is jointly holomorphic and bounded by B_E on the product of weighted balls

$$\mathcal{D}_r = \left\{\vec{\lambda} : \sum_i |\lambda_{z,i}| p_{z,i} < r \text{ for every } z\right\}.$$

All statements use fixed reference measures, fixed events and fixed evaluation maps; if additional parameter dependence is present, the integrands must instead be given holomorphically on this domain with the same phase bound. ∎

Proof. For $\vec{\lambda}\in\mathcal{D}_r$, the triangle inequality and the two capacity inequalities give

$$|\Phi_\omega(\vec{\lambda}) - \Phi_\omega(0)| \le Cr\sum_z W_{\omega,z} + r\sum_b \left(\sum_z a_{\omega,z,b}\right) S_{\omega,b} \le (c/2)W_\omega + (\sigma/2)\sum_b S_{\omega,b}.$$

Thus a single integrable majorant works on the entire parameter domain, independently of $|\mathcal{Z}|$ and the number of directions. Dominated integration proves separate holomorphy and local boundedness, and the finite-dimensional Hartogs theorem gives joint holomorphy. Equivalently, one can apply Morera's theorem successively on each compact polydisc. □

If a designated parameter affects only an event E_a whose majorant has $B_{E_a} \le B\varepsilon q^a$, setting that parameter to zero changes the whole integral by at most $2B\varepsilon q^a$, uniformly in the other parameters on $\mathcal{D}_r$. At their common zero, Cauchy's formula gives the first derivative bound $B\varepsilon q^a p_{z,i}/r$. To see this without subtracting a large unaffected part, differentiate only the integral on E_a; outside E_a the integrand is independent of the designated parameter. For m distinct directions at the same index, Cauchy's formula on circles with radii tending to $r/(mp_{z,i})$ gives

$$\left|\partial_{\lambda_{z,1}} \cdots \partial_{\lambda_{z,m}} I_E(0)\right| \le B_E (m/r)^m \prod_{i=1}^{m} p_{z,i}.$$

Here zero loads mean that the corresponding affine perturbations vanish, and those derivatives are zero. Higher mixed bounds require an appropriate majorant for the history event on which all marked uses occur; they do not acquire a product of rarity factors from holomorphy alone.

The capacity assumptions have content. Without them, let a single history have $W = 1$ and let each of N indices contribute $L_z = p_z = 1$. Every separate perturbation is bounded by $|\lambda_z|W$, but choosing all $\lambda_z = r/2$ gives a total exponent change $Nr/2$. A fixed reserve in W cannot pay this uniformly in N. A proof for the actual formation must therefore assign all simultaneous uses to a common site and action budget, in addition to bounding each separate direction.

4.22.4. *A channel which can be bounded directly.* For $U \in \mathrm{SL}(2,\mathbb{C})$, the determinant identity

$$\det(U - I) = \det U - \operatorname{tr} U + 1 = 2 - \operatorname{tr} U$$

gives $a(U) = \frac{1}{2}\det(U - I)$. With the operator matrix norm,

$$|a(U)| \le \tfrac{1}{2}\|U - I\|^2. \tag{4.dxcvii}$$

For real $U \in \mathrm{SU}(2)$ this is an equality, since the two singular values of $U - I$ coincide.

Consider a regular zone expressed in its own units, with bare mesh η_n, containing N_n unit cells. Suppose the configurations used in the actual substitutions satisfy $\|U_p - I\| \le \alpha_n \eta_n^2$ on that zone. There are at most $C\eta_n^{-4}$ plaquettes per unit cell. Hence

$$|A(\delta c, U)| \le C\alpha_n^2 \|\delta c\|_\infty N_n. \tag{4.dxcviii}$$

Consequently, if the zone load includes $p_n \ge \alpha_n^2 \|\delta c\|_\infty$, this direct Wilson-weight contribution to eq. 4.dxcv is bounded by Cp_nN_n. If the reserve volume dominates the number of such stored cells, it satisfies eq. 4.dxcvi.

The usual scale $\alpha_n^2 \asymp \theta_n^{-1}(\log \theta_n)^{2q}$ has precisely the form of the coefficient multiplying a marginal amplitude in the load. This calculation uses only the stated curvature regularity at the actual formed arguments. It does not prove that every substitution has that regularity; that is a separate inclusion requirement.

4.22.5. *An unrestricted bare zone needs action reserve.* There is a genuine limitation to a reserve measured only by stored sites. On a bare region where the real field is unrestricted, a plaquette can have $U_p = -I$, and then $a_p = 2$. A direction which changes a local Wilson weight by one has an exponent variation of order one at such a configuration. If its proposed load is

$$p_0 = \beta^{-1}(\log \beta)^C$$

and the site reserve is of order $W = N \log \beta$ on a fixed finite region, then

$$\frac{|\delta\Phi|}{p_0 W} \geq c \, \frac{\beta}{(\log \beta)^{C+1}}$$

for an appropriate fixed configuration and fixed N. This diverges as $\beta \to \infty$. Such configurations are obtained, for example, by setting one bond to $-I$ and the other bonds of a small patch to I. The number of altered plaquettes remains bounded. Thus eq. 4.dxcvi with this site reserve cannot hold pointwise on the entire unrestricted bare-field domain.

This does not refute the complex mass estimate. The Wilson factor strongly suppresses those configurations. For a bare insertion $\mathfrak{b}$ satisfying a pointwise action bound

$$|\mathfrak{b}| \leq C_b \|k\|_\infty A_{\text{available}}(U),$$

one instead has

$$|\lambda \mathfrak{b}| \leq \frac{C_b |\lambda| \|k\|_\infty}{\beta} S_{\text{available}}(U),$$

$$S_{\text{available}} = \beta A_{\text{available}}.$$

At a radius $|\lambda| p_0 < c$, with $p_0 \geq C_b \beta^{-1} (\log \beta)^C \|k\|_\infty$, this spends at most $c(\log \beta)^{-C}$ of the available Wilson action. It is a fractional action estimate, not a site-volume estimate.

A correct reserve lemma can include both budgets. If the majorant has the stronger reserve $e^{cV + \sigma S_{\text{available}}}$ and

$$|\Phi(\lambda) - \Phi(0)| \leq C|\lambda| p_n V + \eta(\lambda) S_{\text{available}},$$

$$C|\lambda| p_n \leq c/2,$$

$$|\eta(\lambda)| \leq \sigma/2,$$

the mass proof above applies on the intersection of these parameter domains. A derivative estimate proportional to p_n requires this intersection to contain a disc of radius c'/p_n with a fixed $c' > 0$. One sufficient condition is $|\eta(\lambda)| \leq C_{\text{act}} |\lambda| p_n$; otherwise the Cauchy radius is the smaller action-controlled radius. To use this statement one must identify action genuinely left available after the failed-test payments, gauge fixing, and other insertions. It cannot be spent twice. For several active zone-use parameters, their fractions must have a bounded sum on each shared action piece. The existence of a site-volume reserve alone proves neither of these action-allocation facts.

4.22.6. *What the carrier bounds do not control.* Write a standing exponent as

$$\Phi_\omega(\xi; p) = \Phi^0_\omega(\xi) + \sum_f \phi_{\omega,f}(\xi; p|_{R_f}).$$

The carrier condition bounds the oscillation of each factor in its external pair argument. Choose a permitted anchor $p^0_\omega(\xi)$ and split

$$\phi_{\omega,f}(\xi; p) = \phi_{\omega,f}(\xi; p^0_\omega) + \{\phi_{\omega,f}(\xi; p) - \phi_{\omega,f}(\xi; p^0_\omega)\}.$$

Oscillation controls the braced expression. It controls neither the scalar anchor value nor the dependence of either expression on an input-list parameter. Cauchy's estimate in the pair variables is not Cauchy's estimate in that new input parameter.

A simple exact example separates these statements. Let $\pi_a \downarrow 0$ be a sequence of putative loads, let one stored history have volume $W_a \geq a$, and let its formed exponent be

$$\Phi_a(x;p) = \log \varepsilon - (c+s+1)W_a + xW_a,$$
$$s > 0.$$

It is entire, independent of p, and its carrier oscillation is zero. At $x = 0$ it has the prepaid mass bound $e^{\Phi_a(0)+cW_a} \leq \varepsilon e^{-sa}$. The same bound, with room, holds throughout a fixed ordinary disc $|x| \leq 1/2$. It fails on a disc $|x|\pi_a < c'$: at $x = c'/(2\pi_a)$ the positive exponent eventually overwhelms every fixed reserve coefficient.

This is a counterexample to deriving the enlarged-radius estimate from carrier oscillation and an ordinary reserve alone. It is not a counterexample to the Wilson operation. Even if the incoming direction has size π_a, the example can be produced by an abstract local formation map which multiplies that direction by π_a^{-1}. All input sizes are then small, while the output exponent has the displayed variation. Locality and holomorphy do not exclude this map; a uniform norm bound on formation must exclude it. Exact preservation of a represented integral, by itself, also supplies no such bound on a particular decomposition into exponents and vacuum factors.

4.22.7. *A sufficient structural bound on the actual formation map.* The needed additional statement is precise. For the actual index set and formed arguments in eq. 4.dxcv, prove

$$|L_{\omega,n,k'}[\delta](\xi,p)| \leq C p_n(\delta) V_\omega(\xi) \quad \text{for every admissible } (\xi,p), \tag{4.dxcix}$$

with a separate fractional-action term when the bare zone is unrestricted. The norm must include scalar anchors, not only oscillations. The constant must be independent of the age, the level, and the history. If a parameter changes the arguments as well, prove the corresponding derivative bound throughout its proposed disc and integrate it to obtain eq. 4.dxcvi.

One verifiable route to eq. 4.dxcix is a carrier incidence estimate. Let the charged stored cells be a finite set $\mathcal{C}_\omega(\xi)$ with $|\mathcal{C}_\omega(\xi)| \leq V_\omega(\xi)$, and decompose the scalar part as $\delta c_\omega = \sum_{c\in\mathcal{C}_\omega} \delta c_{\omega,c}$. Assign each formed occurrence to these cells and give nonnegative weights $w_{e,c}$ with $\sum_c w_{e,c} = 1$. Suppose the actual evaluations stay in their original domains and

$$\sum_e |\epsilon_e| w_{e,c} \, \|\delta F_e\|_{\text{evaluation}} + |\delta c_{\omega,c}| \leq C p_n(\delta)$$

at every stored cell c. Summing over the cells proves eq. 4.dxcix. The evaluation norm here is the norm after the specified unit change and counter-insertions. Using a norm at an earlier level without those transformations can lose exactly the scale weights under investigation.

A condition on the sum of sizes of the original direction terms in a unit cell is helpful, but it is not yet this incidence statement. The proof must show that substitutions and repeated occurrences preserve that bound. The formation rules distinguish copies still anchored in a live component, copies whose last anchor is removed now, and copies inside older already formed terms. The first kind is not a small new remainder. The last kind must be summed with its own norm and history mass. Counting its occurrence does not permit its bound to be reused without payment. In particular a factor obtained only after summation of histories is not a pointwise bound on the unsummed exponent.

For the deletion of a class born at level n, use the weighted mass on the class disc with survival ratio q_*. Suppose a term formed at level e is read in a component that remains live until level $j > e$. Its own deletion bound has age factor q_*^{e-n-1} when $e \geq n+2$. The later mass is restricted to histories that carry this anchor from e to j, giving the factor q_*^{j-e}. At healing the anchor is removed and the two factors combine to q_*^{j-n-1}. Keep the size of the older term in this product. A term carried by a component left standing at its production costs a fixed amount per level. The

genuine small remainders also carry the small factors of their producing levels, which sum along the flow.

More precisely, let A_j be the constant after extracting $q_*^{(j-n-1)_+}$ at level j. The per-level sum over the older reads, including the size ϵ_e of their terms, gives

$$A_j \le C + C \sum_{e=n+2}^{j-1} \epsilon_e A_e.$$

Here $\epsilon_e \le \epsilon + \sigma_e$, with the fixed bound ϵ for the standing-component terms and with $\sum_e \sigma_e \le C'$ for the genuine remainders. Iterating the positive inequality bounds A_j by a constant times $\prod_{e=n+2}^{j-1}(1 + C\epsilon_e)$, which is at most a constant times $(1 + C\epsilon)^{(j-n-2)_+}$. Taking $q_* = q_a/(1 + C\epsilon)$ in the weighted mass, by adding $\log(1+C\epsilon)$ to the reserved exponent per age level, recovers $q_a^{(j-n-1)_+}$ with a fixed constant. This calculation uses the mass of the actual histories on the disc. A small new remainder has its domain away from the surviving region. Since a copied term's domain is contained in the domain that carries it, such a remainder contains no copy with an anchor still live there.

For the fresh ordinary crossing terms there is a direct incidence bound at fixed history and stored fields. Assign each complete marked cluster to one visited step cube in the strip $\Omega_t \setminus \Lambda_t$, when its crossing carrier has such a free cube. Retain this assignment while summing the complete clusters. The rooted domain count, with the spare decay in the marked crossing estimate, bounds the sum at a fixed free cube by a constant times the crossing factor and the supremum of its local input loads. For a cluster assigned to an exempt hull H, the corresponding rooted sum costs at most $C\#H$. If the whole hull is charged, distribute this bound over its $\#H$ cells. An exempt hull whose cells are not all charged needs the actual refiling estimate. This argument counts one fresh crossing occurrence once. An old member carried by restriction retains its carrier bound, and repeated reads in later substitutions still require their own incidence count.

If "size in a unit cell" is defined to mean the sum of the evaluated sizes of all formed occurrences, including their scalar parts and the indicated unit changes, then the incidence estimate is already part of that definition. Under that stronger interpretation the reserve implication is proved. The substantive remaining task is to show that directions generated by the actual renormalization step meet that definition with the proposed load. A condition on the unformed entries cannot be silently replaced by this stronger condition.

4.22.8. *Passing the bound through a logarithmic sum.* Suppose that a finite polymer system has activities $z_X(\lambda)$ with a common Kotecký–Preiss majorant r_X, and that the corresponding pinned bound is e^{a_X}. Choose the logarithm defined by the connected expansion, equal to zero at the zero activity vector. Then a useful marked estimate is

$$|\log Z(z(\lambda)) - \log Z(z(0))| \le \sum_X e^{a_X} |z_X(\lambda) - z_X(0)|,$$

To prove it, join the two activity vectors by their straight segment. Every point on that segment has modulus at most r_X coordinatewise. The absolutely convergent connected expansion gives $|\partial_{z_X} \log Z| \le e^{a_X}$ by the pinned bound. Differentiate along the segment and integrate. Thus a summable one-zone age bound on the changed activities passes to the logarithm. No logarithm of an individual possibly zero history integral is required.

For a countably infinite system, apply the same estimate first to finite restrictions of the same activity and incompatibility system. If $\sum_X e^{a_X} |z_X(\lambda) - z_X(0)| < \infty$, the integrated pinned series defines a relative cluster logarithm and satisfies this bound, independently of the finite exhaustion by dominated convergence of the rooted expansions. Writing two separate infinite-volume logarithms requires convergence of both unmarked global series; a common local majorant alone does not

ensure that. This deduction has two inputs: the activity majorant must remain valid on the complex parameter disc, and the changed activities must satisfy the marked bound after the actual formation and copy bookkeeping. A convergence theorem for polymers does not prove those inputs. The exponential reserve can pay a controlled perturbation of an integrand; it cannot manufacture control of the perturbation map.

A recursive treatment of old copied terms can be sufficient instead of a single global phase estimate. Fix $0 < q_0 < q < 1$ and $C > 0$. For example, suppose an already justified local operation estimate gives nonnegative bounds, for $j \geq n+1$,

$$A_{j,n} \leq C q_0^{j-n} + C \sum_{n<e<j} \epsilon_e q_0^{j-e} A_{e,n},$$
$$0 \leq \epsilon_e \leq \epsilon.$$

Divide by q_0^{j-n}. A discrete Gronwall induction gives

$$A_{j,n} \leq C q_0^{j-n} \prod_{n<e<j} (1 + C\epsilon_e) \leq C\{q_0(1+C\epsilon)\}^{j-n}.$$

The induction follows by expanding the product, or using $\prod_{e<j}(1+C\epsilon_e) = 1+\sum_{e<j} C\epsilon_e \prod_{r<e}(1+C\epsilon_r)$. Thus choosing $q_0 \leq q/(1+C\epsilon)$ preserves the desired rate q. No small sum of the ϵ_e is needed. This pays growth of output bounds after local integration. It does not pay an exponentially amplified perturbation inside an unsummed exponent. To apply this alternative one must establish the local parameterized operation bound at each new loss of an anchor and the stated copying recurrence. The sufficient formation test above is not claimed to be the only possible proof route.

The present test therefore proves the reserve implication and the direct regular-zone Wilson channel. It shows why an unrestricted bare channel requires available action, and isolates the additional uniform formation estimate for the remaining entries. The specified carrier oscillation, ordinary presentation bounds, and end-mark definitions do not alone establish that estimate. A proof of it for the actual local substitutions, with their scalar parts and copy incidence, would complete the proposed one-zone argument.

4.23. **Coordinates for quadratic extraction.** The quadratic coefficient of an effective interaction is defined in the physical block field. The field used to normalize a fluctuation Gaussian is a different coordinate. Keeping these coordinates distinct explains both the fixed radii of the unmarked chain and the squared radius ratios in the marked chain. The required inclusion near the trivial field follows from the background and tower estimates already used to define the analytic field domains. It is not an additional loss caused by the number of blocking steps.

All constants below may depend on the fixed blocking and localization parameters. They are independent of the level, torus size and number of earlier levels. The non-Abelian background and tower estimates are explicit hypotheses in the statements that use them.

4.23.1. *Physical fields, Gaussian fields and the coefficient.* At level j, write the configuration in the trivial-field chart as

$$\mathbf{U} = e^{i\eta_j A'},$$
$$v = (A', J),$$
$$\|v\|_{1,j} = \max\{\|A'\|_\infty, \|\nabla_j A'\|_\infty, \|J\|_\infty\}. \tag{4.dc}$$

Here $0 < \eta_j \le 1$ is the bare spacing in level-j units and ∇_j is a difference quotient in those units. The current J is an independent analytic variable. In particular, A' in this chart is a physical potential; no coupling multiplies it by definition.

The block datum of the background is $V = e^{iB}$. Let $p_j(B)$ be its configuration-current pair in a fixed gauge near zero. Derivatives of its configuration entry are taken in the chart in eq. 4.dc. Suppose

$$p_j(0) = (\mathbf{1}, 0), \qquad Dp_j(0)B = \mathfrak{h}_j B = (H_j B, D^* D H_j B). \tag{4.dci}$$

The datum B is again physical. Its continuation radius r_{B} is a radius in e^{iB}, chosen independently of the coupling. For a gauge-invariant local interaction E, the first derivative at the trivial pair vanishes: invariance under constant gauge transformations makes it an invariant linear functional on the semisimple Lie algebra, and that functional is zero. Consequently

$$D^2(E \circ p_j)(0)[B_1, B_2] = \operatorname{Hess} E(0)[\mathfrak{h}_j B_1, \mathfrak{h}_j B_2]. \tag{4.dcii}$$

The possible second derivative of p_j contributes nothing because it is multiplied by $DE(0)$.

The polarisation kernel is the kernel of eq. 4.dcii. Its second spatial moments define the curvature tensor $T[E]$, and, in the invariant scalar channel, the action coefficient $b(E)$. These definitions use derivatives with respect to B. For the Wilson functional of the block datum itself, use the normalization

$$b(A_{\mathrm{block}}) = 1, \tag{4.dciii}$$

whose quadratic part is $\frac{1}{2}\|\mathrm{d}B\|^2$. For a Wilson family evaluated after the background map, the analogous normalization requires the linear-response identities in that map. Likewise $T[\mathsf{A}[c]] = c$ for a constant allowed curvature tensor c is the prescribed counter-insertion normalization. Neither identity for pulled-back families is proved merely by the coordinate change below.

In a fluctuation integral one instead sets $\mathcal{A}_j = g_j \mathcal{A}_j^{\mathrm{s}}$. If $\widetilde{E}_j(B^{\mathrm{s}}) = E(p_j(g_j B^{\mathrm{s}}))$, the chain rule gives

$$\begin{aligned} D^2 \widetilde{E}_j(0) &= g_j^2 D^2(E \circ p_j)(0), \\ T_{\mathrm{s}}[E] &= g_j^2 T[E], \\ b_{\mathrm{s}}(E) &= g_j^2 b(E). \end{aligned} \tag{4.dciv}$$

Thus a fixed probe in the Gaussian variable may fit inside a shrinking physical domain. It extracts the rescaled coefficient in eq. 4.dciv. Recovering the coefficient of the physical action requires division by g_j^2.

For example, impose the response-decay and localization hypotheses of the amplitude proposition below, and suppose that the usable physical radius is a_j and the family norm is at most M_j there. Its radius in B^{s} is comparable to a_j/g_j. The Cauchy radius factor in the amplitude bound then transforms as

$$|g_j^2 b(E)| \le C M_j (g_j/a_j)^2, \qquad |b(E)| \le C M_j a_j^{-2}. \tag{4.dcv}$$

The coupling cancels from the coordinate conversion. The same calculation holds if the physical radius is written g_j^{γ}: the canonical radius is $g_j^{\gamma-1}$, and the physical coefficient bound remains $C M_j g_j^{-2\gamma}$. The change of variables creates no extra loss and removes no loss already present in the physical radius.

4.23.2. *A near-zero ball lies in the hereditary core.* We state precisely the background information needed for this local inclusion. A core at radii (a_0, a_1) is described by the following simple conditions and their tower counterparts. A triple is (U, A', J), with U real and $\mathbf{U} = e^{i\eta_j A'}U$. The real and complex curvatures are smaller than $a_0\eta_j^2$; the real factor has the prescribed local regular gauges; $|A'|, |\nabla_U A'| < a_1$; and $|J| < a_0$. The tower counterparts require the corresponding curvature and current bounds for every allowed restricted tower inside the domain.

By Cor. 3.130, if the simple conditions hold at sufficiently small radii (ϵ_0, ϵ_1), the tower configurations exist holomorphically. Their curvature and current, in the local units of their layer, satisfy the defining tower bounds with radius

$$K_{\mathrm{T}}(\epsilon_0 + \epsilon_1^2). \tag{4.dcvi}$$

The estimate includes the stated change-of-unit factors and holds for both tower rules, every restricted domain and every depth. Its common analytic ball and physical-current bound are proved in Lem. 3.127 and Prop. 3.129.

Proposition 4.83 (Near-zero core inclusion)**.** For sufficiently small a_0, a_1 there is a constant $c > 0$, independent of j, such that

$$\|v\|_{1,j} < r_j,$$
$$r_j = c\min\{a_0, a_1, 1\}$$
$$\Longrightarrow$$
$$(\mathbf{1}, A', J) \text{ belongs to the core at } (a_0, a_1). \tag{4.dcvii}$$

■

Proof. The plaquette product in the exponential chart obeys

$$|\partial e^{i\eta_j A'} - \mathbf{1}| \le C\eta_j^2(\|\nabla_j A'\|_\infty + \|A'\|_\infty^2) \le C\eta_j^2(r_j + r_j^2). \tag{4.dcviii}$$

This follows by expanding a plaquette product: the linear term is the discrete curl and each nonlinear term contains at least two bond potentials. On a fixed small chart the remaining exponential series is bounded by a uniform multiple of the quadratic term. In particular, there is no inverse power of η_j in eq. 4.dcviii. This is the reason for including the first difference quotient in eq. 4.dc.

Choose

$$\epsilon_0 = \frac{a_0}{4K_{\mathrm{T}}},$$
$$\epsilon_1 = \min\{a_1/2, \sqrt{a_0/(4K_{\mathrm{T}})}\}.$$

Taking c smaller if necessary ensures $C(r_j + r_j^2) < \epsilon_0$ and $r_j < \min\{\epsilon_0, \epsilon_1\}$. The real configuration is $\mathbf{1}$, so its curvature and local gauge potential vanish. All simple conditions therefore hold at these reduced radii. Moreover, $K_{\mathrm{T}}(\epsilon_0 + \epsilon_1^2) \le a_0/2$. The tower estimate gives every hereditary clause at the desired radii, and $|J| < r_j < a_0$. This proves eq. 4.dcvii. □

A bound only on $\|A'\|_\infty$ would be different: arbitrary oscillation on the bare lattice can give $\|\nabla_j A'\|_\infty$ of order $\eta_j^{-1}\|A'\|_\infty$. The ball relevant to eq. 4.dcvii is the C^1 ball, not that weaker ball.

For completeness, suppose the continued background in eq. 4.dci is holomorphic for $\|B\|_\infty < r_{\mathrm{B}}$ and satisfies

$$\|\mathcal{H}_j(B)\|_{C^1} + \|J(e^{i\eta_j \mathcal{H}_j(B)})\|_\infty \le C_{\mathrm{B}}\|B\|_\infty. \tag{4.dcix}$$

Then its triple belongs to the core whenever

$$\|B\|_\infty < \min\{r_{\mathrm{B}}/2, r_j/(2C_{\mathrm{B}})\}. \tag{4.dcx}$$

The same conclusion for a first-order response uses the derivative of eq. 4.dcix. eq. 4.dcvii–eq. 4.dcx give a fixed datum radius when (a_0, a_1) are fixed, and a radius comparable to $\min\{a_0, a_1\}$ when they run. The hypotheses are exactly the background continuation, its uniform first-order bounds and the hereditary tower estimate. No analyticity radius in the normalized Gaussian variable is substituted for this physical datum radius.

4.23.3. *Cauchy's estimate, response decay and entropy.* Work first with the infinite-lattice companion. Its torus versions use the uniform response bounds and the lift convergence supplied by the background hypotheses. Consider pointed local families satisfying

$$|E(X, p, z)| \le Me^{-\kappa d(X)}$$

on the core, and assume that the near-zero ball there has usable radius a. Assume also the uniform response decay

$$\|\mathfrak{h}_j \delta_c\|_{1,j;X} \le Ce^{-\delta \operatorname{dist}(c,X)}. \tag{4.dcxi}$$

The distances in this section are measured in the unit of level j. For a fixed root cube, suppose the number of domains with tree length between m and $m+1$ is at most $Ce^{\kappa_{\mathrm{D}} m}$, while the number of pointed sites in such a domain is at most $C(m+1)^4$. These are the usual localization entropy and volume bounds.

Proposition 4.84 (The amplitude bound with its radius)**.** If $\kappa > \kappa_{\mathrm{D}}$ with a fixed positive margin, the polarisation sums converge absolutely and

$$\begin{aligned} |\Pi_{\mu\nu}(u)| &\le Ca^{-2}Me^{-\delta_1|u|}, \\ |b(E)| + \|T[E]\| &\le Ca^{-2}M, \end{aligned} \tag{4.dcxii}$$

whenever the scalar coefficient or the stated summed tensor is defined by the prescribed covariance conditions. The constants are uniform in the level and torus volume. A tensor at a fixed base point satisfies the same bound before any isotropy assertion is made. ∎

Proof. The two-variable Cauchy formula on a bidisc inside the ball gives

$$|\operatorname{Hess} E(X, z)[v, w]| \le Ca^{-2}Me^{-\kappa d(X)}\|v\|_{1,j;X}\|w\|_{1,j;X}.$$

Combining this with eq. 4.dcxi bounds the contribution of one term by

$$Ca^{-2}Me^{-\kappa d(X)}e^{-\delta(\operatorname{dist}(c,X)+\operatorname{dist}(c',X))}. \tag{4.dcxiii}$$

If the localization cubes have fixed side M_0, then

$$|c_- - c'_-| \le \operatorname{dist}(c, X) + \operatorname{dist}(c', X) + CM_0(d(X) + 1).$$

A sufficiently small fixed fraction of the exponents in eq. 4.dcxiii supplies $e^{-\delta_1|c_- - c'_-|}$ for a fixed $\delta_1 > 0$. Choose that fraction so that the remaining localization rate stays strictly above κ_{D}. The remainder is summable. Indeed, root a domain at a cube closest to c. Summing its pointed sites costs at most a polynomial in $m+1$, and summing its shapes costs $e^{\kappa_{\mathrm{D}} m}$. These costs are absorbed by the remaining $e^{-\kappa_{\mathrm{rem}} m}$, where $\kappa_{\mathrm{rem}} > \kappa_{\mathrm{D}}$. Summing the root location is bounded by

the remaining exponential in its distance from c. This proves the first inequality in eq. 4.dcxii and absolute convergence.

The second moment defining $b(E)$ is bounded by $Ca^{-2}M\sum_u |u|^2 e^{-\delta_1|u|}$, a finite constant times $a^{-2}M$. For a tensor at a fixed base point, the two moment factors are bounded by polynomials in the domain diameter and the two response distances. Those polynomials are absorbed by a further fixed fraction of the same exponentials. This proves the tensor bound. Identifying an invariant tensor with the scalar action coefficient uses the separate Ward and lattice-symmetry identities; it is not needed for the amplitude estimate. □

In particular, the extraction norm is uniform on fixed physical radii. On the running radii

$$a_j \asymp \theta_j^{-1/2}(\log\theta_j)^q,$$
$$q \geq 0,$$

the correct general bound has the factor $a_j^{-2} \asymp \theta_j(\log\theta_j)^{-2q}$. One can express uniformity instead as $a_j^2|b(E)| \leq C\|E\|$, provided that this normalization is retained in all later estimates.

4.23.4. *What the squared radius ratios pay for.* Let a remainder born at level j have size r_j on physical radius a_j and have its vacuum value removed. There is no linear term. Assume a gauge-invariant window estimate in which the quadratic curvature factors each scale by $L^{-2(n-j)}$, while a unit volume at level n contains $L^{4(n-j)}$ sites of level j. After these geometric factors cancel, evaluating the quadratic part on a background of radius a_n costs

$$w_{n,j}r_j,$$
$$w_{n,j} = (a_n/a_j)^2. \tag{4.dcxiv}$$

This is the relative quadratic evaluation weight. Extracting the physical coefficient from the resulting family at level n costs a_n^{-2}, so

$$a_n^{-2}w_{n,j}r_j = a_j^{-2}r_j. \tag{4.dcxv}$$

Charging another factor a_j^{-2} on top of the left side would count the same shrinking input radius twice. Omitting the displayed readout factor a_n^{-2} would instead confuse an evaluated potential with its physical quadratic coefficient. The full nonlinear remainder estimate also requires its actual backgrounds to lie in the original analytic domains and the separate control of large domains. eq. 4.dcxiv records the radius factor in that estimate; it provides no continuation outside those domains.

For example, let $r_j \leq C\theta_j^{-\kappa_0/2}$, $\kappa_0 > 4$, and suppose $\theta_j \geq \theta_n + \lambda(n-j) - C_0$ with $\lambda > 0$ and a sufficiently large common lower bound on θ_n. Integral comparison gives

$$\begin{aligned}\sum_{j\leq n} w_{n,j}r_j &\leq Ca_n^2\sum_{j\leq n}\theta_j^{1-\kappa_0/2}(\log\theta_j)^{-2q} \leq C\theta_n^{1-\kappa_0/2},\\ a_n^{-2}\sum_{j\leq n} w_{n,j}r_j &\leq C\theta_n^{2-\kappa_0/2}(\log\theta_n)^{-2q}.\end{aligned} \tag{4.dcxvi}$$

The first loss of one power of θ comes from summing the older levels; the second comes from quadratic extraction. This is the usual g^{κ_0-4} bound, with its logarithmic improvement. The two losses are already present in eq. 4.dcxvi.

The unmarked chain uses fixed physical radii, so eq. 4.dcxii preserves its small interaction bound. The marked chain uses running radii, and its stronger smallness pays the readout loss in eq. 4.dcxvi. These facts establish the radius bookkeeping under the stated background, response and entropy hypotheses. They do not establish every later power-counting assertion. Cancellation in a complex window, removal of every required tensor marginal, weighted sensitivity to earlier members, and differentiated bounds for a large-field zone remain their own estimates. Neither the physical-to-Gaussian coordinate change nor the local core inclusion supplies those conclusions.

5. Couplings, sources and continuum limits

The coupling recursion selects the physical scale and the tuned sequence. Uniform source estimates then bound connected correlations at separated supports. We track their dependence on the number of insertions before taking subsequences, and extend the limiting functionals to Schwartz tests flat on the coincidence diagonals. This gives the quantitative test-space estimates needed for §7.

5.1. **First passage for a marginal flow.** We derive the numerical consequences of a coupling recursion. Its realization by a renormalization step, consistency between tori and cutoffs, and estimates with nonconstant sources remain analytic hypotheses. An individual increment of the recursion is allowed to be negative.

5.1.1. *Hypotheses and first passage.* Fix numbers $c_0 > 0$, $C_0 \geq 0$, $h > 0$, and $0 \leq \epsilon < c_0/4$. For each initial value $\beta \geq h + B$ consider a real run with $x_0 = \beta$. Assume that a next step exists whenever $x_j > h$, and that every such step has the form

$$x_j = x_{j-1} - b_j,$$
$$b_j = b_j^0 + r_j.$$

For every interval of defined steps assume

$$\left| \sum_{l=i+1}^{j} (b_l^0 - c_0) \right| \leq C_0,$$
$$|r_j| \leq \epsilon$$
$$\text{if } x_{j-1} \geq h.$$

All constants are independent of β and of the length of the run. The existence of the next step is an assumption: an inequality about hypothetical increments cannot establish that an underlying analytic construction is defined. Set

$$\lambda = c_0 - \epsilon > 0,$$
$$\Lambda = c_0 + \epsilon,$$
$$B \geq c_0 + C_0 + \epsilon.$$

The one-step case of the interval estimate gives $b_j \leq B$. This is an upper bound, not an assertion $b_j \geq 0$.

Define

$$K(\beta) = \min\{k \geq 0 : x_k \leq h + B\},$$

$$\mathcal{W}_k = \{\beta \geq h + B : K(\beta) = k\}.$$

The minimum is initially a possible stopping index; its finiteness will be proved. At the endpoint $\beta = h + B$ it equals zero. When $\beta > h + B$ it is positive, so the last increment is an actual step of the run.

Proposition 5.1 (Block drift and a protected terminal window)**.** The first-passage time is finite. For defined segments up to that time,

$$\lambda(j - i) - C_0 \leq x_i - x_j \leq \Lambda(j - i) + C_0$$
$$(0 \leq i \leq j \leq K).$$

If $K > 0$, then $h < x_K \leq h + B$. Moreover

$$\max\left\{0, \frac{\beta - h - B - C_0}{\Lambda}\right\} \leq K \leq \frac{\beta - h + C_0}{\lambda}. \qquad \blacksquare$$

Proof. Summing the recursion over a segment gives

$$x_i - x_j = c_0(j - i) + \sum_{l=i+1}^{j} (b_l^0 - c_0) + \sum_{l=i+1}^{j} r_l.$$

The two assumed bounds give the block drift estimate. If the run never reached $h + B$, all its values would remain above h, so it could be extended for every finite number of steps. The lower drift bound would then imply $x_j \leq \beta - \lambda j + C_0$, contradicting $x_j > h + B$ for sufficiently large j. Thus first passage occurs.

For $K > 0$, minimality gives $x_{K-1} > h + B$. Since $b_K \leq B$, $x_K = x_{K-1} - b_K > h$. The upper endpoint follows from the definition of K. The extra width B is exactly what prevents the final step from overshooting the lower reference value h.

Finally $\beta - x_K \leq \Lambda K + C_0$ and $x_K \leq h + B$ give the lower bound on K. Conversely $\lambda K - C_0 \leq \beta - x_K < \beta - h$ gives the stated upper bound for $K > 0$. The endpoint case $K = 0$ also satisfies both inequalities. □

In particular $\beta \to \infty$ forces $K(\beta) \to \infty$. Conversely a sequence with $K \to \infty$ has $\beta \to \infty$, by the lower drift estimate and the terminal lower bound. Since these stopping times are integers, the sets $\mathcal{W}_k$ are nonempty for infinitely many different k. Nothing here says that every one is nonempty, that one is an interval, or that the terminal values in it coincide. Such assertions would require additional information about the dependence of the analytic recursion on β.

For example, $b_j^0 = c_0 + (-1)^j q$, with $q > c_0$ and $r_j = 0$, satisfies the interval hypothesis with $C_0 = q$. Every other increment is negative. Nevertheless the block drift is positive and the preceding proof applies. Replacing block drift by a silently assumed monotonicity would discard this perfectly admissible numerical example.

5.1.2. *Vanishing mean error and the leading logarithm.* Assume in addition that

$$|r_j| \leq \omega(x_{j-1}),$$
$$\omega_*(M) := \sup_{x \geq M} \omega(x) \longrightarrow 0$$
$$(M \to \infty),$$

where ω is nonnegative on $[h, \infty)$. The earlier global bound by ϵ remains in force. No monotonicity of ω is needed.

Lemma 5.2 (Time spent below a fixed inverse coupling)**.** For $M \geq h$, the number N_M of steps $1 \leq j \leq K$ with $x_{j-1} \leq M$ is bounded by

$$N_M \leq 1 + \frac{M - h + C_0}{\lambda}.$$

This bound does not depend on the initial value. ■

Proof. There is nothing to prove if no such step occurs. Otherwise let i be the smallest index in $\{0, \dots, K-1\}$ with $x_i \leq M$. Every counted step has its preceding index between i and $K-1$, so $N_M \leq K - i$. The block drift from i to K gives $\lambda(K-i) - C_0 \leq x_i - x_K < M - h$. The displayed, slightly weaker bound therefore follows. Excursions back above M cause no problem: all subsequent indices are included in this bound on the entire remaining time. □

Proposition 5.3 (Leading first-passage asymptotics)**.** With h and the other constants fixed,

$$\frac{1}{K(\beta)} \sum_{j=1}^{K(\beta)} |r_j| \longrightarrow 0,$$

$$\frac{\beta}{K(\beta)} \longrightarrow c_0$$

$$(\beta \to \infty).$$

If $a_K = L^{-K}$ for a fixed $L > 1$, then $\beta / \log(a_K^{-1}) \to c_0 / \log L$. ■

Proof. Split the steps according to whether $x_{j-1} \leq M$. The lemma gives

$$\frac{1}{K} \sum_{j=1}^{K} |r_j| \leq \frac{\epsilon}{K} \left(1 + \frac{M - h + C_0}{\lambda}\right) + \omega_*(M).$$

First let $\beta \to \infty$ at fixed M, using $K \to \infty$, and then let $M \to \infty$. This proves the first limit. Summing the whole recursion gives

$$\beta = x_K + c_0 K + e_K + \sum_{j=1}^{K} r_j,$$

$$|e_K| \leq C_0.$$

The terminal value belongs to a fixed bounded interval, so division by K proves the second limit. Finally $\log(a_K^{-1}) = K \log L$ exactly. □

If the analytic one-loop calculation establishes $c_0 = 11N^2 \log L / (12\pi^2)$ in the convention $\beta = g_0^{-2}$, this arithmetic yields $\beta / \log(a_K^{-1}) \to 11N^2/(12\pi^2)$. The one-loop coefficient is an input to this implication, not a consequence of the stopping argument. The result is uniform over any family of runs satisfying the same constants and error envelope.

5.1.3. *A quantitative optional error bound.* Suppose $h \geq e$, $p \geq 0$, and $\omega(x) \leq C x^{-1/2} (\log x)^p$. Then

$$|\beta - c_0 K| \leq h + B + C_0 + C' \sqrt{\beta + C_0 + 2}\, [\log(\beta + C_0 + 2)]^p.$$

To prove it, partition $[h, \infty)$ into unit intervals. If two preceding indices $i < j < K$ have values in the same interval, then $x_i - x_j < 1$ and the lower drift gives $j - i < (1 + C_0)/\lambda$. A unit interval

is therefore visited at most $J = 2 + \lceil (1 + C_0)/\lambda \rceil$ times. Also $x_i \le \beta + C_0$ by the lower drift from zero. Summing the supremum of the error envelope in each visited interval consequently gives

$$\sum_{j=1}^{K} |r_j| \le CJ[\log(\beta + C_0 + 2)]^p \sum_{n=0}^{\lceil \beta + C_0 - h \rceil} (h+n)^{-1/2}.$$

The last sum is at most a constant times $\sqrt{\beta + C_0 + 2}$, by comparison with the integral of $x^{-1/2}$. Substitute this bound in the summed recursion. For fixed h this is an $O(\sqrt{\beta}(\log \beta)^p)$ error. It supplies no second logarithmic coefficient, convergence rate for observables, or summable comparison between neighboring cutoffs.

5.1.4. *Depth envelopes and sums over scales.* The same block estimate gives useful bounds measured from the terminal scale. For $0 \le s \le K$, apply it between $K - s$ and K to obtain

$$h + \lambda s - C_0 < x_{K-s} \le h + B + \Lambda s + C_0.$$

This estimate records the possible bounded backward excursions without requiring the inverse couplings to be monotone. It also distinguishes the fixed reference value h from the terminal value x_K, which is allowed to range over its window.

For an explicit scale-summation corollary suppose $h \ge \max\{1, 2C_0\}$. Then the lower bound becomes $x_{K-s} \ge h/2 + \lambda s$. Write $g_j = x_j^{-1/2}$. For every $q > 2$, comparison with a decreasing integral gives

$$\sum_{j=0}^{K} g_j^q \le \sum_{s=0}^{\infty} (h/2 + \lambda s)^{-q/2} \le (h/2)^{-q/2} + \frac{(h/2)^{1-q/2}}{\lambda(q/2 - 1)} \le C(q, \lambda) h^{1-q/2}.$$

The bound is uniform in the number of steps. The first term of the sum is bounded separately, and the integral accounts for all later terms; this explains both the strict condition $q > 2$ and the displayed dependence on the reference inverse coupling.

At the marginal exponent $q = 2$ the integral instead grows logarithmically. Using the two depth envelopes gives, for example,

$$\frac{1}{\Lambda} \log\left(1 + \frac{\Lambda(K+1)}{h + B + C_0}\right) \le \sum_{j=0}^{K} g_j^2 \le \frac{2}{h} + \frac{1}{\lambda} \log\left(1 + \frac{2\lambda K}{h}\right).$$

For the lower bound integrate the decreasing function $(h + B + C_0 + \Lambda s)^{-1}$ from zero to $K + 1$. For the upper bound separate its counterpart's first term and integrate from zero to K. These elementary estimates are often the numerical part of a renormalization argument: sufficiently high powers of the running coupling are summable, whereas the marginal power is not. They cannot replace the analytic cancellation or renormalization that produces those powers in a particular model.

The extra lower bound on h belongs only to this corollary. For a smaller fixed h, separate the finitely many terminal depths $s < 2C_0/\lambda$, bound them using $x_j > h$, and apply the same integral comparison to the remaining depths. The resulting constants may depend on h and C_0.

5.1.5. *An exact change of lattice units.* There is also an identity that requires no coupling-flow assumption. Let $\Lambda_{K,\ell} = (L^{-K}\mathbb{Z}/\ell\mathbb{Z})^4$ be a compatible finite lattice and let b be an integer with $K - b \ge 0$. Dilation $D_b x = L^b x$ maps it bijectively to $\Lambda_{K-b, L^b \ell}$. Transfer a bond variable by $U'_{D_b e} = U_e$. The map bijects positively oriented bonds and plaquettes, preserves their incidence,

and satisfies $U'_{D_b p} = U_p$. Product normalized Haar measure is therefore unchanged, as is the Wilson action $A(U) = \sum_p [1 - \frac{1}{2} \operatorname{Re} \operatorname{tr} U_p]$.

For a test function on T_ℓ, put $f^{[b]}(x') = f(L^{-b}x')$ on $T_{L^b\ell}$. Plaquette barycenters obey $x(D_b p) = D_b x(p)$, so

$$\mathcal{O}_{K-b,L^b\ell}(f^{[b]})(U') = \sum_p f(L^{-b} D_b x(p)) a_p(U) = \mathcal{O}_{K,\ell}(f)(U).$$

No spacing prefactor appears in this observable. Consequently the two Wilson partition functions at the same β are equal, and all joint moments and cumulants satisfy the exact identity

$$S^T_{n;K,\ell,\beta}(f_1, \dots, f_n) = S^T_{n;K-b,L^b\ell,\beta}(f_1^{[b]}, \dots, f_n^{[b]}).$$

This is one finite-dimensional integral written in two units, including the same number of sites in each direction. It is not a comparison between different bare measures.

For $\|f\|_\sharp = \max(\|f\|_\infty, c_M \operatorname{Lip} f)$ the exact norm transformations are

$$\|f^{[b]}\|_\infty = \|f\|_\infty,$$
$$\operatorname{Lip} f^{[b]} = L^{-b} \operatorname{Lip} f.$$

Thus $\|f^{[b]}\|_\sharp \le \|f\|_\sharp$ for $b \ge 0$, and it is at most $L^{|b|}\|f\|_\sharp$ for $b < 0$. All support distances and support radii are multiplied by L^b. The same bond bijection carries a fixed-spacing DLR specification to its dilated specification, since it carries each finite integration set and all plaquettes meeting that set to their counterparts. It therefore also transports infinite-lattice Gibbs states and their local moment identities.

To identify this unit change with two initial portions of a renormalization run requires more: the blocking rules, gauges, auxiliary choices and extraction of increments must commute with the bond bijection. Likewise, torus-independent increments require a separately defined common local construction. Neither property follows from the scalar recursion or the exact dilation identity proved here.

5.2. **The running coupling and first-passage arithmetic.**

5.2.1. *The run, its coefficient, and the analytic requirements.* The numerical running coupling and the auxiliary frame have different roles. This distinction is needed even for a real bare coupling. A frame fixes the tests, cubes, Gaussian references, coordinate choices and large-field operations. The weight of the Wilson action is another entry of the construction. A derivative with the frame fixed differentiates that weight; it does not differentiate a characteristic function whose threshold is moving. We first state the actual analytic requirements on these objects. The arithmetic consequences below are conditional theorems under those requirements.

Fix odd $L > 1$, the block parameter M, and the remaining geometric constants. In the ordinary-source application use its actual $M = L^{m_0}$, fixed collar layers and compatible cofinal tori; admissibility below refers to those assigned lattices. The group is SU(2); in the coefficient formulas we retain $N = 2$. The pointed families, hereditary complex potential/current cores, midpoint tents, companions and Euclidean list norms are those of § 2.2. In particular a pointed family of level j has terms $E(X, P, z)$, where X is a connected localization domain and z is a unit lattice site in X. Its norm is a supremum in z, not a sum in z. The inequality

$$|E(X, P, z)| \le \mathcal{A} e^{-\kappa d_j(X)} \tag{5.i}$$

is required on its declared core. Summing domains requires the separate rooted-domain entropy estimate. A companion agrees on every common nonwrapping lift, with the required collar, for all

admissible tori with the same frame prefix and initial weight. Local analyticity does not establish that compatibility. We write $E^{(j)}$ for a torus family and $\widehat{E}^{(j)}$ for its common infinite-lattice companion. The coefficient of the run is extracted from the latter. A regular list member $G^{(j)}$ has a companion $\widehat{G}^{(j)}$; neither is the additional one-step Gaussian family G_τ. The family created at step $k+1$ has pointed level $k+1$, although its creation choices are those of level k.

Write $P_\circ = (\mathbf{1}, 0)$, and let $\mathfrak{h}_\infty$ be the infinite-volume first response of the background potential/current pair at $P_\circ$. Its existence, gauge covariance, affine reproduction modulo gauge and exponential decay belong to the background hypotheses. For the composed physical Hessian, average over an orthonormal color basis t_a, $1 \le a \le 3$, and set

$$\begin{aligned} \Pi(x,y) &= \frac{1}{3}\sum_{a=1}^{3}\sum_{z}\sum_{X \ni z} D^2E(X, P_\circ, z)[\mathfrak{h}_\infty \delta_x^a, \mathfrak{h}_\infty \delta_y^a], \\ b(E) &= \sum_{u \in \mathbb{Z}^4} \Pi_{\mu\nu}(u) u_\mu u_\nu, \qquad \mu \neq \nu. \end{aligned} \tag{5.ii}$$

The second line is used only after translation covariance and independence of the choice $\mu \neq \nu$ have been justified. Hessians are in the pair exponential chart, not in an unspecified coordinate system. Their directions have norm $\max\{\|A\|_\infty, \|\nabla A\|_\infty, \|J\|_\infty\}$. For $a' = \min\{a_1, c, a_0/C\}$, a ball of radius ca' in this norm must lie in the core. A ball controlled by $\|A\|_\infty$ alone does not supply the uniform mesh normalization.

The coefficient and pointed-cancellation theorem in § 4.2 applies under its full response, summability and symmetry hypotheses. Its consequences used here are absolute convergence, vanishing zeroth and first moments, and

$$\begin{aligned} \sum_u \Pi_{\mu\nu}(u) u_\rho u_\sigma &= b(E)(\delta_{\mu\rho}\delta_{\nu\sigma} + \delta_{\mu\sigma}\delta_{\nu\rho} - 2\delta_{\mu\nu}\delta_{\rho\sigma}), \\ |\Pi(x,y)| &\le C(a')^{-2}\mathcal{A} e^{-c|y_- - x_-|}, \qquad |b(E)| \le C(a')^{-2}\mathcal{A}. \end{aligned} \tag{5.iii}$$

The extraction is linear, holomorphic in admitted parameters and real on real families. It depends on the total, so two coherent localizations of the same physical functional have the same coefficient. A constant total has coefficient zero. At absolute radii the factor $(a')^{-2}$ is a constant depending on M; at running radii it can cost $Cx_j(\log x_j)^{-2q}$. Neither the kernel nor its coefficient depends on which admitted radii were used to estimate it.

Pointed tensors and their period averages. There is a useful distinction between the Hessian of the total and that of a pointed total. Write $K_{\hat z}(x,y)$ for the contribution of the base point $\hat z$ to $\Pi(x,y)$, including the color average and the sum of domains in eq. 5.ii. Assume here the actual pointed Ward identities and absolute moments through order two, uniformly over one period, and covariance under simultaneous translations by $M\mathbb{Z}^4$. These are pointed response hypotheses; the bulk estimate in eq. 5.iii alone does not imply them. Set $\mathcal{C}_M = \{0, \dots, M-1\}^4$ and

$$\begin{aligned} T_{\mu\nu,\rho\sigma}(\hat z) &= \sum_{\substack{x \text{ of direction } \mu \\ y \text{ of direction } \nu}} (x_- - \hat z)_\rho (y_- - \hat z)_\sigma K_{\hat z}(x,y), \\ \overline{T} &= M^{-4}\sum_{\hat z \in \mathcal{C}_M} T(\hat z). \end{aligned} \tag{5.iv}$$

If only the total is invariant under all unit lattice isometries, the conclusion is

$$\overline{T}_{\mu\nu,\rho\sigma} = b(E)(\delta_{\mu\nu}\delta_{\rho\sigma} - \delta_{\mu\sigma}\delta_{\nu\rho}) + c_{\mathrm{top}}\epsilon_{\mu\rho\nu\sigma}. \tag{5.v}$$

In particular an invariant total does not determine $T(\hat z)$ at an individual base point.

Here is the algebra behind this assertion. At the trivial field the first derivative of each scalar pointed total vanishes by constant color invariance. The twice differentiated gauge identity therefore makes its Hessian vanish when either argument is a gradient. One may insert linear and quadratic

gauge polynomials by cutoff and the assumed absolute moments. Linear polynomials give zero row and column sums in each bond direction. A quadratic polynomial $(x-\hat{z})_\mu(x-\hat{z})_\rho$ gives antisymmetry of T under $\mu \leftrightarrow \rho$; the column identity gives antisymmetry under $\nu \leftrightarrow \sigma$. For a repeated index the extra constant from the discrete derivative vanishes by the linear identity. These same zero sums show that replacing lower bond endpoints by midpoints does not change T.

To identify its symmetric part, sum the bulk second moment over one period cell and reindex the M-translates of $\hat{z}$. Absolute moments justify every interchange. For each fixed relative bond position there is exactly one such translate with its lower endpoint in $\mathcal{C}_M$. Translation invariance of the bulk kernel consequently gives

$$\sum_u \Pi_{\mu\nu}(u)u_\rho u_\sigma = -\overline{T}_{\mu\nu,\rho\sigma} - \overline{T}_{\mu\nu,\sigma\rho}. \tag{5.vi}$$

Indeed the $x_\rho x_\sigma$ and $y_\rho y_\sigma$ terms in $(x-y)_\rho(x-y)_\sigma$ vanish by the row and column zero sums; the two cross terms give the right-hand side. Subtract the Maxwell tensor in eq. 5.v, using eq. 5.iii. The residual is antisymmetric under the three transpositions $\mu \leftrightarrow \rho$, $\nu \leftrightarrow \sigma$, and $\rho \leftrightarrow \sigma$. These generate all permutations of four positions, so it is a fully alternating tensor. In four dimensions it is a multiple of $\epsilon_{\mu\rho\nu\sigma}$, proving eq. 5.v.

If the pointed totals themselves are scalar covariant under every unit translation and reflection, $T(\hat{z})$ is independent of $\hat{z}$, and one reflection kills its alternating coefficient. This is the pointed-symmetry case used by the local cancellation theorem. With only period covariance, a local subtraction instead requires its actual period/window argument; it cannot be inferred from the invariant total. The layered estimate below retains these pointed hypotheses.

The pointed Wilson family assigns the action to the same tents as the regular member. Its norm is Ca_0^2, so subtracting its own extracted coefficient preserves a constant multiple of the family norm. This is the subtraction used below. The stronger statement that the remaining translation-invariant quadratic kernel is divisible by three lattice derivatives, with exponentially decaying quotient kernels on a fixed polyannulus, is a separate analytic target when that representation is used. The moment identity alone is not presented as a proof of such division.

Frame, weight, tube and box. The functions used for the auxiliary choices are

$$\begin{aligned} \varepsilon(y) &= A_0 y^{-1/2}(\log y)^{\mathfrak{p}_0}, & \delta(y) &= A_1 y^{-1/2}(\log y)^{\mathfrak{p}_0}, \\ \delta'(y) &= A_1 y^{-1/2}(\log y)^{\mathfrak{p}_1}, & \alpha_\iota(y) &= C_\iota y^{-1/2}(\log y)^{q}, \\ R(y) &= \min\{L^b : L^b \geq (\log y)^r\}, & q &> \mathfrak{p}_0 + 2r, \quad \mathfrak{p}_1 < \mathfrak{p}_0. \end{aligned} \tag{5.vii}$$

The fluctuation scaling is $y^{-1/2}$. The frame also fixes the gauge-fixing weights, the scalings in the large-field stages and their main step, the stage Wilson constants, the Gaussian forms, and both the coefficient and cutoff in the reference laws. Every occurrence of a coupling is assigned either to such a choice or to the action weight, never to both. Cube sizes and waiting depths use the running minimum of the frame.

For a real positive-weight run and a terminal reference $g > 0$, put $h = g^{-2}$. The three real scales are

$$\mathfrak{g}_j = \theta_j^{-1/2}, \qquad g_j = x_j^{-1/2}, \qquad g = h^{-1/2}. \tag{5.viii}$$

The first scales a fluctuation in the fixed-frame step; the second is the actual running coupling on a real positive-weight run; the third is the terminal reference coupling. In a self-calibrated run $\theta_j = x_j$, the first two coincide. On an admitted narrow real tube they are uniformly comparable. Bounds for the creation domains, cutoffs and remainders use the frame scale; numerical sums along the actual flow use g_j.

A finite reference sequence $\theta_0, \dots, \theta_n$ is real, above its floor, and obeys

$$\lambda_\flat(j-i) - c_5 \leq \theta_i - \theta_j \leq \bar{B}(j-i), \qquad \check{R}_j = R(\min_{i\leq j}\theta_i), \quad \check{R}_j \leq L\check{R}_{j+1}. \tag{5.ix}$$

The lower slope $\lambda_\flat$ is the same slope used in the background and history estimates; in the weak triple it is $c_0/4$. The frame is a real reference sequence, not an independently varied list of complex action weights. In the run along this sequence,

$$x_0^\theta = \beta, \qquad x_{j+1}^\theta = x_j^\theta - b_{j+1}^\theta, \qquad z_j = \theta_j - x_j^\theta, \qquad \tau_j = x_j^\theta/\theta_j. \tag{5.x}$$

The frame and weights are separate lists. Put $\mathsf{t}^\sharp(y) = \varpi y(\log y)^{-2q_\mathrm{t}}$. A tube has positive, nonincreasing radii t_j, with $\mathsf{t}_j \le \mathsf{t}^\sharp(\theta_{j+1})$ for $j < n$. For a one-member sequence require $\mathsf{t}_0 \le 2\mathsf{t}^\sharp(\theta_0)$. The constants ϖ, q_t are fixed before the coupling ceiling, with $2\varpi \le \min\{\varpi_0, \sigma_\star\}$ and $q_\mathrm{t} \ge q_0$. The pair is alive through k if its coefficients through k are defined and $|z_j| < \mathsf{t}_j$. It has room r' when $|z_j| + r' \le \mathsf{t}_j$ at every required level.

The box of level k is the full inductive array: weights, regular families with companions and coefficients, remainders, boundary terms and standing large-field operations. It includes the bounds $|E^{(j)}| \le E_0 e^{-\kappa d_j}$, $|R^{(j)}| \le \theta_j^{-\kappa_0/2} e^{-\kappa d_j}$, the covariance and positivity clauses, identification with the two chains below, and the drift bounds. Its reserve constant c_m, also denoted c_r, enters the large-field mass bound; increasing it shrinks the box and does not change the step. An admissible torus must satisfy

$$\tfrac{1}{2}\ell L^{K-i} \ge C(L) M \check{R}_i \qquad (i \le k). \tag{5.xi}$$

All box statements are simultaneous statements on these tori and on their common companions. The positivity of a label measure $\tau_\mathcal{S} = \sum_{\mathcal{S}(h)=\mathcal{S}} \tau_h$ must not be confused with the numerical ratio τ_j.

The history part of each output box has a stronger requirement than small real masses. For the next operation write $i = k+1$, and let X be a component in either of the two classes with a pair-core representation at that level. Use its actual local histories ω, positive reference integration laws μ_ω, Borel supports S_ω, and exponents Φ_ω. All level normalizations remain in these assigned laws. For a nonnegative integrand f, the upper integral is

$$\int^* f\, d\mu = \inf\left\{ \int F\, d\mu : F \text{ is Borel and } F \ge f \right\}. \tag{5.xii}$$

It is used because the core supremum need not have been proved Borel. The required complex mass clause is

$$\frac{1}{|W_4|} \sum_\omega e^{c_\mathrm{m} v^\natural(\omega)} \int_{S_\omega}^* \sup_{\mathbf{p} \in U_i^c(X^\sim)} |e^{\Phi_\omega(\xi;\mathbf{p})}|\, \mu_\omega(d\xi) \le e^{-a_\star p_0(\mathfrak{g}_i)}. \tag{5.xiii}$$

Here W_4 is the finite hypercubic symmetry group, $v^\natural$ is the assigned history volume, $U_i^c(X^\sim)$ is the declared complex pair core, and p_0 is the fixed positive large-field logarithmic penalty. The history measure and integration coordinates are fixed before taking the parameter supremum. This is an integral of a supremum over the core; a pointwise real bound or a small pointwise polymer logarithm does not prove it.

The actual split is $\Phi_\omega = \Phi_\omega^\circ - \frac{1}{2}q_X + V_X$. At real weights Φ_ω° is real, Borel and independent of the pair. The reference quadratic form q_X may depend on the real factor of the triple presenting the pair. Only the combination $-\frac{1}{2}q_X + V_X$ is a function of that pair. A proof must retain this tie. An extra perturbation is absorbed by the reserve only after its actual support estimate $|\Psi_\omega| \le \bar{f}\, n^\sharp(\omega)$ and $c_\mathrm{m}\mathsf{l}_j \ge 2\bar{f}$ have been verified at every relevant level; $n^\sharp$ is the assigned site count and l_j its volume-comparison weight.

Drop-outs have a separate requirement, with their assigned supports Ξ_ω and compatible evaluation fibers $\mathfrak{K}^\sharp(\omega,\xi)$:

$$\frac{1}{|W_4|} \sum_\omega e^{c_\mathrm{m} v^\natural(\omega)} \int_{\Xi_\omega}^* \sup_{\mathfrak{e} \in \mathfrak{K}^\sharp(\omega,\xi)} |\mathsf{E}_\omega(\xi;\mathfrak{e})|\, \mu_\omega(d\xi) \le e^{-a_\star p_0(\mathfrak{g}_i)}. \tag{5.xiv}$$

The majorant E_ω is the one assigned to that evaluation, not a new product-core extension. When its own $1-\chi$ test is counted, the required gain is instead $e^{-2p_0(\mathfrak{g}_i)}$, with its root counted as an

additional event. A later label must read an evaluation in this same fiber at every point of its support. For a later occurrence of a second-class component, its stored variables must lie in S_ω and its later real pair in $U_i^c(X^\sim)$. Those read-out statements are additional geometric requirements. Complex quadratic forms in a drop-out evaluation are admitted only with the specified positive lower bound on their real part.

Complex variation of Gaussian ratios and stage constants additionally requires the actual inner Wilson factor to retain its assigned weight. Discarding that factor, changing its weight without a new comparison, or bounding the two tied summands separately does not establish eq. 5.xiii. The distinction is also relevant to the gauge convention at seams. If inward seam bonds are retained, an absolute contour gauge is invariant only under the corresponding seam-tied site gauges. A relative contour gauge uses its declared boundary reference. An omission convention that removes every bond with an endpoint in the next region can eliminate these seams, but its exact operation and compensators must then be checked. These are history-formation requirements, separate from the scalar flow arithmetic.

The sourced construction also fixes what a read-out means. At a formed level $j = K - u$, set

$$\begin{aligned} \mathsf{D}^{w}_{[u]}(Y) &= \sum_{z\in Y} E^{(j),w}(Y, P_\circ, z) + R^{(j),w}(Y, P_\circ), \\ e_{[u]}(Y; w) &= \mathsf{D}^{w}_{[u]}(Y) - \mathsf{D}^{0}_{[u]}(Y). \end{aligned} \tag{5.xv}$$

The zero-source run in this difference starts from the same real center and frame. The terminal read-out is the actual number $\mathsf{I}_k(w)$ at $k = K - s_\circ$, where $s_\circ$ is the stop depth, and the exact normalized terminal factor is $\widetilde{Z}^\circ(w) = \mathsf{I}_k(w)/\mathsf{I}_k(0)$. The common vacuum convention counts the removed Gaussian numbers once. Neither these read-out identities nor the terminal ratio supplies the complex local-energy or history majorants.

The Gaussian and one-loop requirements; statement 3.3. Let $\Phi_l = \log Z^{(l-1)} - \log Z^{(l-1)}(\mathbf{1})$. The localized Gaussian family is required to satisfy

$$\Phi_l(V) = \sum_X \sum_{z\in X} N^{(l)}(X, P_V, z), \qquad |N^{(l)}| \le E_{\mathsf{N}} e^{-\delta_{\mathsf{N}} M d_l(X)}, \qquad b(N^{(l)}) = b_l^0. \tag{5.xvi}$$

The constants depend only on L. No coupling occurs in these terms. Nonwrapping terms agree on all common lifts, and their pointed totals are covariant under every unit lattice isometry.

For precision, the localization meant here is the following actual one. Set $k = l - 1$, let $A_Y = C^{(k)}(Y)^{-1}$ be the supplied fluctuation form constructed inside Y and compressed to free bonds at depth cM, and define

$$\begin{aligned} f_b(Y) &= \operatorname{tr}(\log A_Y)(b, b), \\ E_{\mathsf{N}}(X; b) &= \sum_{\substack{Y\subset X \\ b \text{ at depth } cM \text{ in } Y}} (-1)^{|X|-|Y|} f_b(Y). \end{aligned} \tag{5.xvii}$$

The free-bond contribution to $N^{(l)}$ is $-[E_{\mathsf{N}}(X; P, b) - E_{\mathsf{N}}(X; P_\circ, b)]/2$, smeared by the midpoint tents. The pivot contribution is the logarithm of its actual elimination factor minus its value at $P_\circ$, smeared by the same tents. The required spectral gap and complex continuation of A_Y, the locality of its walk expansion and the c/M radius ceiling are part of this Gaussian-localization input. Finite Gaussian integration estimates alone do not prove them.

The distinction between an on-shell pair and a critical pair matters. On shell, the explicit current form expresses gauge covariance. Identifying it with the Hessian on a constrained fibre also requires the multiplier equation and actual criticality. The four tempered localization properties used in the one-loop analysis are its sum formula, common lifts, exponential domain decay on the shrinking supremum polydisc of radius $c\eta_l^2$, and invariance under constant gauge transformations. Uniform Hessian Cauchy estimates instead use the pair-direction norm preceding eq. 5.iii. For the canonical proper fluctuation precision, § 5.13 supplies the physical identification, uniform complex spectral

gap and complete local inverse and logarithm families used in eq. 5.xvii. The operator is explicitly eq. 5.cclxxviii: its inner correction uses the first lift, while its outer constraint curvature uses the second lift. The two readouts agree at a physical critical pair. Its relative contour quadratic form agrees with the absolute contour Hessian in the averaged-contour axial representative. An independent signed or counterterm-modified matrix requires its own comparison; zero-fold averaging alone would not justify one.

Input B3 requires, with the fixed momentum convention $(2\pi)^{-4}dq$,

$$\begin{aligned} c_0 &= \frac{11N^2}{12\pi^2}\log L, \qquad \left|\sum_{l=1}^{k} b_l^0 - kc_0\right| \le c_2, \\ |b_{l+1}^0 - b_l^0| &\le C_\alpha L^{-\alpha l} \quad (0<\alpha<1). \end{aligned} \tag{5.xviii}$$

Thus $b_l^0 \to c_0$. The standard convention is $\beta = 2N/g_{\mathrm{std}}^2$, giving the coefficient $11N/(24\pi^2)$ for g_{std}^{-2} per factor L. The numerical value in eq. 5.xviii requires the actual lattice trace calculation. It is not deduced by quoting a continuum perturbative coefficient.

The one-loop calculation has three steps: compose the actual Gaussian integrals, compare their averaging constraints with a positive mass, and evaluate the massive lattice coefficient. The proofs below concern the constructed homogeneous physical background. The complex-current localization requirements in eq. 5.xvii remain separate.

A tempered functional is real analytic near the trivial field on arbitrarily large tori, gauge and lattice-isometry invariant, normalized at that field, and has a plane-wave Hessian per unit volume converging uniformly in momentum to a bounded holomorphic symbol on a fixed strip. For such functionals the background substitution is required to preserve the coefficient. If $\widehat{\pi}^F$ is the limiting bond Hessian symbol with lower-endpoint Fourier convention, its midpoint form obeys

$$\begin{aligned} e^{i(p_\mu - p_\nu)/2}\widehat{\pi}^F_{\mu\nu}(p) &= b[F](|p|^2\delta_{\mu\nu} - p_\mu p_\nu) + O(|p|^4), \\ \widehat{\pi}^{F\circ p_k}(p) &= L^2\widehat{\pi}^F(p/L) + O(|p|^3). \end{aligned} \tag{5.xix}$$

The second formula uses the actual background response and uniform analytic control of its aliased modes. Its factor $L^2 = L^{-1}L^{-1}L^4$ records two form scalings and the volume ratio. The first formula follows from the moment identity and midpoint lattice symmetries.

For the actual Gaussian densities, coefficient preservation is proved in §5.6. The first jet of each invariant density vanishes, so its pullback Hessian uses only the first background response. That response reproduces an affine field modulo a gradient; the two-leg Ward identity removes the gradient, and the physical density normalization supplies the scale cancellation above. The successive maps use the actual nested criticality identity; see eq. 5.clxxvii.

The constrained Gaussian logarithms satisfy $\Psi_k = \Phi_k + \Psi_{k-1}\circ p_k$ by Cor. 5.7. This identity uses the complete constrained Hessian, including the curvature of the nonlinear constraint, before integrating in stages. Coefficient preservation then gives $\sum_{l\le k} b_l^0 = b[\Psi_k]$. The finite Schur representation uses

$$\mathbb{S}(X,Q) = \begin{pmatrix} X & Q^{\mathsf{T}} \\ Q & 0 \end{pmatrix}. \tag{5.xx}$$

Here Q is the covariant form average, R is the covariant site average, D is the covariant gradient, $\Delta = D^{\mathsf{T}}D$ is the site Laplacian, Δ^{W} is the Wilson-action Hessian on forms, and $\mathcal{K} = \Delta^{\mathrm{W}} + DD^{\mathsf{T}}$, $\Xi = \mathcal{K} - DR^{\mathsf{T}}RD^{\mathsf{T}} + Q^{\mathsf{T}}Q$. On the admitted real critical backgrounds with nondegenerate physical Gaussians, Prop. 5.6 gives the representation

$$\begin{aligned} \Psi_k = &-\tfrac{1}{2}\log|\det\mathbb{S}(\Xi - Q^{\mathsf{T}}Q + \mathrm{j}[J,\mu], Q)| \\ &+ \log|\det\mathbb{S}(\Delta, R)| - (\text{the same expression at } \mathbf{1}). \end{aligned} \tag{5.xxi}$$

Here $U = U_k(V)$ is the actual critical background, $J = \nabla_{\mathrm{fine}}A(U) = J_{\eta_k}(U)$, and $\mu = \nabla_{\mathrm{block}}(A\circ U_k)(V)$. The convention is the bilinear color pairing $\langle B, C\rangle = \frac{1}{2}\mathrm{tr}(BC)$; fine-bond inner products

have weight η_k^4, and block-bond inner products have unit weight. Explicitly,

$$\begin{aligned}\frac{d}{dt}A(e^{i\eta_k tB}U)\Big|_0 &= \eta_k^4\sum_b\langle J(b),B(b)\rangle,\\ \frac{d}{dt}(A\circ U_k)(e^{itC}V)\Big|_0 &= \sum_c\langle\mu(c),C(c)\rangle.\end{aligned}\tag{5.xxii}$$

All gradients and adjoints in eq. 5.xxi use those fixed conventions. The form $\mathfrak{j}[J,\mu]$ is fixed by second variation of the actual constrained background problem. To identify it, let $q(a)$ be the recentered logarithmic form of the straightened constraint at U, with $q(0)=0$ and $Dq(0)=Q$. The constrained Hessian on $\ker Q$ is

$$A''(U)-\langle\mu,D^2q(0)\rangle;$$

this is eq. 5.c. It is this fibre Hessian that enters the saddle determinant.

The third-order momentum statement concerns the determinant correction. Let C_k be the difference of the normalized vector logarithms with and without the multiplier term, evaluated at the actual $\mu=\nabla_{\mathrm{block}}(A\circ U_k)$. Then Prop. 5.8 proves

$$\widehat{\pi}^{C_k}(p)=O_k(|p|^3),\qquad b[C_k]=0.$$

In that proof the mixed field–multiplier Hessian has order $|p|$ by the gauge Ward identity, while the derivative of the actual multiplier has order $|p|^2$. Their composition has no quadratic coefficient. This does not give a pointwise third-order bound for the multiplier matrix. For complex continuation the real absolute determinants in eq. 5.xxi are replaced by coherent logarithmic branches on a domain where the constrained forms remain nondegenerate. The physical identity does not define an independent-current extension.

The mass calculation uses finite determinants before any thermodynamic limit. Work here on the unit bare lattice. For an expanding box $\Lambda_R=[-R,R]^4\cap\mathbb{Z}^4$, let ι_R^0 and ι_R^1 be zero extension from its sites and its positive bonds with both endpoints in the box. Put

$$\begin{aligned}U_f(x,1)=\exp(-ifx_2t_3),\quad U_f(x,\nu)=I\quad(\nu\neq1),\quad \tfrac12\operatorname{tr}(t_3^2)=1,\\ \Delta_{f,R}=\iota_R^{0*}\Delta_{U_f}\iota_R^0,\qquad \mathcal{K}_{f,R}=\iota_R^{1*}\mathcal{K}_{U_f}\iota_R^1.\end{aligned}\tag{5.xxiii}$$

These are Dirichlet compressions of the scalar and vector operators appearing in eq. 5.xxi, before its averaged-constraint corrections. The vector Wilson Hessian is defined by second variation against finitely supported bond fields, so no infinite total action is differentiated. The oriented 12-plaquette is $\exp(ift_3)$. Adjoint charged colors therefore carry fluxes $2f$ and $-2f$, while the third color is neutral.

For each fixed $z>0$ and finite box, take the real logarithms near $f=0$, where the massive matrices are positive, and set

$$\begin{aligned}\mathcal{D}_R(f,z)&=\log\det(\Delta_{f,R}+zI)-\tfrac12\log\det(\mathcal{K}_{f,R}+zI),\\ \widetilde{\beta}(z)&=\lim_{R\to\infty}\frac{1}{|\Lambda_R|}\frac{\partial^2}{\partial f^2}\mathcal{D}_R(f,z)\Big|_{f=0}.\end{aligned}\tag{5.xxiv}$$

Prop. 5.9 proves existence of this limit and independence of the lattice Følner exhaustion with the stated zero-extension compression. The identification with the bulk action coefficient uses the actual affine response and physical mass rescaling in eq. 5.clxxix. The order of the limits is the derivative at fixed positive mass, then volume, then $z\downarrow0$; no infinite determinant is differentiated.

The regulator comparison requires the finite-volume normalized Hessian kernels of this determinant pair to converge to the translation-invariant quadratic form denoted $\mathcal{L}(z)$. The bounded-remainder comparison concerns $\mathcal{L}^\sharp = \mathcal{L}(1) - \mathcal{L}'(1) + \mathcal{L}''(1)/2$, uniformly on the prescribed external-momentum strip. The resulting formulas for $N = 2$ are

$$\begin{aligned} \widetilde{\beta}(z) &= \frac{11}{6\pi^2}\log(1/z) + O(1), \\ |z\widetilde{\beta}'(z)| + |z^2\widetilde{\beta}''(z)| &\le C, \\ \sum_{l=1}^{k} b_l^0 &= \widetilde{\beta}(\eta_k^2) - \eta_k^2\widetilde{\beta}'(\eta_k^2) + \tfrac{1}{2}\eta_k^4\widetilde{\beta}''(\eta_k^2) + O(1). \end{aligned} \tag{5.xxv}$$

All field expansions are at fixed positive mass before taking that mass to zero. The vector form need not be nonnegative without its mass; the small-field hypothesis must make the massive form coercive.

The first two lines follow from Prop. 5.9. The third is eq. 5.cxcviii, combined with Gaussian composition and coefficient preservation. Its uniform $O(1)$ term comes from Prop. 5.21, which includes the averaged constraints and the gauge determinants. After the zero-coefficient multiplier correction has been removed, the difference of the two Hessian symbols is bounded on a fixed complex momentum neighborhood. If its bound is C on $\{|p_\nu| < \delta\}$, Cauchy's estimate bounds each mixed second derivative at zero by $C\delta^{-2}$. Both C and δ are independent of the depth. Thus the error compares the full cumulative normalizer with the massive determinant; it is not a sum of one bounded error per scale.

The stronger geometric convergence uses the Taylor triple $\mathfrak{J}_k = (\Delta_k, S_3^{(k)}, S_4^{(k)})$ of $\mathcal{S}_k = A \circ U_k$. With $\Lambda(B,\upsilon) = S(B) + \langle \upsilon, m(B)\rangle$, $\mathbb{G} = (D^2\Lambda(0))^{-1}$, $V_i = D^i\Lambda(0)$ and $\dot{z} = \mathbb{G}(0,C) = (HC, -\Delta_{k+1}C)$, the identity is

$$\begin{aligned} \Phi''_{k+1}(C,C') = {}& \tfrac{2}{3}\langle C, C'\rangle - \tfrac{2}{3}\langle HC, HC'\rangle \\ & - \tfrac{1}{2}\,\mathrm{Tr}(\mathbb{G}V_4[\dot{z},\dot{z}']) + \tfrac{1}{2}\,\mathrm{Tr}(\mathbb{G}V_3[\dot{z}]\mathbb{G}V_3[\dot{z}']). \end{aligned} \tag{5.xxvi}$$

Here $\eta_k = L^{-k}$ in the mass comparison, $S(B) = \mathcal{S}_k(e^{iB}) + \mathrm{GF}_k(e^{iB})$, $m(B) = i^{-1}\log\mathcal{M}(e^{iB})$, $\Delta_k = \mathcal{S}_k''(\mathbf{1})$, and $S_j^{(k)}$ is its degree-j Taylor form in the same chart. The vector HC is the linear constrained background response. Prop. 5.34 derives eq. 5.xxvi with the actual constraint and gauge vertices. Prop. 5.32 proves $\|\mathfrak{J}_{k+1} - \mathfrak{J}_k\| \le C_\alpha L^{-\alpha k}$ in the stated weighted kernel norms, and Prop. 5.36 supplies the uniform continuity of the Gaussian polarization in those norms. Their combination is Cor. 5.37, which proves the second line of eq. 5.xviii on the homogeneous physical germ. The bounded cumulative law alone would not give convergence of individual increments. These estimates preserve the geometric comparison used at equal depth in the stronger matched-cutoff route.

The two-coupling Gaussian factor. At level k, write the fibre form as $\Delta = \Delta_A + \Delta_{\mathrm{GF}}$. The frame fixes the field scaling and gauge-fixing weight; the action weight supplies $\tau\Delta_A + \Delta_{\mathrm{GF}}$. The actual finite-dimensional hypothesis is that Δ_A vanishes on the block gauge directions and Δ_{GF} acts only on those directions, with a positive nondegenerate form on each complementary integration space. Under this splitting the two ordinary Gaussian integrals factor, giving

$$\begin{aligned} \int dB\,\delta(QB)e^{-\langle B,(\tau\Delta_A+\Delta_{\mathrm{GF}})B\rangle/2} &= \tau^{-n_\perp/2}Z^{(k)}(V), \\ \int d\mu_{\tau^{-1}C^{(k)}}(B)e^{-(1-\tau)\langle B,\widehat{G}B\rangle/2} &= \tau^{n_{\mathcal{O}}/2}, \\ n_{\mathcal{O}} = 3\#(\mathbb{T}^{(k)} \setminus \mathbb{T}^{(k+1)}), &\quad n_\perp = 3|\mathfrak{X}_k| - n_{\mathcal{O}}, \quad l = k+1. \end{aligned} \tag{5.xxvii}$$

Here Q is the one-step average on the fibre, not the k-fold average, $\mathfrak{X}_k$ is the free-bond set, and $\widehat{G}$ is the gauge-fixing form in those coordinates. For positive real τ, the formula follows by rescaling only the non-gauge coordinates. Analytic continuation to the right half-plane uses the branch of $\log\tau$ real on the positive axis. Both dimensions are independent of the background. In particular $n_\perp$ is a dimension, while $d_l(X)$ is a domain metric. The two quantities are never denoted by the same unqualified symbol.

Consequently the total of the extra Gaussian family G_τ is $n_{\mathcal{O}}\log\tau/2$. Its physical second derivatives vanish and $b(G_\tau)=0$. Its norm may nevertheless be $K_{\mathbf{M}}|1-\tau|e^{-(1+c)\kappa d}$, with no small-coupling gain. This cancellation is needed to avoid a spurious accumulation of slopes of order θ_k^{-1}. The formula in eq. 5.xxvii presupposes the actual gauge splitting; it is not a consequence of a bound for a general complex Gaussian.

The complete regular family has the form $E^{(k+1)}=N^{(k+1)}+G_{\tau_k}+F$. Its physical step functional, up to field-independent normalizations, is

$$\begin{aligned}\mathcal{E}^{(k+1)}[\theta_k;x;S](V) = {}& \log\Bigl(\mathbf{T}_k^{\mathrm{sf}}[\theta_k]\,e^{-xA(U_k(\cdot))+S(U_k(\cdot))}\Bigr)(V)\\ &+xA(U_{k+1}(V))-S(U_{k+1}(V)).\end{aligned}\tag{5.xxviii}$$

The operator uses the whole torus as its small-field region, and S is the action of the incoming list. Equality between this physical functional and localized totals is asserted on their admitted backgrounds. It is not an identity of a global Gaussian at arbitrary independent-current pairs. The local formulas on such pairs have their own complex cores.

Lists, the two chains, and the increment as a function. A list contains regular families $G^{(j)}$ with their own action counterterms and unpointed remainders $H^{(j)}$. At the output radii $\bar a_\iota$ its required load is

$$\begin{aligned}\mathcal{N}(\mathfrak{f}) &= \sum_{j=1}^{k}\omega_{k+1-j}\|G^{(j)}\| + \sum_{j\ \text{aged}}[\bar a/a_j]^2\|H^{(j)}\|,\\ \omega_n &= (n+1)^{3/2}L^{-\alpha_{\mathrm{H}}(n-1)},\\ |F(X)| &\le K_{\mathbf{M}}\{\delta(\theta_k)+\mathsf{s}\mathcal{N}(\mathfrak{f})+e^{-c\theta_k\delta(\theta_k)^2}\}e^{-(1+c)\kappa d(X)}.\end{aligned}\tag{5.xxix}$$

The radius ratio is the maximum of the two coordinate-radius ratios; $\mathsf{s}=\delta(\theta_k)/\bar a_0$. The first, second and third terms pay respectively for the interaction beyond quadratic order, old-family differences, and failed Gaussian tests. The parameter choices used to infer a power bound for the last term must actually satisfy that power bound.

The fluctuation variable B ranges over nonpivot bonds. Its actual fibre map $B\mapsto V'(B)$ satisfies $\mathcal{M}(V'(B))=V$; the full fluctuation exponent $B'(B)$, including its pivot completion, is analytic and vanishes at $B=0$. It is not identified with the free array B. Old-family amplitude estimates have to hold on this actual map and its declared joint complex domains.

Likewise, in a localized Gaussian deformation with protected collar $Z_0^\sharp$, the independent coarse parameters s_Δ belong only to cubes outside that collar. The collar is a fixed-width cover and neighboring layers, not a rectangular box filled around a thin domain. Removing the protection can destroy invertibility of the compressed form. The unmarked potential-ball theorem applies after its actual matrix comparison, enlarged parameter discs, hereditary filing and smallness conditions are verified. It does not construct those domains. Local bounds on independent-current cores do not become global Gaussian identities away from complete physical pairs.

The regular part has a summable age weight because its own affine quadratic action is removed before localization. A remainder has no such counterterm, so its squared-radius load is not given an age decay. §§ 4.3 and 4.5 prove the corresponding finite implications under their actual background, bond-split, potential, core and boundary hypotheses. Their general polynomial age factors do not automatically give the exact exponent 3/2 in eq. 5.xxix. One must either verify that sharper estimate or allocate a smaller positive exponential rate and prove the resulting comparison.

A Euclidean list has one companion, the correct coefficients of its regular members, pointed totals covariant under the admitted unit lattice isometries, and invariant remainder totals on the declared covariance class. Its radii of covariance obey

$$e_{j'} \le L^{2(j'-j)} e_j \qquad (j \le j'). \tag{5.xxx}$$

Closure means that the actual output again has these properties. Restriction to smaller cores does not prove covariance. The backgrounds of fluctuating fields must first lie in a common covariance class on an open real fluctuation ball; continuation then requires a connected analytic domain on which both expressions exist. The actual domain and naturality hypotheses remain part of closure. For an isometry r, the Gaussian covariance assertion uses the actual orthogonal change of free coordinates O_{r} with $V'_{\mathsf{r}W}(\mathsf{O}_{\mathsf{r}}B) = \mathsf{r}V'_W(B)$. This is not a walk-expansion operator. Translation and cover locality of the supply rules do not by themselves give the full isometry covariance of the new family: that also uses the Euclidean covariance of the entire incoming list and its aged remainders.

For the remainder total, use the all-small-field term on its invariant open real window. The positive step kernels carry the term to its image under the lattice isometry. The localized density format is continuous on this window, so equality of the measures gives equality of the densities at the admitted backgrounds. Divide by the regular factors and inherited remainder factors whose totals are already invariant on the two background windows of the step. The remaining exponential is that of the new remainder total. It is real there, so equality of the exponentials gives equality of the totals. This is the induction at the actual backgrounds for the unsourced run and for invariant real source data. On an admitted connected complex family with the same density identity, the difference of the two totals is continuous with values in $2\pi i\mathbb{Z}$. It vanishes at the real anchor and hence throughout the family. For a holomorphic constant source, equality on the real source interval also gives this continuation.

At the age gate the next lattice's isometries preserve the old partition, so the group available for the total includes all the isometries required at the insertion step. The termwise translation covariance uses the translations preserving the actual partition. The companion and matching index sets are the other inputs for inserting the family in the regular list.

The unmarked chain uses absolute radii and starts with the empty list. The marked chain uses running radii $\check{\alpha}_{\iota,j} = \min\{\alpha_\iota(\theta_{j-1}), \alpha_\iota(\theta_j)\}$ and inserts a remainder only when $M\check{R}_j \le L^{m+1-j}$ at step $m+1$. This age is distinct from the waiting depth of a large-field operation. Before that age the remainder lies outside the regular exponent and contributes to the remainder and boundary outputs.

Restriction from absolute to running radii must restrict the same actual functions. Under that compatibility the marked difference cancels N and G_τ. The required recurrence is

$$\begin{aligned} u_{m+1} &\le K_{\mathbf{M}\mathsf{s}}(\theta_m) \left(\sum_{i=1}^{m} \omega_{m+1-i} u_i + C_{\mathfrak{h}} \theta_m^{-p} \right), \\ p &= (\kappa_0 - 2)/2 > 1, \\ \sum_{j \le m} \frac{\alpha_0(\theta_m)^2}{\check{\alpha}_{0,j}^2} \theta_j^{-\kappa_0/2} &\le C_{\mathfrak{h}} \theta_m^{-p}, \\ C_{\mathfrak{h}} &\le C \left(1 + \frac{1}{\lambda_{\mathfrak{b}}(p-1)} \right). \end{aligned} \tag{5.xxxi}$$

The lower flow bound pays one inverse-coupling power in this sum. With a constant frame its load can grow with the number of levels. Smallness of $K_{\mathbf{M}\mathsf{s}}$, relative to the summable kernel and $C_{\mathfrak{h}}$, closes a weighted supremum induction. This is an actual marked-chain requirement, not a conclusion of an unmarked finite source derivative.

The resulting increment requirement, with independent deviations before imposing their recursion, is

$$\begin{aligned} b_{k+1} &= b^0_{k+1} + f_{k+1}(z_0,\dots,z_k) + q_{k+1},\\ \sup|f_{k+1}| &\le C\theta_k^{-1/2}(\log\theta_k)^{\mathfrak{p}_0} =: \epsilon_k,\\ \sup|q_{k+1}| &\le C_v\theta_k^{-p_R} =: \epsilon'_k, \qquad\qquad p_R = (\kappa_0-4)/2. \end{aligned} \tag{5.xxxii}$$

For f, the supremum is on the whole product $|z_i| < \sigma_\star\theta_i$, with $0 < \sigma_\star \le 1/2$, and requires neither a lower flow bound nor remainders. For q, the frame obeys the weak flow bounds, $|z_i| < \varpi_0\theta_i(\log\theta_i)^{-2q_0}$ with $\varpi_0 \le \sigma_\star/2$, and the admitted aged remainder data range over their stated holomorphic parameter domain. Their bounds are $4\theta_j^{-\kappa_0/2}e^{-\kappa d_j}$, with eq. 5.xxx. The functions are real on real data. Constants are independent of the frame length, torus, cutoff and admitted parameter; the weak triple affects their threshold. These are bounds at every formed step $j \ge 1$ of the box:

$$\begin{aligned} |b^{\mathfrak{A}}_j - b^0_j| &\le \epsilon(\theta_{j-1}), \qquad & |b^{\mathfrak{R}}_j| &\le \epsilon'(\theta_{j-1}),\\ \omega_*(y) &= \sup_{v\ge y}\{\epsilon(v)+\epsilon'(v)\}. \end{aligned} \tag{5.xxxiii}$$

Here ϵ, ϵ' are the two functions in eq. 5.xxxii. The function ω_* is their least nonincreasing majorant on the admitted half-line. Calling a run alive does not replace the separate drift bounds at its earlier levels by a bound only at its last level.

There is also a weaker sufficient marked-multiplier estimate. If the marked exponent has norm $\mathfrak{n}_k \le C\mathfrak{g}_k^{\kappa_0-5}$ and the actual step is holomorphic in its multiplier on a disc of radius comparable to $1/\mathfrak{n}_k$, Schwarz yields

$$|E^{(k+1),\mathfrak{R}}| \le C\mathsf{s}(x_k)\mathfrak{n}_k e^{-(1+c)\kappa d}, \qquad |b^{\mathfrak{R}}_{k+1}| \le C\mathfrak{g}_k^{\kappa_0-7}. \tag{5.xxxiv}$$

This preserves an alternative sufficient error for the real flow; it does not prove the stronger exponent in eq. 5.xxxii. If this weaker error is used in a tuning argument, its actual power must replace p_R in the marked bare-disc estimate, and the summability condition $p_R > 1$ must be checked anew.
Well-founded induction and statement 3.1. The substantive construction input says that, for an admitted box and frame prefix through k, $E^{(k+1)}$ and its coefficient are formed before any choices using θ_{k+1}. They use the creation radii $(1+\beta_{\mathrm{s}})\alpha_\iota(\theta_k)$. The terminal covariance radius is $e_{k+1} = c\varepsilon(\theta_k)$, so it also needs no next frame entry. Once the computed next weight is admitted, the actual **RT** operation closes the next box, consistently on every admissible torus and its companion. The standing-history kernel identity is $(m(\kappa\otimes 1))|_{\mathsf{C}} = (m|_{\mathsf{A}})\kappa$ for a measure on $\mathsf{A}\times\mathsf{B}$ and a kernel from A to C. Here κ denotes a kernel, not a decay rate. This identity preserves the history sum; it does not supply its quantitative mass or locality bounds.

Choose $c_5 = 2c_2$, $C_\beta \ge c_0 + 2c_2 + 1$, and first fix

$$\lambda_\flat = c_0/4, \quad \bar B = C_\beta + 1, \qquad \bar\varsigma = C'\gamma^{\kappa_0-8}, \quad \lambda_\sharp = c_0/2 - \bar\varsigma, \quad B_\sharp = C_\beta + \bar\varsigma. \tag{5.xxxv}$$

The coupling ceiling is chosen so $\bar\varsigma \le \min\{c_0/4, 1\}$. The error exponent and other parameters must permit this ceiling; $\kappa_0 > 8$ is a sufficient choice for the displayed power of γ. An error estimate making that ceiling impossible cannot be used in this parameter selection. The marked-chain constants are computed at the weak triple before this choice. Then choose $Y_H = \gamma_H^{-2}$ above every required floor, with $\epsilon(y) + \epsilon'(y) \le \min\{c_0/4, 1\}$ and $\epsilon'(y) \le \bar\varsigma$ for $y \ge Y_H$. In particular $\gamma_H \le (\gamma^{-2} + c_5 + 1)^{-1/2}$. Increasing a reserve constant beyond $[0,1]$ is allowed only after its stated floor is increased.

Put $s_k = kc_0 - \sum_{l\le k} b^0_l$; then $|s_k| \le c_2$. For any formed prefix in the weak class,

$$\begin{aligned} x_i - x_j - (j-i)c_0 &= s_i - s_j + \sum_{i<l\le j}(b_l - b^0_l),\\ \tfrac34 c_0(j-i) - c_5 \le x_i - x_j &\le B_\sharp(j-i). \end{aligned} \tag{5.xxxvi}$$

The last upper bound uses the individual coefficient bound $|b^{\mathfrak{A}}| \le C_\beta$, $|b^{\mathfrak{R}}| \le \bar{\varsigma}$. The lower bound is stronger than the strong triple, which in turn implies the weak triple. Above a further floor, a bounded one-step drop changes the smallest power $R(y)$ by at most one factor L. Thus the computed next weight extends the frame while it remains above the floor. This is the numerical part of breaking the induction circle. The actual formation and box-closing input has not been proved by that telescoping calculation.

For $h = g^{-2} \ge Y_H$, define

$$K(\beta, g) = \min\{k : x_k(\beta) \le h + B_\sharp\}, \qquad \mathcal{W}_k(g) = \{\beta \ge h + B_\sharp : K(\beta, g) = k\}. \tag{5.xxxvii}$$

The conditional flow statement 3.1 is that the run exists through this index, has the same coefficients on all admissible tori, and

$$\begin{aligned} \lambda_\sharp(j-i) - c_5 \le x_i - x_j \le B_\sharp(j-i) \qquad & (i \le j \le K), \\ h < x_K \le h + B_\sharp, & \\ (\beta - h)/B_\sharp - 1 \le K \le 1 + (\beta - h - B_\sharp + c_5)/\lambda_\sharp. & \end{aligned} \tag{5.xxxviii}$$

At $\beta = h + B_\sharp$, $K = 0$; the terminal inequality still holds. For $K > 0$, the previous value exceeds $h + B_\sharp$ and the last decrement is at most $B_\sharp$, proving its strict lower endpoint. The lower drift forces finite exit. The two bounds for K follow by applying the upper drift to K and the lower drift to $K - 1$. Arbitrarily large β give arbitrarily large K, hence infinitely many nonempty $\mathcal{W}_k$. No stepwise positivity of b_k was used.

At depth s, write $x_{[s]} = x_{K-s}$. The exact envelopes are

$$h + \max\{0, \lambda_\sharp s - c_5\} < x_{[s]} \le h + B_\sharp(s+1). \tag{5.xxxix}$$

Put $\underline{x}_s = h + \lambda_\sharp s - c_5$, $\bar{x}_s = h + B_\sharp(s+1)$, and $g_-(g) = (g^{-2} + B_\sharp)^{-1/2}$. A diagonal subsequence of any first-passage sequence with $K \to \infty$ therefore converges at every fixed depth, to values in the closed versions of these intervals. Its couplings converge as well, with terminal value in $[(h + B_\sharp)^{-1/2}, g]$. A whole-sequence limit along tuned runs requires the later matched-cutoff input; compactness alone gives no such conclusion.

The arithmetic section, § 5.1, proves the leading logarithm from vanishing mean errors, including bounded backward excursions. In the present notation its uniform form is

$$\begin{aligned} |x_{[s]} - x_{[0]} - s c_0| \le \Delta_g(s), \qquad & \Delta_g(s)/s \longrightarrow 0, \\ \left| \frac{\beta}{K \log L} - \frac{11N^2}{12\pi^2} \right| \le \frac{\Delta_g(K) + h + B_\sharp}{K \log L} & \longrightarrow 0. \end{aligned} \tag{5.xl}$$

Here $K \ge 1$, $a_K = L^{-K}$. Denote the displayed relative error bound by δ_K, distinct from the fluctuation threshold δ_j. The function Δ_g can be chosen nondecreasing. Under the stated power/log error bound, with the marked exponent sufficient for the same estimate, one may take $\Delta_g(s) \le C + C(h + c_0 s/2)^{1/2}(\log(h + c_0 s/2))^{\mathfrak{p}_0}$. The smaller ceiling $\gamma_{\mathrm{d}} \le \gamma_H$ imposes the monotonicity and envelope floors for this quantitative bound; its constant is independent of g and s. For fixed g the relative error is $O_g(K^{-1/2}(\log K)^{\mathfrak{p}_0})$. For example $p_R > 1$, used below, suffices for the marked sum. The qualitative limit needs only an error tending to zero.

For the uniform depth statement, apply the arithmetic argument to the segment from $K - s$ to K. Its shifted one-loop partial sums have the same bound $2c_2$. Use the envelope ω_* of eq. 5.xxxiii on the self-calibrated run. One may explicitly choose

$$\Delta_g(s) = 2c_2 + \sum_{u=0}^{s-1} \omega_*(h + \max\{0, \lambda_\sharp u - c_5\})\,. \tag{5.xli}$$

This is independent of the initial coupling and cutoff, nondecreasing, and sublinear by Cesaro averaging. Integral comparison for the square-root/log envelope gives the quantitative bound above.

The sharper two-sided logarithmic comparison retained in statement 3.1 is

$$\begin{aligned} h - 2c_2 + \tfrac{1}{2}c_0(K-k) < x_k \le h + B_\sharp + 2c_2 + \tfrac{3}{2}c_0(K-k),\\ |x_k - x_K - c_0(K-k)| \le \Delta_g(K-k). \end{aligned} \tag{5.xlii}$$

These are the logarithmic inequalities since $\log(L^k a_K)^{-1} = (K-k)\log L$. The upper slope in the first line uses the uniform error bound $|b_l - b_l^0| \le c_0/2$ and the partial-sum bound, not an assumption on the sign of each one-loop increment.

Scale comparisons and layered evaluation. These estimates retain the distinction between a numerical flow sum and an estimate on an actual field. Write $t_p(x) = x^{-1/2}(\log x)^p$, $p \ge 0$. If $-c \le x_m - x_n \le B(n-m)$ for $m < n$, then, above a floor depending on a freely chosen $\beta_0 > 0$,

$$\begin{aligned} t_p(x_n) &\le (1+\beta_0)(n-m)^{1/2} t_p(x_m),\\ t_p(x_m) &\le (1+\beta_0)^2 (n-m)^{\beta_0} t_p(x_n),\\ \check{R}_j/\check{R}_{j+1} &\in \{1, L\},\\ \sum_{j=0}^{k} g_j^p &\le C_p \left(1 + \frac{1}{\lambda_\sharp (p-2)}\right) g_k^{p-2} \qquad (p > 2). \end{aligned} \tag{5.xliii}$$

The last line also assumes the lower drift bound. The first two follow by comparing the square roots and logarithms above their monotonicity floor; a bounded backward excursion is absorbed by the chosen $1+\beta_0$. The third uses the running minimum and the bounded one-step drop. For the last, use $x_j \ge x_k - c_5 + \lambda_\sharp(k-j)$, absorb c_5 by the floor, and compare the decreasing power with its integral. The exponent $p = 2$ is excluded: that integral is logarithmic.

For the field estimate fix an admitted label through k, with layers $\Gamma_n = \Omega_n \setminus \Omega_{n+1}$, $\Omega_0 = T_\ell$ and $\Omega_{k+1} = \emptyset$. The determining sequence starts at $\Omega_1^\sim$. Let Λ_j^+ be Λ_j together with its level-j islands. Base points are the unit sites lying one layer of $M\check{R}_j$-cells inside this set. Let Y be any set of these points and $\mathsf{Y}_n = \mathsf{Y} \cap \Gamma_n$. Here Γ_n is a geometric region difference; the bond record of a determining sequence is a separate object. Write $\#_n(D) = \#(\mathbb{T}^{(n)} \cap D)$. This is a site count, equal to volume in level-n units when D is a union of those unit cubes. It is not a count of localization cells. The cardinality $\#\mathsf{Y}_n$, by contrast, counts the original level-j base points. Remainder norms at a general fixed frame use $\mathfrak{g}_j^{\kappa_0}$; in the self-calibrated array $\mathfrak{g}_j = g_j$, as in the displayed layered bounds.

Assume the actual window/core and boundary hypotheses for these backgrounds, Euclidean regular members of norm at most E_0, remainders of norm at most $g_j^{\kappa_0}$, and the stated boundary-domain decay. In particular the actual boundary terms, indexed by their recorded origins o, must satisfy

$$|B_{\mathcal{S}}(j, X, o)| \le C_B e^{-\kappa d_j^\natural(\mathcal{S}; X)}. \tag{5.xliv}$$

The metric is the one in eq. 2.xxiv of § 2.2: the minimizing tree represents each chosen standing-island hull by one member, rather than filling it with all of its cubes. It is not ordinary d_j-decay

across an island. The retained layered requirements are

$$\begin{aligned}
&\left|\sum_{z\in\mathsf{Y}}\left\{\sum_{\substack{X\ni z\\ X\subset\Lambda_j^+}}[E^{(j)}(X,U_k,z)-E^{(j)}(X,\mathbf{1},z)]-b_jA(h_z,U_k)\right\}\right|\\
&\qquad\le E_1\sum_{n=j}^{k}(1+n-j)L^{-\beta_T(n-j)}L^{-4(n-j)}\#\mathsf{Y}_n,\\
&\sum_{\substack{X\in\mathcal{R}_j\\ X\cap\Omega\neq\emptyset}}|R^{(j)}(X,U_k)-R^{(j)}(X,\mathbf{1})|\\
&\qquad\le R_1g_j^{\kappa_0}\sum_{n=j}^{k}(1+n-j)\#_n(\Gamma_n\cap\Omega^{\sim}).
\end{aligned}\tag{5.xlv}$$

Here $0<\beta_T\le\alpha_{\mathrm{H}}<1$ is fixed, $\mathcal{R}_j$ consists of domains outside Z_j^+, and Z_j^+ is the stored large-field region enlarged by one cell layer. The set Ω is a union of level-k localization cubes and $\Omega^{\sim}$ has one level-j localization layer added. The constant R_1 in this display is not the geometrical gap parameter. Constants may depend on β_T, L, N and the construction parameters, but not on j,k,K,ℓ, the label or the positions.

For clarity, the local estimate behind the first line, when its actual background hypotheses have been verified, is

$$\begin{aligned}
&\left|\sum_{X\in\mathcal{X}}[G(X,U,z)-G(X,\mathbf{1},z)]-b(G)A(h_z,U)\right|\\
&\qquad\le C\mathsf{g}\left\{(\varepsilon_z/a_0)^2\sigma^{4+\beta_T}+e^{-\kappa\min\{\mathsf{D},c/\sigma\}/2}\right\},\qquad \sigma=L^{-(n-j)}.
\end{aligned}\tag{5.xlvi}$$

The member has norm g on radii $a_0\le a_1$, with $a_0\le 1$; the datum is ε_z-regular near z, $\varepsilon_z\le c$, and $\varepsilon_z\sigma\le ca_0$. Every term is evaluated in its actual core. The collection $\mathcal{X}$ contains all domains within D layers of z. With complete near coverage to distance c/σ, the right side is bounded by $C\mathsf{g}(1+(\varepsilon_z/a_0)^2)\sigma^{4+\beta_T}$. The local cancellation and nonlinear remainder sections supply the analytic implication under their full hypotheses, including the boundary-response compatibility and the own tent counterterm. Checking those hypotheses on this layered background remains part of the actual construction.

The tail in eq. 5.xlvi has no factor $(\varepsilon_z/a_0)^2$. For example a wrapping holonomy term, multiplied by its allowed exponentially small domain weight, can have zero nonwrapping companion and coefficient zero while its normalized value is nonzero on a flat torus field. A curvature amplitude cannot control that topological contribution.

To pass to eq. 5.xlv one also needs the actual geometry: $\varepsilon_z\le C\check{R}_n^2\varepsilon_n\le c\alpha_{0,n}$, the comparison $\alpha_{0,n}\le C(2+n-j)^{1/2}\check{\alpha}_{0,j}$, and the available collar depth. The condition $q>\mathfrak{p}_0+2r$ pays the first comparison. The factor $L^{-4(n-j)}$ is used entirely by converting level-j sites to level-n sites. For remainders the corresponding near-domain Cauchy bound is

$$|R^{(j)}(X,U_k)-R^{(j)}(X,\mathbf{1})|\le C(d_j(X)+3)^2L^{-4(n-j)}\left(\frac{\check{\alpha}_{0,n-1}}{\alpha_{0,j}}\right)^2g_j^{\kappa_0}e^{-\kappa d_j(X)}.\tag{5.xlvii}$$

Far domains use their norm, not this amplitude estimate. The second line of eq. 5.xlv also holds with $1+n-j$ replaced by $\varpi_{jn}=\max\{1,(x_j/x_n)^2\}$. Both dominate the required squared-radius ratio up to fixed constants. The two resulting summations give $|\mathbf{R}_k(U_k)|\le C\sum_n g_n^{\kappa_0-6}\#_n(\Gamma_n)$.

The regular counterterm in eq. 5.xlv is the sum of its own tents. An arbitrary smooth weight equal to one on Ω differs from that sum on its collar; it produces a new action term without an

age gain. For the actual profile φ_j, $\varphi_j h_z = h_z$ at every base point. The remaining rim terms obey $0 \le A(\varphi_j h_y, U_k) \le C\alpha_{0,j}^2$. The needed geometrical count is $\sum_j \#_j(Z_j^+) \le C\sum_n \#_n(\Gamma_n)$. It includes the stored collars of healed components, not just the re-done small-field regions. It is an actual window/history count and is not proved by a local Cauchy estimate.

Here $\mathbf{R}_k$ denotes the sum of the normalized remainder differences on the label. The net regular action $\mathbf{E}_k$ includes its profile counterterms and rim terms. With those counts and boundary sums, $|\mathbf{E}_k(U_k)| \le C\sum_n \#_n(\Gamma_n)$. For admitted complex perturbations of total coefficient size $\bar{c}$, regular norms at most $E_0 + 1$, remainder norms at most $4g_j^{\kappa_0}$, and the same boundary hull bounds, the sum of the elementary moduli is at most $C(1+\bar{c})\sum_n \#_n(\Gamma_n)$. This is a pointwise estimate on the admitted arrays; it is not an assertion that arbitrary such arrays are produced by the RG map. Its constants and evaluation floor need no new dependence on $\bar{c}$. The variable action coefficient is

$$x_k(y) = \beta - \sum_{j\le k} b_j \varphi_j(y), \qquad |x_k(y) - x_k| \le B_\sharp \#\{j \le k : \varphi_j(y) < 1\}. \tag{5.xlviii}$$

It equals x_k one coarse cell inside all the small-field regions. Let $A_{k,\mathcal{S}}$ be the ACTUAL label exponent and $\mathcal{E}_k$ its once-counted field-independent number. The sign convention is $\mathcal{E}_k = -E_{(k)}$, where $E_{(k)}$ is the accumulated log vacuum normalizer of eq. A.lxvi. Thus the constant part of the exponent is $E_{(k)}$. The exact density format, which is a construction input, identifies the sum of the elementary regular, remainder, rim and boundary terms with the expression on the left of

$$|A_{k,\mathcal{S}}(U_k) + \mathcal{E}_k + A(x_k(\cdot), U_k)| \le C(1+\bar{c})\sum_n \#_n(\Gamma_n). \tag{5.xlix}$$

Their modulus sum proves this consequence on the admitted backgrounds. Defining an exponent by a bound would not prove the required exact density format.

5.2.2. *A common companion and the torus floor.*
Statement 3.4 and its compatibility hypotheses. For each fixed frame and weight prefix there must be a single family $\widehat{E}^{(j)}(\widehat{X}, P, z)$ on the infinite level-j lattice, and likewise a companion for $R^{(j)}$. For every admissible (ℓ, K'), $K' \ge j$, and every label, it agrees with the torus term when the projection of $\widehat{X}$ is injective with its margin and lies one full level-j cell layer inside Λ_j. A sufficient margin places $\widehat{X}$ in a rectangle with sides less than half the corresponding torus side. The admissibility used here is

$$\ell L^{K'-i} \ge 2L^{11} M \check{R}_i \qquad (i \le j). \tag{5.l}$$

The family has the same analytic bounds and cube-translation covariance on every such lift. Its coefficient b_j is a function only of the frame and weights through level $j-1$.

Uniqueness follows because every bounded domain, collar included, embeds in arbitrarily large admissible tori. Existence requires more. First, the walk, propagator, localized background and gauge choices must be made once by a rule natural under covering maps, cube translations and the later dilations. Independently chosen objects on separate tori cannot be compared. Second, each local formation formula must use only its supplied neighborhood, earlier terms restricted there and the common numbers x_i, b_i. The induction is simultaneous over tori of unbounded side; it does not define b_j using only domains that happen to fit a particular torus.

Third, formation must be local in the history trace on the prescribed one-layer windows X_i^+. A chart identifying these traces, the bare weight, prefix coefficients and incoming local terms identifies the newly formed term on the common local core. In the one-layer interior the standing history has empty trace: healed components have already been absorbed into local terms. This actual standing-history property is what makes that interior term independent of the label. It is not implied by an inequality for the modulus of an activity.

The order $E^{(j)}, b_j, x_j, R^{(j)}$ avoids a circular definition. In particular the new large-field weight x_j does not enter the preceding extraction of b_j. This compatibility is an input to the full interacting

construction. The finite formulas proved elsewhere can verify pieces of it; their holomorphy alone does not prove it.

A locality-preserving choice of the supplied kernels. There is a conditional construction of a natural supply rule that also explains a restriction on gauge representatives. Suppose the real frame prefix and numerical parameters have first been fixed, and the actual finite-world construction has supplied local coefficients $\mathsf{K}_\omega[\mathfrak{s}; P]$, the declared joint complex charts and their uniform bounds, and its exact operator or functional sum rule. A setting $\mathfrak{s}$ records the geometric and regional data; its continuous field variables remain in P. Assume that the finite-cover identity for the total and the actual filing of lifted walks hold. Those are properties to check for the supplied linear algebra, not conclusions about an arbitrary collection of small functions.

Let $\mathcal{T}_{\mathfrak{w}}$ be the finite translation group of a world under which the class of settings is closed. Average by

$$\mathsf{K}^{\flat}_{\omega}[\mathfrak{s}; P](z, z_1) = \frac{1}{|\mathcal{T}_{\mathfrak{w}}|} \sum_{a \in \mathcal{T}_{\mathfrak{w}}} \mathsf{K}_{\tau_a \omega}[\tau_a \mathfrak{s}; \tau_a P](z + a, z_1 + a). \tag{5.li}$$

The norm and decay bounds are convex, so averaging preserves them. If two settings have the same trace on the supplied reading neighborhood, each pair of summands reads the same translated trace; the averaged terms therefore remain local. Covariance follows by reindexing the finite group. A single representative of each translation orbit would not do this: its translating displacement can depend on data outside the local hull.

For gauge orbits, the representative is instead fixed by an actual comb tree of a specified box and its entrance bond, with the root outside the box. Put the gauge equal to the identity outside and propagate its values from the root along that tree. Every tree bond then becomes the identity. This determines the gauge uniquely. Under a site gauge u, each root-to-site transport changes to $u(o)\, U[o, x]\, u(x)^{-1}$. Consequently $\mathrm{rep}(\mathcal{O}^u) = \mathrm{rep}(\mathcal{O})^{u^\natural}$, where $u^\natural = u$ outside the box and $u^\natural = u(o)$ inside. The entrance bond and the exterior root are part of its reading data. Selecting a representative by a global orbit ordering would not prove this local law.

The margins needed for this construction are also part of the input. Write ξ_l for lattice spacing and w_l for the assigned cell side at level l. A region Ω_i used to form a cover or cutoff has level at least i. Its cutoff makes its whole transition within distance less than one of its own cell sides from its complement. A walk cell of index n has size $O(M_1 \xi_n)$; write $\mathsf{q}^{\boxplus}$ for its enlargement by $5M_1\xi_n$ in the maximum norm. If n^* is the largest index with $\mathsf{q}^{\boxplus} \not\subset \Omega_0$, require $CM_1\xi_{n^*} < \mathsf{w}_{l(\Omega_0)}$; the condition is absent when no such cell occurs. Each layer enlargement adds exactly one layer of the assigned cubes, and inclusion, touching and component rules read the region within its one-cell margin. Finally each representative box, with its required neighborhood, fits in a closed cube of side less than one quarter of the side of each compared world. These conditions turn graded reading sets into the asserted local ones. Averaging alone does not verify them.

Push the averaged coefficients from a cofinal sequence of covering worlds to a fixed world and take a diagonal normal-family limit on their common finite-dimensional complex charts. Discrete settings, walks and matrix entries are countable; a countable compact exhaustion of those charts suffices. The relevant bounds are uniform before the limit. The cover filing may give a multiplicity at most $|\omega| + 1$. Its first moment is summable when the rooted walk entropy and $(CM_1^{-1/2})^{|\omega|}$ have a strict margin. Dominated convergence then preserves the exact sum rule. This uses the actual cover identity and the same declared cores throughout; it is not an extension of a physical identity to independent currents. Resolvents and square roots can subsequently be formed from the limiting basic coefficients on their supplied spectral domains. There is no need to diagonalize an uncountable list of resolvent parameters. This argument constructs coherent choices conditional on the uniform matrix, chart, reading and filing inputs just stated.

Under these inputs, the coefficient of the physical totals, taken in the large-torus limit, equals the companion coefficient in eq. 5.ii. Use the all-small-field totals for their unit-lattice symmetries;

a truncated label total has no such invariance in general. On nonwrapping domains the Hessians agree by compatibility and the torus response converges to $\mathfrak{h}_\infty$. Fix first a probing length R_{pr}, measured in level-j units and unrelated to the cube-size function $R(y)$. Take the torus side to infinity at this fixed length; once it exceeds $2R_{\mathrm{pr}}$, the relevant bounded domains are lifts. Only afterwards send R_{pr} to infinity. Domains escaping the probe carry the supplied tree-length tail, with rate after entropy $(\kappa - \kappa_{\mathcal{D}})(R_{\mathrm{pr}}/(2M) - 2)$. The rooted entropy is absorbed by the chosen κ; response decay controls remote differentiations. Dominated convergence therefore passes the differentiated invariant totals to the companion kernel. This proves the sum-rule identification, including that a constant total has coefficient zero. It requires the uniform response convergence and domain bounds just stated. The response limit need exist along a coherent admitted family of representatives, not along every possible gauge choice on separate tori. An oscillating fine gauge fixing the unit-lattice sites can destroy such a derivative limit. If two admitted limits differ by $(\mathrm{d}\lambda_B, 0)$, the differentiated gauge Ward identity annihilates that direction in the Hessian at $P_\circ$; the coefficient is therefore unchanged. This independence does not prove existence of the all-level response limit.

Wrapping domains have $d_j(X) \geq c\ell L^{K-j}/M$. Their exponential decay is used directly and does not define an additional renormalized coefficient. For a self-calibrated run, the cube ratio shows that eq. 5.l at the terminal level implies it at all preceding levels. Since $x_K \leq h + B_\sharp$, it suffices that

$$\ell \geq \ell_\star(g) := 2L^{11}MR(g^{-2} + B_\sharp). \tag{5.lii}$$

Write $\mathfrak{L}(g)$ for the compatible torus sides above this floor. The same floor works on the reference line, whose terminal value is h. The side is selected after g; the cutoff K remains unrestricted. This statement is a uniform construction requirement, not an assertion of infinite-volume uniqueness.

5.2.3. *Frozen choices, slopes, and tuned bare couplings.* The reference line for a run of length K is

$$\theta_k = h + c_0(K - k), \qquad h = g^{-2}. \tag{5.liii}$$

Equal depth in runs of lengths K and $K+1$ gives equal frame numbers, lattices, partitions, radii and cube sizes. It does not give equal tests, since their backgrounds live over different bare lattices, and it identifies no labels or histories between those runs. The line beginning at depth s is the reference line of $g_{[s]} = (h + c_0 s)^{-1/2}$.

For fixed choices, every inserted characteristic function is the same real Borel function of its integration fields. The actual operations act linearly on the initial density. If their required dominated analytic estimates hold, applying them to $e^{-(\beta-\zeta)A}$ gives holomorphic measures and local families in ζ. No derivative of a cutoff is taken. Continuity of the real run follows from the actual fixed-frame input-list Lipschitz estimate while the arrays retain their tube room. It is continuity, not a contraction. When each bare coupling chooses its own frame, the tests and domains can change discontinuously and this argument does not apply. For a fixed-frame remainder comparison, both real centers β, β' must be alive through the compared prefix. The interpolated aged remainder list is

$$H_\upsilon^{(j)} = R_{\beta'}^{(j)} + \upsilon(R_\beta^{(j)} - R_{\beta'}^{(j)}). \tag{5.liv}$$

At their common frame domains, the individual norm bounds give $\|H_\upsilon^{(j)}\| \leq 4\theta_j^{-\kappa_0/2}$ for $|\upsilon| < 3/2$. Its companion, covariance radius and invariance properties must be those required by the admitted list slot. The holomorphic list estimate then applies to this actual interpolation; an unrelated real center or an unspecified change of the earlier histories cannot be substituted for it.

The exact decompositions of unity and normalized gauge factors imply that the bare measure, partition function and observable integrals are independent of admitted auxiliary choices. Intermediate densities after a large-field operation need not coincide. Comparing their extracted couplings

requires E4. The retained self-calibrated versus reference-run target is

$$\max_{k\le K}|x_k(\beta)-x_k^{\natural}(\beta)|\le Cg(\log g^{-2})^{3\mathfrak{p}_0+1}\le 1. \tag{5.lv}$$

It is required for first-passage data with $\varrho\ge B_\sharp+1$ and $0<g\le\gamma_{U'}\le\gamma_U$. Threshold and large-field changes contribute at most $C\theta_k^{-(\kappa_0-4)/2}$ per step, and gauge-fixing changes at most $C\theta_k^{-3/2}(\log\theta_k)^{3\mathfrak{p}_0+1}$. Proving those actual comparisons remains necessary. Equality of bare integrals does not prove eq. 5.lv.

The small-field coupling polydisc has relative radius $\sigma_\star\theta_j$. The large-field tube is narrower. On a level-j unit cube, an action-weight change has size

$$|x-\theta_j|\alpha_{0,j}^2\le C\mathfrak{t}_j\theta_j^{-1}(\log\theta_j)^{2q}. \tag{5.lvi}$$

A logarithmic tube factor at least $(\log\theta_j)^{-2q}$ keeps this bounded. A fluctuation difference gains a further $\delta_j/\alpha_{0,j}$. This explains the different roles of the full small-field polydisc and the large-field tube. It does not justify extending the entire interacting history construction to the larger polydisc. Complex bare couplings in the latter construction are obtained near admitted real runs through the fixed-source analytic domain.

Statement 3.5: the weaker marked-disc slope route. For this paragraph require $p_R>1$. The unmarked term has the independent-variable bound in eq. 5.xxxii. Along the actual run the marked term is allowed a different analytic input: on a disc in the bare variable about each admitted real centre, of radius at least $c_\beta\varrho$, it is holomorphic and bounded by ϵ_k'. Bounds are uniform on centres whose required prefixes retain the prescribed tube room. On a smaller concentric disc, Cauchy therefore gives $C\epsilon_k'/\varrho$. This hypothesis includes the actual remainder dependence on that bare variable. It does not assert that this dependence is a function of independent deviations alone.

On the admitted constant-source disc this bound has a native frozen-step calculation. Form $E^{(k+1)}$ on the whole lattice with the real fluctuation Gaussian, its bond cut and the source vertex. The input list consists of the renormalized regular families and the vacuum-subtracted remainders that pass the age test. Form $P^{\flat(k+1)}$ with the same Gaussian, cut and running shifts, keeping just the recursively unmarked regular families. Put $Q^{(k+1)}=E^{(k+1)}-P^{\flat(k+1)}$.

At the frozen shift ζ_k, write $s=1-\zeta_k g_k^2$. The quadratic part of the source vertex is $-\frac12(s-1)\langle B,\Delta B\rangle$; together with the real Gaussian it gives the Gaussian of the unmarked recursion at ratio s. Its other vertices are the remaining terms of the same rewritten interaction. On a common cut and common radii the renormalized inputs agree by induction, up to field-free constants, with the unmarked list evaluated at the running shifts. Those constants do not enter the marginal coefficient. Hence the unmarked output supplies the one-loop and f_{k+1} terms in eq. 5.xxxii, and the marked coefficient is $\beta[Q^{(k+1)}]$.

In the frozen integral, split each inherited regular group by linearity of its own marginal subtraction. The groups from $Q^{(j)}$, together with the admitted remainders, are exactly the marked inputs. The first-stage contour estimate bounds their total weight by the small fluctuation factor times the sum of the renormalized Q loads and the aged remainder load. Removing these inputs leaves the unmarked integral. The second-stage cluster comparison bounds $\|Q^{(k+1)}\|$ by a fixed multiple of that marked weight. In the supremum form of eq. 5.xxxi, choose the coupling small enough that this multiple times the fluctuation factor and the total regular-group kernel is at most $1/2$, and the remainder load has coefficient at most $1/2$ as well. The remainder weight here is comparable to x_j/x_{k+1}; its sum uses the smallness at birth. Since both the earlier supremum and that load are bounded by the current envelope, the new Q lies in the same envelope, of size $C\theta_k^{-(\kappa_0-2)/2}$. Extracting the coefficient on the admitted running radius costs $C\theta_k$, giving the required $C\theta_k^{-p_R}$ on the bare-variable disc. This calculation requires holomorphic inherited remainders and the identification of the actual frozen production with these lists, including its cut and radii.

For the inherited remainders, the native step uses two bounds on the same constant-source disc. The contribution from summing healed components has weighted norm at most $Ce^{-p_0(g_{k+1})}$ on domains away from the one-layer enlargements of the live regions. Separate the empty-family term before taking the polymer logarithm. A polymer disjoint from all second-class strips contains a healed operation. The terms meeting those enlargements go into the boundary list and use the relative hull bound there. The complete boundary slot also retains its empty-family term with the ordinary amplitude.

The second contribution comes from the ordinary fluctuation integral. Keep its normalized reference Gaussian and its cut fixed as in [B88b, (3.26)–(3.29)]. Use two potential parameters. The first multiplies the boundary terms, including the changes of the stored operations, the weight variation near the large-field region, the bounded rim part of the quadratic gauge correction, and the change-of-variables terms of the rim. The second multiplies the recent remainders evaluated as differences between the pre-integration and post-integration backgrounds. For an origin j, first subtract the vacuum value of $R^{(j)}$. The vertex in the interpolation is the difference $R^{(j)}(U_k) - R^{(j)}(U_{k+1})$, evaluated on the two actual backgrounds in the variables of this integral. The boundary expectation varies the first parameter with the second at one. The recent-remainder expectation varies the second with the first at zero. The logarithm with both parameters zero uses the aged, vacuum-subtracted remainders with the regular vertices. The Gaussian normalizer belongs to the regular part of the step and the reference Gaussian used for these expectations has unit mass before the cut.

The two changes of the logarithm are the integrals of the corresponding normalized expectations. In the local expansion, the second change selects precisely the clusters with at least one marked recent vertex on the same cut. File its terms on the one-layer inset as $R''^{(k+1)}$. Its terms in the rim, and the first expectation's terms, go in the boundary family. The conditional Gaussian in the history can have a nonzero mean. With precision blocks A_{II} and A_{IE}, and exterior field a_{E}, the mean is $-\mathsf{A}_{\mathrm{II}}^{-1}\mathsf{A}_{\mathrm{IE}}a_{\mathrm{E}}$. The restriction to the centered term takes place after decoupling. In eq. 4.xcv every parameter off the carrier Z is zero. A walk meeting a cube off Z then has weight zero. The remaining Gaussian terms use the restricted form, its resolvent and the exterior columns carried by Z. A nonzero column must carry the whole closed bond segment of its exterior argument. For $Z \subset \Lambda_{k+1}$ there are no such exterior or crossing bonds. The localized mean therefore vanishes and every fluctuating bond of Z has the interior cutoff T_k. With the same reference scale and Gaussian factor the localized operators are those of the constant sequence of regions [B88b, p. 278]. In the logarithm each such Z, and the full collar of each selected potential, lie in the filing domain X. The marked coefficient is thus the centered coefficient at the same local pair and with the same restricted list of input potentials. Match the decoupling guard to compare individual summands. Regrouping the decoupling brackets gives the guard-independent coefficient. A term reading the rim uses the conditional formula and is filed at the boundary. The one-layer inset decides where the centered recent coefficient is filed.

The comparison uses a common localization and source presentation. For the presentation which instead puts the constant shift into the Gaussian, the comparison of marginal coefficients uses the identity of the totals up to the field-independent Gaussian normalization.

The recent input band is $J_{\mathrm{rec}}(k) = \{j \le k : M\check{R}_j > L^{k+1-j}\}$, restricted to existing remainder families. In particular it is defined at the input step, and includes the level k family when it fails the ageing test. A localized vertex from j is estimated first in its own box. In comb gauge the scaled bond logarithm there is bounded by $CD_Y t^2$ times the output radius, where D_Y is the diameter of the input domain plus the box margin in its own units. The first localization is at input level k, so $t = L^{j-k}$. Scale these bond logarithms by one complex parameter and use the admitted background map on the resulting disc. The first derivative at the trivial pair is an invariant linear functional for the adjoint action of the constant gauge group and vanishes by semisimplicity. The second-order Schwarz estimate bounds the vacuum-subtracted value by the input size times $CD_Y^2 t^4$ times the

squared radius ratio. The difference of the two background values has the same bound up to a fixed factor. If the scaling disc has radius at most one, use the input bound at the admitted endpoints. In the rooted sum the output tree length is at most t times the input tree length. The spare decay sums the diameter factor. A domain extending beyond the containing box has input tree length at least of order t^{-1}. For $j < k$, extract t^4 from its spare exponential tree decay and keep a positive tree rate for summation. At $j = k$ the input and root weights already leave a positive tree rate and $t^4 = 1$. In both cases the $O(t^{-4})$ fine anchors in a root cell are paid by the t^4 gain.

In the first localization of these marked vertices, fix a real fluctuation B on the cut $\sup|B| \le T_k$. The response estimates of [B88a, (1.17)–(1.22)] on the cut-parameter contours bound the undilated response on the read set by $K_R g_k \sup|B|$ and the part localized at a block by $K_R \eta g_k \sup|B|$. Here $\eta \le 1$ is the decay factor from the block to the read set and K_R is uniform on the output tube. The estimates apply also to complex B. If a is the amplitude of the localized part, the sufficient containment inequality is

$$(1 + \eta|a|)K_R g_k \sup|B| \le \alpha_{*,k},$$

where $\alpha_{*,k}$ is the response radius. The top layer uses the base and dilated parts separately within its analyticity margin. At older layers the shift gains the decaying transfer factors and uses the corresponding layer room. With $\theta_k = K_R g_k T_k/\alpha_{*,k} \le 1/3$, the disc in the rescaled amplitude ηa has radius $\theta_k^{-1} - 1 \ge 2$. If the vertex differs from its vacuum value there by at most N, its change from the undilated vertex is bounded by $2N$. The Schwarz estimate on the subdisc $|\eta a| \le 2$ bounds the change by $4N/(\theta_k^{-1} - 1) \le 6\theta_k N$. Each differentiated cut parameter, integrated over $[0, 1]$, contributes at most $e^{\kappa_1}(e^{\kappa_1} - 1)^{-2}$ by Cauchy's formula on $|\sigma| = e^{\kappa_1}$. The rooted sum therefore has the factor $\sigma_k \le C(\log x_k)^{\mathfrak{p}_0 - q}$ on the fixed real cut.

The second localization at zero exterior fluctuation keeps this cut in the Mayer factors. In eq. 4.xciv, Y_0 contains the free bonds read by each selected potential that requires a field box, including each marked one. The failed-cut bonds lie outside Y_0. For the conditioned Gaussian formula of [B88a, (2.5)–(2.6), (2.14)], let C_σ be the conditional covariance on the integration region and $\Gamma_\sigma X$ the exterior linear term, written in real auxiliary Gaussian coordinates X. The inner integral uses the real variable B, with Gaussian density of covariance C_σ and the multiplier $\exp(-\langle B, \Gamma_\sigma X\rangle)$. The cut-parameter contours complexify C_σ and Γ_σ. The potentials in the integrand are still evaluated at B with the factor χ_{Y_0}, and each Mayer contour multiplies its potential by a scalar. Take the potential bound on the support of χ_{Y_0} before enlarging the Gaussian domain for the modulus estimate. The determinant and Gaussian bounds then justify continuation on the same real integration space. Thus the small factor from the first localization is available on the contours used to form the ordinary Mayer activities.

Scale the marked activities together by a complex parameter. If their norm is ε_m, the unused activity margin gives a disc of radius proportional to ε_m^{-1} on which the localized output has the usual uniform decay bound. Subtract its value at zero and apply the Schwarz estimate at one. This makes the output proportional to the marked activity norm in the same weighted family. The bound for this contribution is therefore

$$C\sigma_k \sum_{j \in J_{\mathrm{rec}}(k)} w_{k,j} g_j^{\kappa_0},$$

where $w_{k,j}$ is the squared ratio with the enlarged radius of this step in the numerator. The amplitude bound uses the remainder's own analyticity domain for each read. The Mayer bound uses the same cut on every marked read and the activity margin uniformly on the admitted source disc. With the running-radius estimate $w_{k,j} \le C(k+2-j)$, the sum of these ratios is at most $C(1+\#J_{\mathrm{rec}}(k))^2$. To bound the band length, take $u = \lceil C(1+\log\log x_k)\rceil$ with the constant large enough. The flow gives $x_{k-u} \le x_k + C'(1+u)$ when $k \ge u$. Then $M\check{R}_{k-u} \le L^{u+1}$ by the logarithmic bound on $\check{R}$. Thus $k-u$ has already reached the ageing test. The grid rule $\check{R}_i \le L\check{R}_{i+1}$ implies $L^i\check{R}_i \le L^{k-u}\check{R}_{k-u}$ for $i \le k-u$, so those levels have reached it as well. If $k < u$, the whole list has length at most

u. The reference flow then gives $g_j^{\kappa_0} \le C g_{k+1}^{\kappa_0}$ throughout this band. For the native reference radii the sharper comparison is

$$w_{k,j} = \tfrac{9}{4}\,\frac{x_j}{x_k}\left(\frac{\log x_k}{\log x_j}\right)^{2q}.$$

Here the numerator uses the radius enlarged by $1+2\beta_s$ at input level k. The adjacent-scale room puts the actual output space with radii $(1+\beta_{\mathrm{pr}})\alpha_{k+1}$ inside this space, using $(1+\beta_{\mathrm{pr}})\alpha_{k+1} \le (1+\beta_s)\alpha_{k+1} \le \hat{\alpha}_k$ componentwise. Since $x_j = x_k + O(1+k-j)$ in the band, $w_{k,j} \le 3$ at small coupling, so this reference estimate costs only a single power of the band length. For $q > \mathfrak{p}_0$, even the running-radius bound with the squared count tends uniformly to zero after multiplication by the fluctuation factor.

Each contribution is at most $g_{k+1}^{\kappa_0}/2$ at weak coupling. Both bounds use the native enlarged remainder charts. In the recent term the running shifts are the functions of the single bare constant source on its disc. The marking parameter is independent of that source. The healed term is holomorphic by the majorized resummation, and the recent term by the fixed-domain fluctuation expansion. Restrict their output to the running remainder radii when taking the inherited norm. The sum has norm at most $g_{k+1}^{\kappa_0}$ on the constant-source disc, so the next frozen integral can use it as inherited data. For this application the actual formation and norm domains must agree with the native ones.

The inherited family also needs the common-lift and symmetry properties. Compare the partial maps on the same local field arguments, using the same reference sequence, local operator terms, weights, source, increments and inherited lists. For coherent input, the earlier lists are determined on their own read sets by the standing history. In this history the healed components have already been integrated out. The remaining large-field regions are nested into the current complement, so the standing trace on an interior window is empty. The trace uses one layer of the label cells at each relevant level. On a carrier with this window inside Λ_{k+1}, the local data are those of the all-small-field history. This identifies the inherited coefficients as functions on the common domain. An evaluation in the actual history uses its own local field argument. A common non-wrapping lift transports the walk terms, cutoffs and inputs by a translation preserving their grids. The cluster logarithm and the filing therefore give the same coefficient on the lift. At a real constant source, evaluate on the backgrounds of the common hereditary window of very regular block fields. For isometries preserving the level-$(k+1)$ label cubes, the density obtained by summing the histories with the all-small-field label and the regular integral with its aged inputs are invariant. In the quotient of these densities the carried background factors are invariant too, since the new label cubes are unions of the older ones. Remove those factors and normalize at the trivial field. The quotient is now the exponential of the vacuum-subtracted new total. Its exponents at a field and at its isometric image are real and therefore equal. Holomorphy extends that identity to the connected constant-source disc on the same backgrounds.

When a remainder of origin j first enters the regular integral at step $k \to k+1$, the ageing rule gives $M\check{R}_j \le L^{k+1-j}$. Both lengths are powers of L on the nested grids. Thus the origin cube side divides the spacing of a level-$(k+1)$ block in origin units. Coarse unit translations and the coordinate isometries preserve the origin cube partition. The invariance of the earlier total therefore suffices for its use in the regular integral of this step.

For the strip estimate in the healed contribution, measure lengths in localization cubes of side M. Work on the class of boxed components of Z separated by at least $\check{R}_k$ cubes.

First consider the plain values in the input of the strip estimate. For a value unit v with carrier K_v, adjoin the full components of Z sharing a cube with K_v to obtain its filing domain Y_1. This leaves $Y_1 \setminus Z = K_v \setminus Z$. A tree for K_v meets every cube of $Y_1 \setminus Z$, so $d_Z(Y_1) \le d_k(K_v)$. For an

exterior Y_1, fix a cube $\Delta \subset Y_1 \setminus Z$. Every carrier in the fibre contains Δ, giving the bound

$$e^{ad_Z(Y_1)} \left\| \sum_{v:\, Y_1(v)=Y_1} \mathrm{val}_v \right\| \le \sum_{v:\, K_v \supset \Delta} e^{ad_k(K_v)} \|\mathrm{val}_v\|, \qquad a = 31\kappa/20.$$

Thus one needs a weighted sum at a cube outside Z. This first filing spends no decay and introduces no factor for the size of a component of Z.

The current chain values filed at $m < k$ are confined to a single component of Λ_k^c, by connectedness and $\Omega_{m+1}^c \subset \Omega_k^c \subset \Lambda_k^c$. A carrier of this kind meeting Z stays in Z. For those filed at k, the stage norm at $8\kappa/5$ bounds the column at rate a by $C_0^\sharp$ per stage. The current chain therefore costs at most $N(g_k)C_0^\sharp$.

For the plain top-level values left by an earlier arrest, put $j = k - s$, $s \ge 1$. Their native carrier X meets Ω_k^c. If its coarse closure $\bar{X}$ meets both Z and its complement, it crosses the collar between Ω_k^c and Λ_k. Consequently

$$d_j(X) \ge (2\check{R}_k - 1)L^s, \qquad d_k(\bar{X}) \le L^{-s} d_j(X) + c_{\mathrm{tr}}.$$

Coarsening spends at most $31\kappa/60$ of the native rate $8\kappa/5$, leaving $13\kappa/12$. Use the resulting factor $e^{-\kappa \check{R}_k L^s}$ and sum the native weighted sizes over the L^{4s} fine cubes in Δ. The stored values are a subsum of their birth-stage norm, which already sums the formed terms over the components of that stage. In this count each formed term is taken once. The bound over all stages and ages is thus

$$C_0^\sharp e^{ac_{\mathrm{tr}}} \sum_{s \ge 1} N(g_{k-s}) L^{4s} e^{-\kappa \check{R}_k L^s},$$

where the sum uses only existing earlier levels. The reference flow gives $N(g_{k-s}) \le C(\log x_k + c_s)^{r_{\mathrm{pr}}}$ with $c_s = O(\log(2+s))$. The width bound $\check{R}_k \ge (\log x_k - 1)^{r_{\mathrm{pr}}}$ bounds this count by $C(2+c_s)^{r_{\mathrm{pr}}} \check{R}_k$ for $\log x_k \ge 2$. Since $\check{R}_k \ge 1$, one has $\check{R}_k e^{-\kappa \check{R}_k L^s} \le 2(e\kappa L^s)^{-1} e^{-\kappa L^s/2}$. This bounds the contribution uniformly in k and the coupling. At the final stage, a lower-filed term whose carrier reaches bonds adjacent to an arrested piece must also satisfy the collar test if it enters the exterior column. When its native carrier passes this test at level $\ell < j$, use the birth-stage norm at $4\kappa/5$ and coarsen from ℓ. The spare rate is at least $17\kappa/60$, so its stage contribution is bounded by $CL^{4t} e^{-17\kappa \check{R}_k L^t/60}$, with $t = k - \ell$. At this filing level there are at most t earlier birth steps and at most $C(2 + c_t)^{r_{\mathrm{pr}}} \check{R}_k$ stages at each step. The collar factor sums these terms by the same absorption.

The change-of-variables terms of an earlier arrest use their own filing level $\ell < k$. Set $t = k - \ell$. Their connected exterior domains X meet their stage band inside Ω_k^c, so $d_\ell(X) \ge (2\check{R}_k - 1)L^t$. After coarsening, a native pointwise rate of $4\kappa/5$ leaves $17\kappa/60$. In using this pointwise estimate we must count the birth blocks even when several terms have the same localization domain.

For terms carrying their stage-cover anchor in X on the filing grid, there is at most one term per cover block, and the bands of simultaneous arrests are disjoint. At a fixed birth step and stage the number of such blocks for X is therefore at most a fixed multiple of $1 + d_\ell(X)$, by the cube count for a tree meeting X. The same bound applies for anchors in a fixed-width enlargement on this grid. The share $\kappa/20$ of the spare rate sums the rooted domains with this additional linear factor. The remaining $14\kappa/60$ pays the collar, and the L^{4t} fine roots in the coarse cube give a stage bound of the form

$$CL^{4t} \exp(-\tfrac{14}{60} \kappa \check{R}_k L^t).$$

There are at most t possible earlier birth steps at this filing level. Their stage counts are bounded by $C(2 + c_t)^{r_{\mathrm{pr}}} \check{R}_k$. Thus the sum over $t \ge 1$ is uniform by the same exponential absorption as for the top-level values. For a cover on a different grid we must show that its localization still has this anchor count in filing units, or use its own rooted norm before summing the scales. For the bond-indexed terms of an interrupted change of variables, the bound on each bond term gives

its size on the admitted chart. We must also identify the localized carriers and show the required tree-length decay on them.

The two kinds of stored boundary terms use different carriers. The boundary term formed in the **T**-operation has a pointwise bound at rate at least 2κ on its native domain. At $j = k$, the spare rate $2\kappa - a = 9\kappa/20$ sums the domains through the fixed root. At an earlier level $j = k - s$, the same coarsening bound leaves $89\kappa/60$. Spend $\kappa/20$ on the rooted native domain count and use the collar to bound the rest. With $\kappa \geq 10 \log L$ and $L \geq 3$, the remaining $86\kappa/60$ pays the L^{4s} fine roots and leaves $e^{-\kappa \check{R}_k L^s}$ for the sum over ages.

The boundary term formed in the **R**-operation is stored on its relative label, whose coarse image serves as the filing carrier. At the filing site the term is from an earlier level $j = k - s$, since the new one is formed after filing. Its label meets an earlier strip or zone inside Ω_k^c. For an exterior value the label therefore crosses the same collar. On the label the stored rate is at least κ, and coarsening spends at most $31\kappa/60$. Of the remaining $29\kappa/60$, use $\kappa/20$ for the rooted label count and split the rest into two equal parts. The first pays the fine roots since $\frac{13}{60}\kappa L^s \geq 4s \log L$. The second gives the summable factor $e^{-13\kappa \check{R}_k L^s/60}$. The skeleton fibres are summed when the stored terms are formed. This estimate uses their resulting bounded prefactor and the decay on the labels.

For a chain term with a nonempty decoupling bracket, the original filing level supplies the rate before the bracket enlargement. At the current level the rate $8\kappa/5$ leaves $\kappa/20$ after allocating a to the original carrier. At a lower level $j < k$, coarsening leaves $4\kappa/5 - 31\kappa/60 = 17\kappa/60$ in level-j units. The fixed prefactor $e^{ac_{\mathrm{tr}}}$ goes into the constant paid by the inverse localization parameter of the bracket estimate. The added decoupling carriers are charged in that estimate.

For the terminal, renormalized, tail and boundary rows of the size table, keep the point anchor when taking the weighted domain sum. In a zone n, set $u = L^{j-n}$ for an anchor of level $j \leq n$. The $O(u^{-4})$ fine points in a zone cell use up the u^4 in a short piece or a local Wilson term. For a short boundary piece, the anchor must lie in a slab of thickness $O(1 + n - j)$ fine units around a zone face. The slab count is $O((2 + n - j)u^{-3})$, leaving $(2 + n - j)u$ after the size is inserted. For an old tail the lower bound on its diameter supplies u^5 from the spare decay, so the same fine-point count leaves u. The frozen core has the extra power $u^{\hat{\alpha}}$ with $\hat{\alpha} > 0$, and the defect row has $L^{-(k-j)/2}$. The renormalized remainder row uses its admitted weighted sum over levels after the u^4 and fine-point count cancel.

In the rooted column the weight $7\kappa/4$ spends at most $7\kappa/12$ in level-j units when $j < k$. At $j = k$ the ordinary rows present there have the improved rate 2κ. After the rooted domain count and diameter factors, keep $e^{-\delta\kappa d_j(X)/4}$ for the point anchors. For anchors in the current zone, use the per-cell scale sums and then sum over cells. There are at most $(2i+3)^4$ cells in a current cube shell of radius i, and a domain reaching the root from this shell has length at least $(i-1)_+$ in its native units. For a unit born at $j = k - s < k$ with anchor in an old zone, the domain must cross the collar as well. One can split the remaining exponential into two halves and use $d_j(X) \geq (2\check{R}_k - 1)L^s$ in one and the distance from the anchor to the root in the other. In current units there are at most $C(ML^s)^4(2i + 3)^4$ fine anchors in a shell of radius i, and the distance bound in fine units is at least $L^s(i-1)_+$. The shell sum is bounded by a constant times L^{4s}, which is summable in the ages against the retained collar factor. These estimates use the assigned sizes and their native anchor domains, including the domains of the subtracted copies.

The short singles and the Wilson terms across the boundary use an enlarged filing label $\mathrm{lab}_1 = K_v \cup \mathfrak{h}_v$, where $\mathfrak{h}_v$ covers the additional reads. Write c for the fixed bound on $d_k(\mathrm{lab}_1) - d_k(K_v)$. For these terms split the filed value into the uncut value, which is charged at the size in the table, and its difference from the cut value. The carrier estimate bounds the absolute difference by $\mathfrak{N}^\flat(v)$ on the admitted cut chart, including when all decoupling families are empty. To use this estimate we must verify that the auxiliary consumer lies in its filing domain and is admitted on the cut chart.

For the exposed units in this exterior column, their point lies in a level-k collar cell or in a level-k cell next to the treated boundary on the Ω_k side. The cell weight there is 3. For such a cell Δ', the sum of $\mathfrak{N}^\flat(v)e^{(a+9)d_k(K_v)}$ over its point anchors is bounded by $27\mathsf{K}^\flat$ by the per-cell estimate at $a+9 \le 8\kappa/5$. If the enlarged label contains the exterior root Δ, its connectedness gives $d_k(K_v) \ge (i-1-c)_+$, where i is the cube distance between Δ' and Δ. Therefore even at the activity weight $a+8$ the cost of summing the difference over the anchors is at most

$$27\mathsf{K}^\flat e^{(a+8)c}\sum_{i\ge 0}(2i+3)^4 e^{-(i-1-c)_+}.$$

The constant is uniform in the coupling and in the level. This sum uses the location of the exterior point anchors. At an anchor beside a foreign arrest window the per-cell estimate uses its window weight. The amplitude Cauchy estimate for a pointed piece supplies the extra factor there, even for its continuation with all subsequent cut families empty.

For the terms with cut families, keep a connected label A and a separate read set $\mathcal{R}$ at each link. If Δ is a cut cell, let $\rho(\Delta)$ be the smallest size of a connected cut family joining it to a source cell. Here source cells are the designated cells adjoining the exempt boxes. The first link for plain interior terms cuts only cells disjoint from $\Lambda^\sim$, and links two to four leave cells meeting Λ uncut. Each contributing connected component of a cut family contains a source cell and meets the reads, with a source cell at a box meeting the reads also counted. The latter condition allows the cell's current parent to be at distance up to $c_\rho\rho(\Delta)$ from A. For a read already in the label this distance is at most one. At an exempt box it is bounded by the box diameter. At the rim of a component already met by the label it is at most $100\check{R}_k+1$, and the nearest source box is at distance at least $9\check{R}_k$ from the rim. At the first plain interior link the read set is $X_v \cup \hat{X}_v$ in the treated component. Cells eligible there are current cells. Their parents are within one cube of K_v, or within the hub diameter plus one for a source cell seeing the reads across a hub. These bounds apply on the separated geometry. At each link we must check them for the actual reads, including reads along a live strip.

Apply the fundamental theorem of calculus separately in each nonexempt cut variable. The term with all cut families empty is the value at the zero cuts. In every other term use the mixed derivative in precisely the selected variables, integrated over their real intervals. Cauchy on the common product polydisc of radius e^{κ_1} gives a factor $e^{-(\kappa_1-1)}$ per selected variable, since the circle at a point of $[0,1]$ can have radius up to $e^{\kappa_1}-1$. For a boundary-type term use its supremum on this chart. For a pointed term one can subtract the comparison value, which is constant in the cut variables, and use the smaller difference bound. For an interior term with reads deep in the core, the depth estimate gives the additional factor $Ce^{-\delta_P\hat{D}_v/4}$, where $\hat{D}_v$ is the depth of the read hull. The mixed Cauchy argument requires one product domain for the whole cut family and the source. In the first two background comparisons of the terms with reads off Z, we must check this domain by the lower-layer membership induction on the actual auxiliary carrier, including any portion inside the treated component. The sealed cut discs for the later comparisons apply at their own background layers.

At a link with family y, the new label is the old label joined to the current parents of the selected cells. Add the connecting cubes to the label and across the exempt boxes used by the family. A connected part with n cells reaches the old label by a corridor of length at most $c_\rho n$, and the bridges across its boxes cost a bounded number of cubes per cell. Thus the new tree length is at most $d_k(A)+c_l|\mathsf{y}|$ with c_l fixed. To sum at weight r, spend $c_l r$ per selected cell, leaving $\lambda_r = \kappa_1 - 1 - c_l r$ for counting. A connected family through a cell at depth t in the grid has at least $t+1$ members if it reaches a source. If it sees the reads from a current parent at distance x, it also has at least x/c_ρ members. Thus the exponential reserve pays both the L^{4t} fine cells in a parent and the polynomial shell count in x, as well as the exponential count of connected families through each cell. With the lower bound on λ_r, the sum for one connected part is at most a small constant times the number

of cubes of A. The sum over unordered sets of parts is bounded by the exponential of that sum. The constant can be chosen so the resulting factor is at most $e^{d_k(A)+1}$.

For a sum rooted at a prescribed cube, distinguish whether that cube is in A or in the addition. In the first case, after summing the other parts, one more unit of the old-label weight supplies the distance from the root to the parent of the cell seeing the reads. The reach correction costs at most $c_\rho \rho(\Delta)$, which is paid by the connected-family reserve. In the second case, mark a connected part of size n responsible for the root. A parent of one of its cells lies within $c_\rho n$ of the root. There are at most $O((1+n)^4)L^{4n}$ choices of parent and fine cell, and exponentially many connected parts through that cell. One of its n cells sees the reads. The factor $e^{\rho(\Delta)}$ to recover the reader sum costs at most e^n, so the same reserve sums over the marked parts. Finally the readers seen from Δ have a label cube among $O((1+\rho(\Delta))^4)$ candidates. The factor $e^{-\rho(\Delta)}$ in their sum absorbs this count and reduces it to the ordinary rooted label norm. Write Q_r for the supremum over a root cube of the sum of the assigned sizes times $e^{r d_k(A)}$ over the labels A through that cube. Thus a link, including the empty family, satisfies

$$Q_r(\text{after the link}) \le (1 + C_\Sigma C_e)\, Q_{r+2}(\text{before the link}),$$

where C_Σ is the count for the two root positions and C_e bounds the number of nearby label cubes with its $e^{-\rho}$ weight.

After the last link, fill in the components of Z that meet the final label. This adds no cube off Z, and a tree for the label bounds $d_Z(Y_4)$. A nonempty cut term filed off Z has both a source cell at distance at least $9\check{R}_k - 1$ from Z^c and an exterior cube in its connected label. Its length is therefore at least $\check{R}_k - 2$. Spend one unit of the final weight to extract $e^{-(\check{R}_k - 2)}$. Summing in reverse link order gives the rooted bound at weight a from the input rooted norm at $a+9$ for the four links of the plain interior terms, and at $a+7$ for the three cut links of the plain exterior terms with no amplitude. Choose the cut radius with $\kappa_1 - 1 \ge c_l(a+9) + \lambda_*$, where λ_* the counting threshold. The plain interior input uses the shallow column and the depth-weighted column in the core. For the exterior input, the root of the intermediate sum may lie inside Z. Choose an exterior cube on the same initial label and spend one more unit of weight to sum its distance from that root. This uses the size column at $a+8$, including the exposed difference estimate on its enlarged label. The two bounds are a polynomial in $\log x_k$ times the collar gain.

For a compact point-anchored amplitude piece p, the input to the later links has label $K_p \cup \mathfrak{h}_v$ and reads the domain $Y_0(p)$. Keep its amplitude disc of radius $\rho_A = \mathsf{w}_L/(\eta_p \mathsf{f}_v)^{1/2}$ throughout these links, where η_p is the decay to the amplitude block and f_v the decay from the point's window to the source region. On the common product chart, amplitude Cauchy contributes $2/\rho_A$ to the dilated size, and the cut variables have their own factors $e^{-(\kappa_1 - 1)}$. The factor $\mathsf{f}_v^{1/2}$ pays the cubic window weight in the pointed size column. The factor $\eta_p^{1/2}$, with a reserve from the first cut family, sums the possible amplitude blocks in shells around the cells already reached. This sum is made over the pieces behind one coarse root, retaining their actual zone and cut-cell levels. It gives a bound proportional to w_L^{-1} for the input rooted norm. Three further links and the transfer to an exterior input root use at most seven more units of weight. The small factor is already in the amplitude column, including its empty continuation.

The chain and long terms grouped into bundles use the sum over blocks and fine cells in the term's own grain before the three later links. For a bundle the comparison disc acts on that sum. The small factor belongs to the resulting rooted bundle norm. For a wrapped term of level j, let A_v be its connected label and $K_v = [A_v]_k$. Its true read consists of A_v and the attached older strips, each touching A_v. An attached strip healed at this step lies in the core of a treated component, and the adjacent label cube lies in that component's inner box. A strip that stays live is separated from the treated components. Thus the true read meets Z exactly when K_v does. When filing a value, adjoin the treated components met by K_v. This already includes all the healed strips read

by the term. For analytic evaluation also include the live strips touching the label in the enlarged background domain. In the integration over a treated component, the fields on the older live strips are parameters. Two polymer factors that share only these parameters factorize in that integral. Hence the older live strips are background reads and the connected label is what enters the length and compatibility tests.

In the cut expansion, keep the actual read at each link. It consists of the original reads, the previously selected cells and their touched boxes, with the rim of the preceding domain as an overestimate. A cell on a live strip is eligible for a cut under the same exemption rule as the other cells. Its parent is within $101\check{R}_k + 1$ of the old label, while a family from that strip to a source has size at least $10\check{R}_k$. The analogous rim estimate allows one more cube. This pays the corridor from the cell to the label by $c_l|\mathsf{y}|$. The rest of the live strip need only be adjoined to the background read domain. We must check that the global chain stays in the joined chart for the stored wrapped term, using inherited tubes on live strips and containment on healed strips. Keep the twist in the common admitted source slot and take the stored norm on the complex orbit domain, since contour gauges can be complex. On that product chart the same mixed Cauchy bound applies to each tuple of the composed layer, current and gauge readers, including one whose only cut is at the first link. At the third layer the support test applies to the primitive current entering its inverse.

For a term with the whole read in a core, if all cut cells stay in Z, each connected family seeing the reads stays in the same component. Its parents and connecting cubes stay in that box. Induction over the four links then keeps the final label inside the component. Thus an exterior tuple of such a term triggers the core depth estimate, and its assigned size in the exterior sum is the stored size times $C_{3F}e^{-\delta_P d^\wedge(X_v,\mathsf{C}_C^c)/2}$, with X_v the true read and C_C the core. Use the unmodified stored size for the other wrapped terms. The depth factor is assigned only in the majorant for exterior tuples.

There is a separate count for the initial wrapped reads. Let $\mathsf{b}_k(s)$ bound the weighted label column at native level $k-s$, with the spare native rate for labels finer than the probing cell. If the read through a cell of level n comes from an attached strip of level m, count labels of level $j \geq m$ by a cube touching that strip. At level j there are at most $(s_j+3)^4$ such cubes, where s_j is the strip side in those units. Since $s_j \leq 101\check{R}_m$, this count has no factor for the fine volume of the strip. A native probe meets at most 2^4 live strips, all with $m \geq n$. For a read through the label itself, use the native meeting convention for unlike levels, which requires a common interior point. The levels $j \geq n$ have a bounded number of anchor cubes per level. At $j < n$ the label must reach from the probe to an older strip. With $t = n - j$ the spare rate bounds the fine-anchor count by a constant times $L^{4t}e^{-c(L^t/2-2)_+}$. These are the two parts of the read count for a fixed probe. On the native cut geometry, $k - n + 1 \leq \rho(\Delta)$. For a cell contained in a live strip, a minimal path to a source must leave the birth-scale collar of width $5\check{R}_m/2$. Before its first source it takes no hub jump, and in that collar each cell spans at most one birth unit. In particular $\check{R}_m \leq 2\rho(\Delta) + 2$. Multiplying the read count by $e^{-\rho(\Delta)}$ absorbs its powers of the age and strip side and bounds the reception sum by $C_{\mathsf{a}}(1)\mathsf{b}_k(0)$. For a source cell seeing the read through an exempt box, its contribution is instead bounded by $h_\sharp^4 Q^\star_{a+9}$, where $h_\sharp$ bounds the box side and $Q^\star$ is the rooted norm for terms meeting Z with the assigned sizes above.

The first-link family includes an empty choice for a term meeting Z. A term disjoint from Z enters through one of four successive background differences, each with a nonempty first family. Use the reception bound for the nonempty first families, with at most four copies. The next three links use the two-unit weight estimate. For an exterior final label the collar length is at least $\check{R}_k - 2$. For a label reaching a live strip this follows from its reach to Z, supplied by a source cell if the original term was disjoint. Otherwise the label reaches from an inner box of a treated component to an exterior cube. Spending one unit of weight yields the exterior rooted bound

$$e^{-(\check{R}_k-2)}(1+C_\Sigma C_e)^3\big[(1+4h_\sharp^4 C_\Sigma)Q^\star_{a+9} + 4C_\Sigma C_{\mathsf{a}}(1)\mathsf{b}_k(0)\big].$$

For $Q^\star$, labels joining a live strip to the treated region already have a collar length in their own units, which pays the number of fine roots. Shallow labels attached only to healed strips are counted through the core on the native grids, using the collar for levels finer than its rim level. Deep labels use the depth factor when summing the core cells. For the deep count, assign the depth to a cell whose closure contains a point realizing the least distance to the core rim and whose interior meets the read. Use half of its depth weight to pay the probe count, and sum the remaining half by the core shell estimate. Its prefactor is the area of the core rim box, with side at most $104L\check{R}_{h+1}+2$ in level-h units. Here h is the level of the cells on the inner side of the core rim. These counts bound $Q^\star_{a+9}$ by a polynomial in the stage count and the radius at the core rim. The weighted column, depth estimate and joined chart must hold for the actual stored terms in this format before using the bound.

In the total pre-filed family, separate the ordinary values, the brackets, and the source-free remainder of the Wilson expansion. The all-empty term of an ordinary exterior unit is a value. A plain interior term whose domain stays inside its component goes into the interior volume sum. The first-link amplitude term and its later nonempty continuations count in the same amplitude budget, with each tuple charged once. The nonempty wrapped terms have their own budget. The Wilson family here consists of the action remainders after removing the explicit source-weight term at fixed background. The background arguments remain those of the chain. File the treated-component cell terms at their native anchors, the terms depending on the whole component at that component, and the terms in Ω_k off Z at their exterior cubes. Each resulting cut tuple belongs to the Wilson family alone. Use the absolute exterior bound and the summed strip bound $1+c_I M^5$ for this family from the Wilson localization estimate in Bałaban, Comm. Math. Phys. 122 (1989), pp. 374–375, (1.66)–(1.68). The bound for the denominator term $I(U_0)$ in (1.11) is charged once per component. To use these bounds, the localized Wilson family must agree with the one in that estimate on the admitted backgrounds.

For the Wilson cell terms of a treated component, the local bound follows from

$$a(W) = -\tfrac{1}{2}\,\mathrm{tr}_{\mathrm{norm}}((W-1)^2W^{-1}),$$

where $\mathrm{tr}_{\mathrm{norm}}$ is the normalized trace. If the plaquette increment at a level-n cell is at most $\widehat{\theta}(\eta/\ell_n)^2$, the plaquette count cancels the fourth power of η/ℓ_n in the density. Here η is the fine spacing and ℓ_n the spacing of the cell's grid. The bound on a cell with action coefficients at most x_n is $6M^4x_n\widehat{\theta}^2$. In the core subtract the value at zero cut parameters with the real rim datum fixed. Plaquettes entirely in zone zero cancel because the two backgrounds have the same datum there. For the other plaquettes the linearized holonomy difference is a covariant first difference of the displacement around the plaquette, with a term proportional to $1-\mathrm{Ad}_W$. The latter has an extra curvature factor. The commutators in the product of the four bond exponentials are quadratic in the displacement. Thus if the scaled displacement bound is B at the cell, the plaquette difference is at most $CB(\eta/\ell_n)^2$. The quadratic density identity then bounds the cell oscillation by $CM^4x_n(\widehat{\theta}B+B^2)$. The admitted exponential depth estimate for B makes this sum proportional to the core boundary count. Off the core use twice the cell bound and count the preparatory shells. These two counts give a polynomial in $\log x_k$ for the Wilson cell descendants. Four links give those descendants leaving Z the same collar gain as other plain interior terms. This estimate for the cell descendants supplements the absolute bound for the full Wilson family.

Thus the exterior input norm is bounded by the sum of the value bound, the bracket bound, and the Wilson bound. Once their admission has been verified, the plain interior and exterior cut estimates take one half of the bracket budget, the amplitude terms take one half, and the wrapped terms take one, for a total bound of two.

Use the prescribed disjoint strips $C^\sharp$ of width $m=\lfloor(\check{R}_k-1)/2\rfloor$ about the separated components C of Z. A pre-filed domain Y_4 is wall-connected and meets Z in a nonempty union of full components. File its term on Y obtained by adjoining every strip that shares a cube with Y_4. This

partitions the terms into fibres and preserves the sum. The true reads are inherited from the terms in each fibre, including the enlargement of any wrapped read.

For an exterior output Y, filing adds no outside-strip cubes, so all preimages share a root cube there and a relative tree for Y_4 also meets every cube of $Y \setminus Z^\sharp$. Thus $d_\sharp(Y) \le d_Z(Y_4)$. A wall path in Y_4 from Z to the outside of $Z^\sharp$ visits an exterior cube touching Z and an exterior cube at distance m from Z. A relative tree meets both cubes. The distance to Z changes by at least $m-1$ between the two points, so the tree has length at least $m-1$. With $b = 3\kappa/2$ and $\lambda = \kappa/40$, the input rate $a = 31\kappa/20 = b + 2\lambda$ therefore gives

$$e^{-ad_Z(Y_4)} \le e^{-bd_\sharp(Y)} e^{-\lambda(m-1)} e^{-\lambda d_Z(Y_4)}.$$

To count preimages of length at most n, traverse a relative tree twice and cut the walk into arcs of length at most one. Each arc meets at most 3^4 cubes, so the cubes met by the tree form a touching-connected family of $O(n+1)$ cubes through the root. A depth-first walk on this family gives exponentially many choices in $n+1$. Select the outside cubes among them, then select the full components of Z incident to the selected cubes. Every component in the preimage is incident to an outside cube, by wall connectedness and separation of the components. Each outside cube is incident to at most 3^4 components. This count sums the last factor in the fibre when λ exceeds its entropy rate. Thus the exterior strip amplitude is at most $C\|\mathfrak{v}\|_a e^{-\lambda(m-1)}$, where $\|\mathfrak{v}\|_a$ is the weighted exterior input norm. The interior fibre of $C^\sharp$ is the sum of the inputs contained in that strip and uses a volume bound. With no prescribed exterior root the free-family sum at a single link costs $e^{d_k(A)+1}$. Applied backward four times starting at weight zero, it gives $e^{4(d_k(K_v)+1)}$ times the assigned plain size. The bound for a wrapped unit, with its value included, has the additional factor four for the possible first brackets. The four units of tree-length weight are available at the unit's native rate, with a fixed coarsening offset absorbed in the constant.

For the running chain choose one anchor in the filing-level stage region of each term. At a given stage and anchor the weighted sum is the corresponding stage-norm sum. At a cell of zone n, the bound on the number of such stages grows as $1 + \log(1 + \log x_n)$, using the running stage count and $x_n \ge x_k - 2c_2$. Charge the other ordinary terms at the old determining cells of their zones. A window cell coarsened by e levels has at least L^{4e} distinct old cells to charge. This absorbs its cubic window weight, bounded by $27\mathsf{L}_0^{6(e+1)}$, since $\mathsf{L}_0^2 \le L/3$. For a frozen chain make this charge at its own pre-arrest cells. A level-m stage anchor meeting its band contains a cell of the band grid, and distinct anchors at that level contain distinct band cells. If $j+1$ is the band level, the number of band cells is at most a constant times $\check{R}_{j+1}^4 \sum_X (d'_{j+1}(X) + 1)$, where X runs over the band-containing components. The number of possible filing levels is bounded by a constant times $\check{R}_{j+1}$. Thus the frozen volume allowance is a sum of $\check{R}_{j+1}^5 (d'_{j+1}(X) + 1)$ over the stages and components of that arrest. The count uses the actual native anchor and band inclusion for the stored terms.

An exterior bracket filed wholly inside $C^\sharp$ reaches a cube of $C^\sharp \setminus C$. Charge it there using the exterior rooted sum, which is at most one per cube for the plain exterior brackets. Add the ordinary value allowance on those strip cells and one Wilson allowance for the entire component. This bounds the sum over all inputs contained in the strip. The finite filing preserves holomorphy on the common admitted source tube. The exterior gain absorbs the polynomial logarithmic factors in the pre-filing bound, including those from the Wilson vertices. Since the width grows at least as a fixed positive multiple of $(\log x_k)^{r_{\mathrm{pr}}}$ with $r_{\mathrm{pr}} > 1$, its gain beats every fixed inverse power of x_k, also after taking the cube root of the amplitude.

To pass from the filed potential to the healed remainder, fix the standing part of the history. Let W be the union of the strips of components that stay as second-class regions in this operation. Their variables are parameters in the healed sum. Keep their tests, group delta factors and component integrals outside that sum. A term on a single strip is local to its own component and is included in that component's operation. For the other domains, write the exponential as $1 + (e^{V^\sharp(Y)} - 1)$

at each domain Y. In a summand the integrations run over the chosen healed components. Each interaction factor reads the integration variables of a chosen component only if its domain includes that component's strip. A connected class consists of the touching parts off W, also joined whenever one interaction domain reads more than one of those parts. Each chosen healed component belongs to exactly one class. The class factors therefore multiply at fixed exterior data. Conversely, classes with disjoint and nontouching parts off W can be assembled by taking their union, by the locality of the history format. This gives a hard-core gas whose empty family has value one. For a nonempty healed set the term with no exterior interactions still contains the component masses. The class activity sums the compatible internal choices of healed components and interaction domains with that class's domain. Use the component operation of § 4.17 with its original measure factors, tests and internal history sum. Its localized action on the indicated reads is needed for the factorization.

For the component mass in this argument, keep the stored integration coordinates real on the supports of their original tests. In the inner Wilson factor the field assembled from these coordinates is unitary, while the source changes its weight. Let c_j be the unshifted nonnegative coefficient including its cutoff, and c_j^w the shifted coefficient. On the admitted source tube $\operatorname{Re} c_j^w \geq (1-\theta_W)c_j$ with $\theta_W \leq 1/4$. Plaquette by plaquette, $a_p(U) \geq 0$ for the real stored field, so

$$\left|e^{-A(c_j^w,U)}\right| = e^{-A(\operatorname{Re} c_j^w,U)} \leq e^{-(1-\theta_W)A(c_j,U)}.$$

This comparison also applies inside the nested component operations. In particular each Wilson test gain retains the fraction $1-\theta_W$ of its real exponent. The exterior pair can be complex. The quadratic form depending on it uses its source-independent complex-form estimate. The other quadratics, tree constraints, Jacobian factors and tests keep their real integration data. The sourced strip interaction is bounded by the exponential of its supremum on the same chart. Its ordinary value budget is charged to the original cells, and the frozen contribution to the stage cells of its arrest. The strip collar adds a fixed volume factor. The additional weights of the inner real fluctuation integrals use their per-cell bounds. For an unmatched counterterm on the regular part of its cutoff collar, the action on a native cell has modulus at most $C\varepsilon(\gamma)^2$. The source bound on its coefficient is $b_+ + 2r_{msrc}/3$ on the disc of radius $2r_{msrc}$. Thus its modulus costs at most e per native cell once $(b_+ + 2r_{msrc}/3)C\varepsilon(\gamma)^2 \leq 1$. Include that cost in the existing per-cell allowance. This yields a majorant before integrating the stored coordinates.

For a new region detected by a refused rim bond at level j, keep the corresponding gain from the constrained quadratic form. If the full form has lower bound γ_0, so does its Schur complement on the retained coordinates: minimizing $\langle (y,x), \mathcal{A}(y,x)\rangle$ over the discarded coordinate y gives at least $\gamma_0\|x\|^2$. With $\mathfrak{b}_j = g_j^{-1}\delta_j$, the rim test forces $|x_b| \geq \mathfrak{b}_j/(4\Theta_1)$ at each refused bond b. Spend one quarter of the quadratic form on the test gains and retain the other quarter in the density. The resulting factor at each such bond is $e^{-\gamma_0\mathfrak{b}_j^2/(64\Theta_1^2)}$. Its first square root pays the sum over refused-bond sets. At fixed ordinary test region each set is counted once and the sum is bounded by a product of $1 + e^{-\gamma_0\mathfrak{b}_j^2/(128\Theta_1^2)}$ over rim bonds. The other square root gives an exponent of at least $\gamma_0\mathfrak{b}_j^2/(256\Theta_1^2)$ per covered cube, since each bond covers at most two. The ordinary fluctuation tests use disjoint witnessing coordinates in this split. The rim gain therefore joins the Wilson and ordinary fluctuation gains in the cascade bound, and its cost is charged at its own level.

The cascade charge estimate uses the cover by the coarsened predecessor regions and the current test witnesses, including the cubes of the refused bonds. Write $\mathsf{P}_n = p_0(g_n)$ and Q_n for the common gain per created cell after setting aside the refused-bond count. For a created region H of level n, the cell count satisfies $d'_n(H) + 1 \leq \sqrt{4}\,|H|_n$, where $|H|_n$ is its cell count. Split $\mathsf{Q}_n|H|_n$ into halves. One half gives the deposit $\mathsf{Q}_n(d'_n(H)+1)/(2\sqrt{4})$ and the other leaves $2\mathsf{P}_n$ when $\mathsf{Q}_n \geq 4\mathsf{P}_n$. In unrolling the charge recursion, a quiet successor spends its current charge from the balance. A re-created successor adds its new test gain P_n before spending its charge. A join collects the predecessor balances and the birth deposits and releases the older creation reserves other than the

one at the earliest birth of the joined region. Thus each member keeps the balance and one oldest reserve of $2\mathsf{P}_{j_0}$. With the positive balance on the admitted family and the internal history count paid in the per-level charges, the exponent retains that reserve at the final component. Compare $p_0(g_{j_0}) \geq p_0(g_k)/(1+\beta_0)$ along the reference flow. In the complex modulus estimate there is one remaining factor e, giving the bound

$$|\mathbf{T}'_k(X;w)F| \leq e\, e^{-2p_0(g_k)/(1+\beta_0)} \sup |F|.$$

The supremum is on the internal support at fixed external data. For a product of compatible healed component operations use this bound successively, provided the admitted chart and the support bounds are valid with the other integration variables fixed. The same integrable majorant permits holomorphic integration of the analytic factors. To apply this estimate we must identify the actual real Wilson arguments, witnesses, charge family and common complex chart for the component integral. These checks concern the stored histories that enter the gas.

Let A denote one activity domain and $d_{\mathrm{out}}(A) = d_W(A)$. The tree for A off W is formed from the relative trees of its chosen interaction domains and a path through the cube centers of each chosen healed strip. A path in a rectangular strip of N_h cubes has length at most N_h in cube units. Join these trees and paths along a spanning tree of the class graph, at cost at most $2\sqrt{4}$ per join. The number of cubes off W is bounded by the sum of the N_h's and a constant times $\sum_Y (1 + d_\sharp(Y))$. Thus in the input rate $(1+2\beta_s)\kappa$ one can allocate $(1+\beta_s)\kappa$ to the output length, half of $\beta_s\kappa$ to the cube count and the other half to counting the interaction domains. If $\alpha^\sharp$ is the exterior strip amplitude, spend one third of its logarithm per chosen interaction to pay the fixed join and cube-count costs. For a healed component the modulus bound pays for the strip, whose cost is at most $2\kappa(100\check{R}_k)^4$ per box. The positive coefficient $2/(1+\beta_0) - 3/2$ at $\beta_0 \leq 1/7$ gives the room for this cost and the sourced modulus prefactor. With the degree ceiling the remaining factor is $e^{-3p_0(g_k)/2}$ per chosen healed component.

At fixed healed components the remaining interaction weights have the form $u_Y = (\alpha^\sharp)^{2/3} e^{-\beta_s \kappa d_\sharp(Y)/2}$. Every interaction domain contains an exterior cube off the strips used by that summand. The rooted domain count bounds $\sum_Y u_Y$ by a constant times $(\alpha^\sharp)^{2/3}$ times the number of cubes off W in A. If the interaction family is nonempty, $\prod_Y (1+u_Y) - 1 \leq (\sum_Y u_Y) e^{\sum_Y u_Y}$. Keep a factor $(\alpha^\sharp)^{1/3}$ and bound the remaining prefactor by an exponential in the cube count. The same count pays the exponential from $e^{V^\sharp(Y)} - 1$. The resulting cube penalty is small compared with the allocated cube-count decay. A class containing a strip in W necessarily has a nonempty interaction family, so it has the cube-root factor.

A class disjoint from W contains at least one healed component, since each interaction meets a component of that summand. This includes the class consisting of one healed strip and an empty interaction family. Extract $e^{-p_0(g_k)}$ from the product of the component factors and use the remaining $e^{-p_0(g_k)/2}$ per component for counting. Each candidate box is specified by its lowest cell and four bounded integer side lengths. At fixed A, the number of unordered sets of q such boxes is bounded by the q-th power of the candidate count divided by $q!$. The resulting exponential in the number of cubes is paid by the remaining volume decay. Thus the activities have rate $(1+\beta_s)\kappa$ in d_{out}, with amplitude $e^{-p_0(g_k)}$ off W and $(\alpha^\sharp)^{1/3}$ when they meet W.

For the logarithm only connected incompatibility graphs contribute. On a connected cluster the relative trees join at the touching cubes off W, with at most $2\sqrt{4}$ of extra length per edge of a spanning tree. Reweight each activity by $e^{(1+\beta_s/2)\kappa(d_{\mathrm{out}}(A)+2\sqrt{4})}$. The remaining $\beta_s\kappa/2$ in the length pays the exponential count of domains through a cube and the exponential of their cube count in the polymer criterion [KP86]. Indeed, each incompatible domain contains an exterior cube touching one of the cubes of the given domain off W, and for each such root the weighted series is bounded by a constant times the maximum activity amplitude. For weak coupling that constant times the maximum is small, giving the criterion with size equal to the number of cubes off W. To bound

the logarithmic coefficient at a fixed union, mark a cube of the union off W. Each cluster has at least one polymer covering it. Summing the mark over the polymer indices changes the factor $1/n!$ into $1/(n-1)!$ with the marked polymer first. The rooted cluster majorant then sums the other polymers and leaves the weighted rooted sum of this first polymer. In particular, for a union disjoint from W its amplitude is $e^{-p_0(g_k)}$. The logarithm is absolutely convergent on the admitted complex domain and the output decay rate is $(1+\beta_s/2)\kappa$.

Classify the resulting domains using the one-layer enlargements of the standing large-field region and the newly retained second-class components. Away from them the output length is d_k and the prefactor is $Ce^{-p_0(g_k)}$. The spare $\beta_s\kappa/2$ pays the rooted sum at rate κ, giving the healed contribution to the inherited remainder bound. The other terms are new boundary terms. Their bound uses the relative length off W; the prefactor can be taken as a fixed multiple of the larger of the two activity amplitudes. To store them on relative labels, sum the domains having a given skeleton. The count contributes $e^{\lambda_\theta(d_k(A)+1)}$ for the skeleton A, and $\lambda_\theta \le \beta_s\kappa/4$ leaves the stored rate $(1+\beta_s/4)\kappa$. This last step uses the skeleton length comparison and the relative-format bound for the actual complex charts.

The dimension-free polydisc lemma, Lem. A.14, gives on the half polydisc

$$\sum_i r_i|\partial_i F| \le \tfrac{4}{3}\sup|F|, \qquad |F(z)-F(z')| \le \tfrac{4}{3}\sup|F|\max_i |z_i - z_i'|/r_i. \tag{5.lvii}$$

One proves it by sending a single unit disc through the point with coordinate disc automorphisms, choosing their phases to align the derivative terms, and applying the one-variable Schwarz inequality. Integrating the derivative bound on the segment gives the second formula. Neither bound contains the number of earlier levels. Neither implies age forgetting: the bounded function $F(z) = Bz_0/(\sigma_\star\theta_0)$ already has a nondecaying weighted derivative in its first coordinate.

Here is the needed forced derivative estimate, including the marked term. Let $b_i' = db_i/d\beta$, $M_i = \max_{0\le j\le i}|x_j'|$, with $x_0' = 1$. The frame is fixed, so $z_j' = -x_j'$. The tube constants and coupling floor put these evaluation points in the half polydisc required in eq. 5.lvii. Since $\min_{j<i}\theta_j \ge \theta_{i-1} - c_5 \ge \theta_{i-1}/2$ above the floor, eq. 5.lvii and the separate bare-disc Cauchy estimate imply

$$\begin{aligned} &|b_i'| \le a_i M_{i-1} + d_i, \\ &a_i \le C\theta_{i-1}^{-3/2}(\log\theta_{i-1})^{\mathfrak{p}_0}, \quad d_i \le C\varrho^{-1}\theta_{i-1}^{-p_R}. \end{aligned} \tag{5.lviii}$$

The θ^{-1} factor in a_i is the unmarked independent-polydisc gain. The factor $1/\varrho$ in d_i comes from the actual bare-variable disc and must not be replaced by $1/\theta_i$.

Put $V_i = 1 + \sum_{l\le i}|b_l'|$. The differentiated recursion gives $M_i \le V_i$, and hence

$$V_i \le (1+a_i)V_{i-1} + d_i, \qquad \sum_{i=1}^K |b_i'| \le e^{A_K}(1+D_K) - 1, \quad A_K = \sum_{i=1}^K a_i, \quad D_K = \sum_{i=1}^K d_i. \tag{5.lix}$$

Indeed iterating the scalar inequality gives $V_i \le \prod_{l\le i}(1+a_l) + \sum_{l\le i} d_l \prod_{m=l+1}^i (1+a_m)$; each product is at most e^{A_i}. No triangular estimate for the physical field response is hidden in this one-dimensional calculation.

On the reference line, integral comparison yields, uniformly in K,

$$A_K \le Ch^{-1/2}(\log h)^{\mathfrak{p}_0}, \qquad D_K \le C\varrho^{-1}h^{1-p_R}. \tag{5.lx}$$

The condition $p_R > 1$ is exactly what makes the second bound uniform over all depths for a fixed bare-disc radius. For the original full Lipschitz numbers one may now take $\mathsf{a}_{[K-i]} = (4/3)a_i + d_i$, once the uniform slope bound below is imposed. Thus

$$\sum_{s<K} \mathsf{a}_{[s]} \le C\{h^{-1/2}(\log h)^{\mathfrak{p}_0} + \varrho^{-1}h^{1-p_R}\}. \tag{5.lxi}$$

The sharper original $O(g(\log g^{-2})^{\mathfrak{p}_0})$ rate follows when $p_R \geq 3/2$, in particular in the intended large-κ_0 regime. For merely $p_R > 1$, retain the general forced rate displayed here. Choose h large enough that $e^{A_K}(1+D_K)-1 \leq 1/3$. Then $|x'_j - 1| \leq 1/3$ at every admitted prefix. On real intervals, $2/3 \leq x'_j \leq 4/3$. The statement is uniform only where the analytic inputs and room conditions hold. It does not identify different frames.

The stronger independent marked-coupling polydisc route in the comparison appendix remains available separately. Under its actual hypotheses the marked row has order $\theta^{-p_R-1}\log^C\theta$; it is not the premise used in eq. 5.lviii–eq. 5.lx. Both routes require their actual domains. In particular a fixed physical-source disc alone does not supply the unmarked independent-variable gain.

Canonical tube and conditional tuning theorem 3.2. For a general finite reference sequence of length $n \geq 1$, the largest permitted tube is

$$\mathsf{t}^*_j = \min_{1\leq t\leq \min\{j+1,n\}} \mathsf{t}^\sharp(\theta_t). \tag{5.lxii}$$

This is just the combination of all preceding upper bounds and the requirement that tube radii do not increase with the level. For $n = 0$ the largest radius is instead $2\mathsf{t}^\sharp(\theta_0)$. The exponent q_{t} and the coefficient ϖ are the ordinary tube constants, not an insertion rate. The floor is chosen with $h \geq e^{2q_{\mathrm{t}}}$ and $c_5/h \leq 1$ when the terminal comparison is used. A constant-tube criterion follows by setting $\mathsf{K}(a) = \max\{1, (4a/e)^a\}$, with $\mathsf{K}(0) = 1$. Maximizing $t^a e^{-t/4}$ gives $(\log y)^a \leq \mathsf{K}(a)y^{1/4}$ for $y \geq 1$. In particular $\mathsf{K}(2q_{\mathrm{t}}) = \max\{1, (8q_{\mathrm{t}}/e)^{2q_{\mathrm{t}}}\}$. If the frame floor is $x_\star \geq e$ and $\mathsf{K}(2q_{\mathrm{t}})t \leq \varpi x_\star^{3/4}$, then

$$t \leq \frac{\varpi y^{3/4}}{\mathsf{K}(2q_{\mathrm{t}})} \leq \varpi y(\log y)^{-2q_{\mathrm{t}}} \qquad (y \geq x_\star). \tag{5.lxiii}$$

Thus the constant sequence of radius t is a tube; its criterion uses the floor rather than the frame length. On the line in eq. 5.liii, set

$$\begin{gathered} \iota_k = \epsilon_k + \epsilon'_k, \qquad T_K = \varrho + c_2, \qquad T_k = T_K + \sum_{j=k}^{K-1} \iota_j, \\ F_k(\beta) = \theta_k - x_k^\natural(\beta) + s_k, \qquad \widehat{\mathsf{t}}_k = T_k + c_2 + 2R', \qquad R' = 4\varrho. \end{gathered} \tag{5.lxiv}$$

This is the canonical tube: in depth notation $T_{[s]} = T_{[0]} + \sum_{u<s}\iota_{[u]}$. The correction by s_k removes the bounded one-loop oscillation, giving $|F_{k+1} - F_k| \leq \iota_k$. The accumulated drift satisfies $\sum_{j=k}^{K-1}\iota_j \leq C\theta_k^{1/2}(\log\theta_k)^{\mathfrak{p}_0}$ in the stated power regime. For sufficiently large h, uniformly over K and k, this and the fixed additive terms are smaller than $\varpi\theta_{k+1}(\log\theta_{k+1})^{-2q_{\mathrm{t}}}$. The same holds at the terminal convention. Thus $\widehat{\mathsf{t}}$ is an admitted tube. The choice is made after ϱ, not by shrinking the prescribed offset range as K grows.

We spell out the domain premise needed by the interval argument. At a prefix satisfying $|F_j| \leq T_j$, the actual array is defined with room $2R' = 8\varrho$. The next coefficient is formed using that prefix before the new large-field operation. The uniform bounds and the marked bare-disc hypothesis above apply on a neighborhood of every such prefix. Whenever the computed next value satisfies $|F_{k+1}| \leq T_{k+1}$, the next array closes with the same room. These are the actual prefix formation/closure hypotheses, not consequences of the scalar intermediate value theorem.

Define $I_0 = \{\beta : |F_0(\beta)| \leq T_0\}$. Since $F_0 = \theta_0 - \beta$, this is a compact interval mapped decreasingly onto $[-T_0, T_0]$. Choose the floor so all its initial weights are admitted. Inductively suppose I_{k-1} has this property for F_{k-1}, and every earlier prefix lies in its required room. The preceding domain premise defines b_k, hence F_k, on a neighborhood of I_{k-1}, even before restricting its new output to the target window. eq. 5.lviii–eq. 5.lx make $F'_k = -x'_k$ strictly negative there.

At the left endpoint, $F_{k-1} = T_{k-1} = T_k + \iota_{k-1}$, so $F_k \geq T_k$. At the right endpoint the corresponding inequality is $F_k \leq -T_k$. Continuity supplies unique points with values T_k and $-T_k$, and

strict monotonicity orders them. Their intervening compact interval

$$I_k = \{\beta \in I_{k-1} : |F_k(\beta)| \le T_k\} \tag{5.lxv}$$

is mapped decreasingly onto the whole target interval. On it $|\theta_j - x_j| \le T_j + c_2$ for $j \le k$, leaving room $2R'$ in eq. 5.lxiv. The actual closure premise therefore permits the induction to continue. This proves existence and connectedness of the interval from the closure premise.

At K, $x_K = h + s_K - F_K$. Since $|s_K| \le c_2$, its image contains every x with $|x-h| \le \varrho$. Each such value has exactly one preimage in I_K. Let $\gamma_U \le \gamma_J \le \gamma_H$ impose the preceding conditions for the fixed ϱ, with γ_J also imposing the admitted source analytic domain. For every K and $0 < g \le \gamma_U$, the conditional tuning theorem is

$$x_K^\natural(\beta_K^\natural) = g^{-2}, \qquad \tfrac{1}{2}c_0K - c_5 \le \beta_K^\natural - g^{-2} \le \tfrac{3}{2}c_0K + c_5. \tag{5.lxvi}$$

The common companion makes this the same number on every admissible torus. Uniqueness has been proved in the admitted canonical interval, not among arbitrary disconnected presentations at all bare couplings. Also $|\beta_K^\natural - h - c_0K| \le 2c_2 + \sum_k \iota_k$. The single-run spacing estimate is

$$\tfrac{1}{2}c_0(j-i) - c_5 \le x_i^\natural - x_j^\natural \le \tfrac{3}{2}c_0(j-i) + c_5 \qquad (0 \le i \le j \le K). \tag{5.lxvii}$$

It follows by summing $|b_l - b_l^0| \le c_0/2$. It gives eq. 5.lxvi, but gives no bound between the tuned numbers for two different cutoffs.

The bare offset t and terminal coordinate x are distinct: $x_K^\natural(\beta_K^\natural - t) = h - t + O(c|t|)$ when the slope error is at most c. The reference frame is independent of β; the self-calibrated frame $\theta_j = x_j(\beta)$ and its frozen shifted run are other applications of the uniform prefix induction. For a constant source ζ, the frozen shifted weights are $x_j(\beta) - \zeta_j$, and their slope normalization is $x_j'(\beta)$. Identifying this derivative with a particular F3 witness still requires that witness's admitted run and comparison hypotheses.

A finite nontriangular comparison lemma. The stronger two-run route uses an estimate different from eq. 5.lix. Fix integers $n \ge 1$, $0 \le r_0 < n$, numbers $0 < \rho < 1$, $\Pi, \mathsf{M} \ge 0$, nonnegative y_w for $r_0 < w \le n$, and nonnegative D_u, $k_{u,w}$, h_u, h' for the finite indicated ranges. Put

$$S_w = \frac{\rho^{n-w+1}}{1-\rho} + (w - r_0)\Pi. \tag{5.lxviii}$$

Suppose, for $r_0 \le s < n$ and $r_0 \le u < n$,

$$\begin{aligned} y_{s+1} &\le \sum_{u=r_0}^{s} D_u, \\ D_u &\le \mathsf{M}(\rho^{n-u} + \Pi) + \sum_{w=u+1}^{n} k_{u,w} y_w, \\ \sum_{w=u+1}^{n} k_{u,w} S_w &\le h_u S_{u+1} + h'\Pi, \qquad \sum_{u=r_0}^{n-1} h_u + h' \le \tfrac{1}{2}. \end{aligned} \tag{5.lxix}$$

Then $y_{s+1} \le 2\mathsf{M}S_{s+1}$. Indeed $S_w > 0$ and increases with w. Let $Z = \max_{r_0 < w \le n} y_w/S_w$, a finite number. The forcing sum is at most $\mathsf{M}S_{s+1}$. The kernel sum is at most

$$Z\left(\sum_{u=r_0}^{s} h_u S_{u+1} + (s - r_0 + 1)h'\Pi\right) \le \tfrac{1}{2}ZS_{s+1}. \tag{5.lxx}$$

Taking the maximum gives $Z \le \mathsf{M} + Z/2$, as claimed. The sums couple a difference to later depths, so this is weighted-max absorption, not a triangular recursion. Its actual profile-kernel bound in eq. 5.lxix remains a substantive two-run input. Bounds on increments alone do not establish that input.

Statement 3.6: real presentations of the same measure. A real presentation over a frame is an actual inductive array whose weights remain in the tube. At each level it carries one Euclidean member, with one scalar coefficient common to all sites and no defect, and one shift c_j. These shifts obey the admitted $\bar{c}$ bound, with the frame floor chosen in terms of $\bar{c}$. Members, companions and coefficients are independent of the admissible torus and real at real fields. The all-small-field label is the label whose regions fill the torus. In its exponent the action coefficient is $x_j - \mathsf{c}_j$. The weight actually used in the Gaussian step is x_j, and $\mathsf{c}_j A$ is carried in the local action. A spatially varying source array with defects is not a presentation of this special kind.

Write $b_j = x_{j-1} - x_j$, let $\widehat{b}_j$ be the coefficient actually extracted at step j, and set $u = \mathsf{c}_0$. Coefficient bookkeeping gives

$$\mathsf{c}_j = u + \sum_{l=1}^{j} (\widehat{b}_l - b_l), \qquad x_j - \mathsf{c}_j = x_{j-1} - \mathsf{c}_{j-1} - \widehat{b}_j. \tag{5.lxxi}$$

In particular $\widehat{b}_j$ need not equal the planned decrement b_j when the shifts vary with the level.

The comparison hypothesis is equality of the all-small-field measures at every level, on every admissible torus, for two real presentations over the same frame. Require hereditary open windows $\mathfrak{O}_m \ni \mathbf{1}$ of block fields: their backgrounds lie in every needed core, all the relevant tests equal one, and $\mathcal{M}^i U_m(V) \in \mathfrak{O}_i$ when $V \in \mathfrak{O}_m$ and $i < m$. Also require the common connected analytic fluctuation domain on which continuation from such a window to the next actual integral is used. These are properties of the actual maps and tests.

Under these hypotheses the conclusions are

$$\begin{aligned} x_j - \mathsf{c}_j &= x'_j - \mathsf{c}'_j, \\ \widehat{b}_j &= \widehat{b}'_j, \\ \sum_X (E^{(j)} - E'^{(j)})(X, U) &= \tfrac{3}{2} |\mathfrak{X}_{j-1}| \log(x_{j-1}/x'_{j-1}). \end{aligned} \tag{5.lxxii}$$

The first line holds through level n, and the coefficient equality through $n+1$ only when both presentations admit that next step. The total identity is evaluated at backgrounds $U = U_m(V)$, $j \le m \le n$, of the common windows. On those backgrounds the remainder totals agree, and the vacuum constants agree. When the total suppresses z, $E^{(j)}(X, U) = \sum_{z \in X} E^{(j)}(X, P_U, z)$. No assertion identifies individual localized terms of the two presentations.

Here is the induction. At the bare level equality identifies the effective weight $\beta - u$, since the action is not a constant function. On an open small-field window the positive continuous densities agree everywhere if they agree almost everywhere, because product Haar measure has full support on the open window. Their logarithmic exponents are real, so their equality involves no integer ambiguity. Analytic continuation on the admitted fluctuation domain therefore identifies the next unnormalized integral. The normalized Gaussian in each presentation uses that presentation's own weight. Its normalization has the term $-3|\mathfrak{X}_{j-1}| \log(x_{j-1}/\theta_{j-1})/2$. It follows that the next regular totals differ by the field-independent constant displayed in eq. 5.lxxii. The common-companion sum rule makes their extracted coefficients equal. eq. 5.lxxi then identifies the next effective weights. The same physical formation identities on the hereditary windows identify remainder totals and the once-counted vacuum constants. This completes the induction. It uses all-torus compatibility to extract a coefficient from a constant total; one finite torus alone is insufficient.

Apply the result to a real β whose prefix along θ has room 2ϱ, and a real $|\zeta| < \varrho$ for which both constructed presentations are admitted. One presentation starts at $\beta - \zeta$ with no shift; the other starts at β with constant source ζ and running shift ζ_k. The exact identity is

$$x_k^{\theta}(\beta - \zeta) = x_k^{\theta}(\beta) - \zeta_k. \tag{5.lxxiii}$$

The slope bound keeps the running shift at most $4|\zeta|/3$ in its stated range. For $\theta = x(\beta)$, this describes the frozen shifted run, not the self-calibrated run of $\beta - \zeta$. For the reference line it identifies the two presentations of $x_k^\natural(\beta - \zeta)$.

Complex gluing also uses one frame. First restrict the real centres to the canonical interval I_K constructed above, or to one of its admitted prefix intervals. Each source disc is supplied by the actual analytic source construction. Where a real point in that disc also belongs to the canonical interval, eq. 5.lxxiii identifies its continuation with the real run. If two discs about such centres overlap, their real overlap contains an open interval in I_K: the segment between the centres lies in I_K, and the open real disc intervals overlap along that segment. For coincident centres at an endpoint, a one-sided open interval inside the nondegenerate I_K suffices. The identity theorem therefore identifies the coefficient functions on the full complex overlap.

The union carries a single holomorphic bare-coupling function. Remainder totals on common windows glue likewise; regular totals glue after accounting for their explicit Gaussian constant. This proves uniqueness of the supplied continuations, not their original bounds or radii.

For arbitrary admitted real centres, every overlap used for gluing must contain a common open interval of admitted real runs, or the prefix/source-disc construction must prove real admission there. This condition requires a separate proof when the admitted real set has disconnected components. Geometric intersection of two discs alone does not settle it. With the stated admission property the same identity theorem proof applies. Nothing here identifies runs made with different frames, individual localized terms about different centres, or functions on independent-current cores from equality only on a physical graph.

5.2.4. *Units, common prefixes and change of reference.*
Statement 3.7: the finite dilation identity. For every integer b with $K - b \geq 0$ and $L^b\ell$ in the compatible torus family, the map $D_b x = L^b x$ identifies the bare lattices at (K, ℓ) and $(K - b, L^b\ell)$. For negative b use the inverse of the corresponding positive relabeling. The exact result of § 5.1 is

$$\begin{aligned} Z_{K,\ell,\beta}(w) &= Z_{K-b,L^b\ell,\beta}(w^{[b]}), \\ S^T_{n;K,\ell,\beta}(\underline{f}) &= S^T_{n;K-b,L^b\ell,\beta}(\underline{f}^{[b]}), \quad f^{[b]}(x) = f(L^{-b}x). \end{aligned} \tag{5.lxxiv}$$

There is no spacing prefactor in $\mathcal{O}(f) = \sum_p f(x(p))a_p$. The map transports bonds, plaquettes and Haar variables bijectively; both sides are the same finite integral. The partition identity is entire in its finite source variables and bare coupling. Logarithmic derivatives use its nonzero domain. The same transport identifies periodic Gibbs states on the two infinite lattices. Radii and distances multiply by L^b, $\operatorname{Lip} f^{[b]} = L^{-b} \operatorname{Lip} f$, and $\|f^{[b]}\|_\sharp \leq \max\{1, L^{-b}\}\|f\|_\sharp$. The free bilinear form is invariant. This proves neither convergence nor agreement of two RG constructions.
Statement 3.8: what the step reads. Construction naturality is the additional assertion that step k reads only its actual tower through k, partitions, frame and weight prefixes, earlier outputs and fixed supply rules. Those rules are made for the lattice, not for its unit of length. For two presentations of the same bare lattice, their images under D_b therefore identify the histories and their measures, regions, healing data and local nonwrapping terms through level $K - b$, provided the prefixes agree. This is required for both fixed-frame and self-calibrated runs. Separate arbitrary choices on the two lattices would not establish it.

For a self-calibrated run this permits continuation from first passage at g to first passage at g', provided the prolonged run remains below the anchor ceiling and the rescaled torus is admissible. Its history law through the earlier level is unchanged. For reference runs, $\theta_{[r+s]}(g) = \theta_{[r]}(g_{[s]})$; the prefix at g, down to depth s, is the reference run at $g_{[s]}$ of length $K - s$, on $T_{L^s\ell}$. Its deviations, increments and tube are the same. The implication $\ell \in \mathfrak{L}(g) \Rightarrow L^s\ell \in \mathfrak{L}(g_{[s]})$ uses the stated torus floor and parameter choices. Here the needed scalar comparison is $R(y + c_0) \leq LR(y)$ for $y \geq h$ above the chosen floor; it is a comparison of the function R, whereas a general run uses its running-minimum values $\check{R}_j$.

Keep the beyond-first-passage scope separate. If $\beta \in \mathcal{W}_{K'}(g)$ and $K = K' + q$, $q \geq 0$, then eq. 5.lxxiv identifies the cutoff-K measure with the first-passage measure on $T_{L^q\ell}$. Estimates for it require $L^q\ell \in \mathfrak{L}(g)$. A torus volume factor becomes $\exp[nc_V(L^q\ell)^4]$, whereas a per-ball estimate has its radius and separation changed to L^qR, L^qd and no side dependence in its constant:

$$|S^T_{n;K,\ell,\beta}(\underline{f})| \leq A(L^qd; L^qR)B(L^qR)^n(n!)^{\varkappa_\star} \prod_i \|f_i\|_\sharp. \tag{5.lxxv}$$

The stated lower torus floor for that bound also applies. For $q < 0$, use the identity in reverse, require $L^q\ell \in \mathfrak{L}(g)$, and allow a norm cost at most $L^{|q|}$ per test. Applying this to tuned offsets requires the separate comparison $|K(\beta^\natural_K - t, g) - K| \leq C(\varrho)$. It does not follow from tuning at a frozen frame.

Statement 3.9: all four reference-change targets. Let

$$S^{[t]}_\ell[g] = \lim_K S^T_{\cdot;K,\ell,\beta^\natural_K(g)-t}, \qquad \mathsf{J} = [-\varrho/4, \varrho/4]. \tag{5.lxxvi}$$

Existence along the whole sequence, its common complex offset strip and moving-offset continuity require E3 and the terminal-coordinate comparison in appendix A.8. The strip width and the cutoff floor may depend on the fixed torus. The coordinates are

$$\Xi_K(t) = x^\natural_K(\beta^\natural_K - t), \qquad \Xi_{\infty,s}(t) = \lim_K x^\natural_{K-s}(\beta^\natural_K - t). \tag{5.lxxvii}$$

The depth limit requires the matched comparison. Terminal matching uses $n_K = \Xi^{-1}_{K+1} \circ \Xi_K$ on its admitted common strip. Its near-identity and summable-error properties remain E3 hypotheses, not consequences of the existence of individual tuning inverses. First choose ϱ large compared with $c_2, B_\sharp + 1$ and a bound for the tuned increments; then choose g small. The bound for those increments is a two-run comparison requirement fixed before ϱ, not a consequence of one-run spacing.

(i) At fixed depth s, the same bare coupling has two offset labels:

$$\begin{aligned} \widehat{t}_{K,s} &= \beta^\natural_{K-s}(g_{[s]}) - \beta^\natural_K(g), \\ \beta^\natural_K(g) - t &= \beta^\natural_{K-s}(g_{[s]}) - (t + \widehat{t}_{K,s}). \end{aligned} \tag{5.lxxviii}$$

Require the actual two-run estimate $|\widehat{t}_{K,s}| \leq C(c_2 + \sum_{K-s\leq j<K} \iota_j)$, its summable cutoff increments, and the comparison domain on which both presentations exist. The initial comparison requires $2c_2 + \sum_{K-s\leq j<K} \iota_j \leq \varrho$; a smaller fixed fraction of that bound keeps the offsets in the inner window. For g small in terms of the fixed s, these offsets lie in $\frac{1}{2}\mathsf{J}$ and converge to $\widehat{t}_s$. The whole-sequence moving-offset limit then gives

$$\begin{aligned} S^{[t]}_\ell[g](\underline{f}) &= S^{[t+\widehat{t}_s]}_{L^s\ell}[g_{[s]}](\underline{f}^{[s]}), \\ \widehat{t}_{s+s'}(g) &= \widehat{t}_s(g) + \widehat{t}_{s'}(g_{[s]}). \end{aligned} \tag{5.lxxix}$$

Here $t \in \frac{1}{2}\mathsf{J}$; each depth condition must hold at its displayed reference coupling. The condition on g is an upper bound, never a lower bound. The terminal coordinate on the right is the limiting depth coordinate $\Xi_{\infty,s}(t)$. Its existence belongs to the matched comparison.

(ii) For arbitrary sufficiently small g, g' and $t \in \mathsf{J}$, retain the stronger target that some $t' \in \mathsf{J}$ and integer b satisfy

$$S^{[t]}_\ell[g](\underline{f}) = S^{[t']}_{L^b\ell}[g'](\underline{f}^{[b]}). \tag{5.lxxx}$$

Its torus conditions are both $\ell \geq \ell_\star(g)$ and $\ell \geq L^{(|g'^{-2}-g^{-2}|+C)/\lambda_\sharp}\ell_\star(g')$. The sign of b is that of $g'^{-2} - g^{-2}$, up to a bounded ambiguity. The number of intervening passage levels lies between $|g'^{-2} - g^{-2}|/B_\sharp - 1$ and $(|g'^{-2} - g^{-2}| + C)/\lambda_\sharp$; $|b|$ differs from it by $O(1)$. This assertion needs recognition of the same bare run in both calibrated families, not merely eq. 5.lxxiv.

(iii) Choose once an anchor $0 < \gamma_\star \le \gamma_J$, sufficiently small in terms of the fixed large-field window dials w, c_a. For any proposed $\mathbb{R}^4$ limit at $g \le \gamma_\star$, retain the prolonged-run target: after a subsequence, $K(\beta_j, \gamma_\star) - K_j = s_\star$ is constant, of order $g^{-2} - \gamma_\star^{-2}$, and

$$S_n(\underline{f}) = S'_n(\underline{f}^{[-s_\star]}). \tag{5.lxxxi}$$

The anchor limit uses the same bare-coupling sequence. eq. 5.lxxxi is the exact image under the point map $x \mapsto L^{s_\star} x$, expressed by the test $f^{[-s_\star]}(x) = f(L^{s_\star}x)$. No extra spacing factor is inserted in the observable. This preserves the target for arbitrary defining sequences carrying the required construction and recognition hypotheses. It does not give an automatic mirror/cone theorem for unrestricted growing-torus limits. Dilation-invariant properties need be checked at only one reference coupling once this target is established.

(iv) The bare tuned increments $\alpha_K = \beta^\natural_{K+1} - \beta^\natural_K$ are a new notation, unrelated to the field radii. The proposed conclusion is

$$\alpha_K \longrightarrow c_0, \qquad S^{[t]}_\ell(\underline{f}) = S^{[t-bc_0]}_{L^b \ell}(\underline{f}^{[b]}) \quad (b \ge 1,\ t, t - bc_0 \in \mathsf{J}). \tag{5.lxxxii}$$

For completeness the shape convention is $\mathfrak{T}_{\mathbb{R}^4}(d;\vartheta)$: both profiles are nonnegative nonzero Lipschitz functions supported in radius-d balls, with support distance in $[d, 6d]$, and each obeys $\int f \ge \vartheta d^4 \|f\|_\infty$ and $\operatorname{Lip} f \le \|f\|_\infty/(\vartheta d)$. Clause (iv) retains the condition $\mathfrak{T}_{\mathbb{R}^4}(1;\vartheta) \ne \emptyset$ and $g \le \gamma_W(\vartheta)$. The proof also needs the actual uniform smooth-profile envelopes on the pairs used in its iteration; class nonemptiness by itself is not an envelope estimate. The comparison appendix proves this implication with the actual two-run depth/profile estimates, summable comparison errors and uniform two-point envelopes. Those envelopes are uniform in the offsets and tori needed for repeated blocking; the fixed shape class must be nonempty. Two distinct cluster increments would give an offset period by analyticity, and repeated blocking would contradict the uniform short-distance envelopes. The unique increment limit is then c_0 by the averaged one-loop law. The same argument yields $\beta^\natural_{K+b} - \beta^\natural_K \to bc_0$ for every fixed integer b. The exact input hypotheses remain in force; finite dilation and weak numerical inequalities do not establish them.

Vacuum constants and the interfaces used later. The vacuum recursion is eq. A.lxvi of appendix A.8. Each assigned step number, Gaussian local number and regular/remainder value at $P_\circ$ is counted once. Using the normalized N requires adding its removed local numbers; using N° does not. At fixed calibration these numbers have zero source derivative. They are not additional freely chosen normalizations.

The further vacuum estimates required are

$$\begin{aligned} \log(\mathsf{c}_k(\theta_k) Z^{(k)}(\mathbf{1})) &= \mathsf{N}^{(k)} + \sum_X \sum_{z \in X} \mathsf{n}^{(k+1)}(X, z), \\ \mathsf{n}^{\mathrm{tot}}_k &= 36 N_{k+1} \log L - \tfrac{1}{2} \log\det(\mathsf{C}^{\mathsf{T}} \Delta^{(k)} \mathsf{C})|_{\mathbf{1}}, \quad |\mathsf{n}^{\mathrm{tot}}_k| \le C N_{k+1}, \\ \mathsf{n}^{\mathrm{tot}}_0 &\le -3(L-1)^4 N_1 \log 2 < 0. \end{aligned} \tag{5.lxxxiii}$$

Here N_j counts sites, c_k is the actual change-of-variable normalization and $\mathsf{N}^{(k)}$ is the free-bond/coarse-site count, with $-3 \log \theta_k/2$ per free bond. The map C is the actual linear embedding of nonpivot coordinates into full constrained fluctuations; this determinant is on the free color coordinates. It is not the covariance $C^{(k)}$. The local numbers are Gaussian values before normalization, real and coupling independent, with common nonwrapping lifts and the Gaussian domain bound. Their coefficients vanish. The count alone is not the entire step number. The determinant estimates and first-step sign in eq. 5.lxxxiii remain actual Gaussian targets, beyond the once-only accounting identity.

The explicit leading vacuum requirement is

$$\left| E_{K,\ell,\beta} + \tfrac{3}{2}(N^2-1)(L^4-1)\sum_{j=0}^{K-1}(\log x_j)N_{j+1} \right| \le CN_0, \tag{5.lxxxiv}$$

uniform in the admitted runs, tori and cutoffs. It is not proved merely by naming a field-independent constant.

Choose the constants in the following order. Fix the geometric exponents and L, with the Gaussian constants and one-loop data; then choose κ above the domain entropy, the required lower block scales and M. Choose $\sigma_\star$, absolute radii below c/M, $K_{\mathbf{M}}$, and $E_0 \ge \max\{2E_{\mathsf{N}}, 4K_{\mathbf{M}}\sigma_\star\}$. Next choose $N_\star$, the ceiling on s, the unmarked constants, C_β and the weak triple. Compute the marked-load and tube constants at that triple before choosing γ, the strong triple, γ_H and the smaller drift ceiling. The source radius and comparison windows have their stated place before the final smallness of g. Only then are ℓ, β, K varied. Each claimed uniformity depends on respecting this order.

For the germ comparisons, let $\mathfrak{P}_n(d;\vartheta)$ consist of real Lipschitz tuples with disjoint supports in one ball of radius $5d$, satisfying $\operatorname{Lip} f_i \le \|f_i\|_\infty/(\vartheta d)$. For $n = 2, 3$, a modulus (C, r_0) for $\sigma \approx_n \sigma'$ means

$$|(\sigma - \sigma')(\underline{f})| \le Cr^{4-n}\prod_i \|f_i\|_\infty \quad (0 < r \le r_0, \quad \underline{f} \in \mathfrak{P}_n(r;\vartheta) \cap C^2). \tag{5.lxxxv}$$

A comparison for every C^1 tuple is stronger and implies this one on the C^2 subclass. The converse requires its own density argument with the stated shape bounds. Transitivity adds the constants and takes the smaller radius. If $(\mathsf{T}_b\sigma)(\underline{f}) = \sigma(\underline{f}^{[b]})$, the modulus becomes $(L^{(4-n)b}C, L^{-b}r_0)$, directly by substitution. This accounts for the factor in an anchor comparison and keeps the smoothness quantifiers of the short-distance input explicit.

Later applications use the following hypotheses. Beyond-first-passage data use eq. 5.lxxv; prolonged runs use statement 3.8; fixed-depth reference prefixes and terminal coordinates use eq. 5.lxxix. The germ/rigidity route in the comparison appendix also carries its own shape and second-difference hypotheses. In the anchor unit its correlation constants acquire $L^{-(4-n)s_\star}$. Blocking and distinct-member comparisons use eq. 5.lxxxii, not just a relabeling of K. The sub-unit cells of the angular route keep their separate moment, mirror and ultraviolet interfaces. The ordinary interacting source construction, clean-class two-point extraction, cited reconstruction theorem and full gauge-theory identification retain their stated hypotheses.

5.3. **Gauge changes in the physical Gaussian integral.** The Gaussian normalizer on an averaging fibre contains a constraint Jacobian and a gauge Jacobian. Both must be retained when a contour gauge is replaced by a background gauge. We prove the finite-dimensional identity with its compensating factor, then apply it to the actual constraint and the complete constrained Hessian. The hypotheses needed for this application are a differentiable physical background graph, its local gauge covariance, and a nondegenerate physical Gaussian. The identity does not construct that graph or an independent-current extension of its Hessian.

5.3.1. *Constrained Lebesgue integrals and saddle determinants.* All spaces in this subsection are finite-dimensional real inner-product spaces. Lebesgue measures and determinants are defined by their orthonormal coordinates. Thus the formulas also apply to physical lattice measures, after those measures have been put into the inner products. Let $Q : E \to F$ be onto, put $n = \dim E$, $m = \dim F$, and let $T = T^*$ be positive on $\ker Q$. Define

$$I(T, Q) = \int_E \delta_F(Qa)e^{-\langle a, Ta\rangle/2}\, da. \tag{5.lxxxvi}$$

The delta function is normalized by the Lebesgue measure of F. This convention is important when the constraint is changed.

Lemma 5.4. With

$$\mathbb{S}(T,Q)=\begin{pmatrix}T & Q^*\\ Q & 0\end{pmatrix},$$

one has

$$I(T,Q)=(2\pi)^{(n-m)/2}|\det\mathbb{S}(T,Q)|^{-1/2}. \tag{5.lxxxvii}$$

For every symmetric $H : F \to F$, the saddle determinant and the integral are unchanged by $T \mapsto T + Q^*HQ$. ■

Proof. Split $E = E_0 \oplus E_1$ orthogonally, where $E_0 = \ker Q$, and write $Q = (0, Q_1)$. The square matrix $Q_1 : E_1 \to F$ is invertible and

$$\delta_F(Qa)\,da=|\det Q_1|^{-1}\,da_0\,\delta_0(da_1).$$

Consequently the integral equals $(2\pi)^{(n-m)/2}(\det T_{00})^{-1/2}(\det QQ^*)^{-1/2}$. Eliminating the T_{00} block in the saddle matrix gives

$$\det\mathbb{S}(T,Q)=(-1)^m\det T_{00}\det(QQ^*).$$

The remaining two-by-two block has determinant $(-1)^m|\det Q_1|^2$, independently of its upper-left entry. This proves both assertions. In particular no positivity of T on all of E was used. □

5.3.2. *The relative gauge determinant.* Let H be a fine site space and K a coarse site space. Write $D : H \to E$, $\mathrm{d} : K \to F$ for the two infinitesimal gauge actions. Assume initially that D and d are injective. Let $R : H \to K$ and $Q : E \to F$ be onto and satisfy

$$QD=\mathrm{d}R. \tag{5.lxxxviii}$$

Let $B = B^*$ satisfy $BD = 0$. Assume that its restriction to $\ker Q$ is nonnegative and that its kernel there is exactly $D(\ker R)$. Put $h = \dim H$, $k = \dim K$, and $H_0 = \ker R$. A residual gauge coordinate is a linear map $G : E \to Z$, where $\dim Z = h - k$, such that

$$GD_0 : H_0 \longrightarrow Z \quad \text{is invertible,} \qquad D_0 = D|_{H_0}.$$

It follows that $B + G^*G$ is positive on $\ker Q$, so its constrained integral is finite. Define

$$\mathcal{J}(B,Q,R,G)=\sqrt{\det(RR^*)}\,|\det(GD_0)|I(B+G^*G,Q). \tag{5.lxxxix}$$

The determinant of GD_0 uses the induced inner product on H_0; it is not a coordinate determinant in an unnormalized list of site values.

Proposition 5.5 (The gauge and constraint change identity)**.** The quantity $\mathcal{J}$ is independent of G. If $T : E \to K$ and

$$Q'=Q+\mathrm{d}T, \qquad R'=R+TD \tag{5.xc}$$

are onto, with the same nondegeneracy on the physical quotient, then $\mathcal{J}(B,Q',R',G') = \mathcal{J}(B,Q,R,G)$ for every admitted G'. The factor $\sqrt{\det(RR^*)}$ in eq. 5.lxxxix is necessary with the delta normalization eq. 5.lxxxvi. ■

Proof. Choose any full gauge coordinate $C : E \to H$ for which CD is invertible, and consider

$$\mathcal{Z}(C,Q)=|\det(CD)|\int_{E\times K}\delta_F(Qa-\mathrm{d}\xi)e^{-\langle a,Ba\rangle/2-\|Ca\|^2/2}\,da\,d\xi. \tag{5.xci}$$

This is a finite Gaussian integral. Indeed, if $Qa = \mathrm{d}\xi$, choose $v \in H$ with $Rv = \xi$. Then $a - Dv \in \ker Q$, and the value of B is unchanged by this subtraction. Its only null directions on that constrained space are gauge directions. The full coordinate C controls them, while injectivity of d controls the remaining ξ variable.

To prove independence of C, choose a fixed complement $E = E_{\mathrm{tr}} \oplus \operatorname{ran} D$ and write $a = b + Dv$. The Jacobian of this fixed decomposition is a constant independent of C and Q. In the other variable replace ξ by $\zeta + Rv$. Then

$$Qa - \mathrm{d}\xi = Qb - \mathrm{d}\zeta, \qquad \langle a, Ba\rangle = \langle b, Bb\rangle.$$

The integral in v is

$$\int_H e^{-\|Cb+CDv\|^2/2}\, dv = (2\pi)^{h/2} |\det(CD)|^{-1}.$$

It cancels the prefactor in eq. 5.xci and is independent of b. Thus $\mathcal{Z}$ is independent of C.

It is also unchanged by $Q \mapsto Q + \mathrm{d}T$. In eq. 5.xci, make the triangular change $\xi \mapsto \xi + Ta$, holding a fixed. Its Jacobian is one, and it removes $\mathrm{d}Ta$ from the argument of the delta function. The action and gauge weight are unchanged.

It remains to express $\mathcal{Z}$ by a residual gauge coordinate, retaining all measure factors. Choose $c : F \to K$ such that cd is invertible, and take

$$Ca = (Ga, cQa) \in Z \oplus K.$$

Its target has dimension h. In the orthogonal splitting of H, use the right inverse $R^\dagger = R^*(RR^*)^{-1}$ and write

$$v = v_0 + R^\dagger \eta, \qquad v_0 \in H_0.$$

The Jacobian of $(v_0, \eta) \mapsto v$ is $(\det RR^*)^{-1/2}$. The matrix of CD in these coordinates is block triangular:

$$\begin{pmatrix} GD_0 & GDR^\dagger \\ 0 & cd \end{pmatrix}.$$

Therefore

$$|\det(CD)| = \sqrt{\det(RR^*)}\, |\det(GD_0)|\, |\det(cd)|. \tag{5.xcii}$$

For a fixed ξ, the constrained integral with $Qa = \mathrm{d}\xi$, action B, and gauge weight $\|Ga\|^2/2$ equals the one with $Qa = 0$. To see this choose

$$v_\xi = R^\dagger \xi - (GD_0)^{-1} GDR^\dagger \xi,$$

where the second term is regarded as a vector in H_0. Then $Rv_\xi = \xi$, $GDv_\xi = 0$, and translation $a \mapsto a + Dv_\xi$ preserves the action and residual gauge weight. On the constraint, $cQa = cd\xi$. Hence the remaining integral in ξ in eq. 5.xci is $(2\pi)^{k/2} |\det(cd)|^{-1}$. Combining it with eq. 5.xcii yields

$$\mathcal{Z}(C, Q) = (2\pi)^{k/2} \mathcal{J}(B, Q, R, G).$$

The two independence assertions for $\mathcal{Z}$ now give the proposition. □

The constraint change in eq. 5.xc alters only the coarse gauge component of Qa. Its effect on the residual fine gauge group is $R \mapsto R + TD$. Omitting the resulting coarea factor would make the invariance statement false, even though the quotient of physical variations is the same.

5.3.3. *The background-gauge formula.* Let $\Delta = D^*D$. Since D is injective on H_0, its compression Δ_{00} to H_0 is positive. Write

$$P_0 = 1 - R^*(RR^*)^{-1}R$$

for the orthogonal projection onto H_0, and choose the residual coordinate $G = P_0 D^* : E \to H_0$. Then

$$GD_0 = \Delta_{00}, \qquad G^*G = DP_0D^*.$$

The same saddle calculation as in Lem. 5.4 gives

$$|\det \mathbb{S}(\Delta, R)| = \det(RR^*) \det \Delta_{00}.$$

Consequently

$$\mathcal{J} = \frac{|\det \mathbb{S}(\Delta, R)|}{\sqrt{\det(RR^*)}}\, I(B + DP_0D^*, Q). \tag{5.xciii}$$

In particular, if $RR^* = 1$, its logarithm is

$$\log \mathcal{J} = -\tfrac{1}{2}\log|\det \mathbb{S}(B + D(1 - R^*R)D^*, Q)| + \log|\det \mathbb{S}(\Delta, R)| + \tfrac{n-m}{2}\log(2\pi). \tag{5.xciv}$$

The site operator in the second determinant is the constrained site Laplacian. The gauge form in the vector determinant is $D(1 - R^*R)D^*$. It need not be the projected Landau gauge form used to construct the physical background; the gauge-change identity justifies this change in the integral.

5.3.4. *The actual constrained Hessian.* We now specialize the algebra. Let $U(V)$ be an actual differentiable critical background on a neighborhood of a real coarse field V_0, satisfying the prescribed homogeneous constraint $\mathcal{M}^j U(V) = V$. Assume its orbit is locally unique, is gauge covariant, and has a nondegenerate Gaussian on its physical fibre. Put $U_0 = U(V_0)$ and

$$S_c(V) = A(U(V)).$$

The action S_c is gauge invariant. All derivatives in what follows use the actual logarithmic fine and coarse coordinates at U_0, V_0, with the physical measures declared for the construction.

Let $q_0(a)$ be the logarithm of the plain constraint:

$$\mathcal{M}^j(e^{i\eta a}U_0) = e^{iq_0(a)}V_0, \qquad q_0(0) = 0, \quad Dq_0(0) = Q_0.$$

At a constrained-critical point,

$$DA(U_0) = Q_0^*\mu, \qquad DS_c(V_0) = \mu. \tag{5.xcv}$$

The second equality follows from the first by differentiating the constraint along $U(V)$. The derivative of that graph is a right inverse of Q_0, so no inverse of $Q_0^*Q_0$ is implicit here.

Let $q(a)$ be the actual straightened constraint with its actual node factor $v(a)$, as in eq. 3.cccxliii. Thus the plain coarse field and $e^{iq(a)}V_0$ are related by that node gauge. Gauge invariance gives the exact nonlinear identity

$$S_c(\mathcal{M}^j(e^{i\eta a}U_0)) = S_c(e^{iq(a)}V_0). \tag{5.xcvi}$$

For the convention in which a site tangent acts by D, differentiation of the node factorization gives

$$Q = Q_0 + \mathrm{d}T, \qquad R = R_0 + TD, \qquad QD = \mathrm{d}R. \tag{5.xcvii}$$

Here $Q = Dq(0)$, R_0 is evaluation of a fine gauge parameter at the coarse nodes, and T is minus the derivative of the node factor in that convention. Equivalently the first identity defines its sign. The second identity also follows by differentiating the same factorization along a fine gauge transformation. The resulting R is the actual transported site average, not an independently chosen map. Its formula is the own-block average in the field intertwining identity.

Consider the gauge-invariant fine function

$$\widetilde{A}(W) = A(W) - S_c(\mathcal{M}^j W). \tag{5.xcviii}$$

Its first derivative vanishes at U_0, by eq. 5.xcv. Let B be its Hessian there. Gauge invariance at a critical point gives $BD = 0$. The chain rule in eq. 5.xcvi gives the complete formula

$$B = A''(U_0) - \langle \mu, D^2q(0)\rangle - Q^*H_cQ, \qquad H_c = D^2S_c(V_0). \tag{5.xcix}$$

The middle term denotes the symmetric form

$$(a, b) \longmapsto \langle \mu, D^2q(0)[a, b]\rangle.$$

Thus, on the linearized fibre $\ker Q$, the actual quadratic action is

$$B_{\mathrm{fib}} = A''(U_0) - \langle \mu, D^2q(0)\rangle. \tag{5.c}$$

It contains the curvature of the nonlinear constraint. The last term in eq. 5.xcix does not change its saddle determinant, by Lem. 5.4. This derivation defines the physical current and multiplier correction from the actual constraint; it is not a form selected to obtain a determinant identity.

The same construction with q_0 gives the plain-fibre Hessian. The full B is the same for both constraints, because it is the Hessian of the single function eq. 5.xcviii. This is the reason the constraint-change part of Prop. 5.5 applies.

5.3.5. *The two actual site Jacobians.* In fine physical measure η^4, node evaluation has

$$R_0 R_0^* = \eta^{-4} I. \tag{5.ci}$$

This is a field-independent factor. By contrast the transported site average is a coisometry:

$$R R^* = I. \tag{5.cii}$$

To verify the latter at one step, write its value as the normalized sum of the transported fine site values in a block. Each real adjoint transport is orthogonal, distinct blocks have disjoint site sets, and the fine measure divided by the coarse measure is precisely the reciprocal of the number of sites in a block. Multiplying the average by its physical adjoint therefore gives the identity. For a homogeneous composition, write the site average as the composition of its one-step averages. Each is a coisometry between its own physical site spaces, so their composition is a coisometry as well. This calculation does not require flatness. Here the straightened constraint is re-centered at the actual U_0, so its relative contour logarithms vanish at $a = 0$. Equation eq. 5.cii concerns that derivative. It does not identify the effective gauge derivative of a fixed-flat-reference nonlinear chart at a nonzero field with a coisometry.

The actual contour gauge on the plain fibre supplies a residual coordinate G_{ax}. Its derivative along a gauge parameter which vanishes at the coarse nodes is triangular in the levels, with field-independent determinant. Here is the local verification. A contour from a block node y to x transforms by its two endpoint gauges. At the axial representative its value is one, so its logarithmic derivative along $v_t = e^{it\lambda}$ is $\lambda(y) - \lambda(x)$, with the fixed sign convention. Group the noncoarse sites by their first parent in the nested block hierarchy. The map from site values to these parent differences is triangular with diagonal entries $\pm I_3$, since the final coarse-node values are zero. Its determinant has absolute value one in these unweighted site coordinates. Transported frames insert adjoint rotations of determinant one. Physical measures and fixed gauge weights insert only constants depending on the mesh and the numbers of sites. Therefore

$$\sqrt{\det(R_0 R_0^*)}\,|\det(G_{\mathrm{ax}} D|_{\ker R_0})| = c_{\eta,j}, \tag{5.ciii}$$

where $c_{\eta,j} > 0$ is independent of the background. For one step the endpoint derivative is exactly $GT = -I$ from eq. 4.ccxviii; the preceding triangular calculation is its composition over the hierarchy.

Let $\Psi_j(V)$ be the logarithm of the actual physical Gaussian normalizer on the plain fibre, minus its value at the trivial background. Its Haar factors at the centre are field independent in left exponential coordinates. The nonpivot elimination factor is precisely the constraint coarea factor in eq. 5.lxxxvi. The reference contour-gauge normalizations and the constant eq. 5.ciii also disappear from this normalized difference.

Proposition 5.6 (The physical saddle representation)**.** On every admitted actual background domain described above,

$$\begin{aligned}\Psi_j(V) = {} & -\tfrac{1}{2}\log\left|\det \mathbb{S}\left(A''(U_0) - \langle \mu, D^2 q(0)\rangle + D(1 - R^* R)D^*,\, Q\right)\right| \\ & + \log|\det \mathbb{S}(D^* D, R)| - (\text{the same at } V = 1).\end{aligned} \tag{5.civ}$$

The multiplier and the constraint curvature use their physical coordinate normalizations. The formula is a physical-pair identity. It does not specify how either determinant is extended off that manifold to an independent current. ■

Proof. At a coarse field with no infinitesimal stabilizer, d is injective. The fine gradient is injective as well: $D\lambda = 0$ implies $\mathrm{d}R_0\lambda = 0$, hence $R_0\lambda = 0$; a parallel fine field which is zero at a coarse node is zero on its component. The same observation makes D injective on $\ker R$ without the generic coarse-field restriction.

The physical Gaussian is nondegenerate on the plain fibre modulo its residual gauges. Because the two constraints differ by a coarse gauge component, their physical quotients are isomorphic: given a vector on one constraint space, correct its coarse gauge value by $D\lambda$, using surjectivity of the other site map. The value of B is unchanged. Thus the required quotient nondegeneracy holds for both Q_0, R_0 and Q, R. The same argument shows Q is onto: if $Q_0 a = f$, then $Qa = f + \mathrm{d}Ta$; choose λ with $R\lambda = -Ta$ and replace a by $a + D\lambda$.

Apply Prop. 5.5 to the common gauge-invariant Hessian B. On the plain side use G_{ax} and eq. 5.ciii. On the straightened side use the background gauge and eq. 5.cii. Formula eq. 5.xciv gives the two logarithms. Replace B by B_{fib} using eq. 5.xcix and Lem. 5.4. All remaining constants cancel in the difference at $V = 1$, giving eq. 5.civ.

The auxiliary integral eq. 5.xci is singular when d has a kernel, so it is not used at such a field. After its coarse-gauge factors have been canceled, both sides of eq. 5.civ are finite constrained Gaussian or saddle-determinant expressions. Their nondegenerate fibre forms vary continuously on the admitted background domain. Irreducible coarse connections are dense near the trivial field: two small loop holonomies with distinct colour axes have no common nonzero adjoint fixed vector. Perturbations of links can create such loops on the connected periodic four-dimensional lattice. Thus the finite final identity extends to the trivial field and to fields with stabilizers by continuity. No continuity of the uncanceled auxiliary integral is asserted. □

On an admitted complex background domain with coherent logarithm branches, use bilinear physical transposes and the logarithm branches continued from the real positive Gaussians. The determinant identity then continues holomorphically wherever the constrained forms remain nondegenerate. Absolute values belong only to the displayed real formula. In particular one cannot insert them in a holomorphic localization.

5.3.6. *Gaussian composition with nonlinear constraints.* We also record why Gaussian integration in stages uses the complete constrained Hessians. This identifies the algebraic composition needed before a one-loop coefficient is extracted. Let $M : E \to F$ and $N : F \to G$ be onto. Let $T = T^*$ be positive on $\ker(NM)$, and let $H : F \to E$ be its constrained minimizer:

$$MH = 1, \qquad \langle u, THb\rangle = 0 \quad (u \in \ker M).$$

Put $T_2 = H^*TH$. The change $a = u + Hb$, $u \in \ker M$, has Jacobian $(\det MM^*)^{-1/2}$; this follows first for the orthogonal right inverse of M, and then for H, whose difference from it is a shear into $\ker M$. The constraint becomes $Nb = 0$, and the exponent splits. Hence exactly

$$I(T, NM) = I(T, M)I(T_2, N). \tag{5.cv}$$

Only positivity on the indicated constraint spaces is needed. There is no additional determinant of N or M: both are already included by the two delta functions with their declared measures.

For the nonlinear application let m_1, m_2 be the actual successive constraint maps in their local coordinates. Let $x = x(y)$ be the first physical critical graph and y a critical point of $S_1(y) = F(x(y))$ under $m_2(y) = z$. Write

$$M = Dm_1(x), \qquad N = Dm_2(y), \qquad DF(x) = M^*\mu_1, \qquad DS_1(y) = N^*\mu_2.$$

Differentiation of the first graph gives $\mu_1 = N^*\mu_2$. The complete first-stage Hessian is

$$B_1 = F''(x) - \langle \mu_1, m_1''(x) \rangle.$$

With $H = Dx(y)$, differentiation of the criticality equation gives

$$MH = 1, \qquad \langle u, B_1 H b \rangle = 0 \quad (u \in \ker M), \qquad S_1''(y) = H^* B_1 H. \tag{5.cvi}$$

For the last equality, differentiate $m_1(x(y)) = y$ twice and pair with μ_1. Its acceleration term cancels the corresponding acceleration term in $D^2(F \circ x)$. This calculation uses the multiplier term in B_1.

The total constraint has second derivative

$$D^2(m_2 \circ m_1)[a, a] = m_2''[Ma, Ma] + N m_1''[a, a].$$

Therefore its complete Hessian is

$$B_{\mathrm{tot}} = B_1 - M^* \langle \mu_2, m_2'' \rangle M. \tag{5.cvii}$$

In the coordinates $a = u + Hb$, this is the direct sum of $B_1|_{\ker M}$ and $S_1'' - \langle \mu_2, m_2'' \rangle$.

Gauge fixing does not spoil this decomposition. Choose the actual first-stage axial representative throughout the first background graph. Its first gauge coordinate vanishes along that graph, so its derivative G_1 satisfies $G_1 H = 0$. The second-stage gauge coordinate acts on $b = Ma$. The total quadratic gauge weight is then $\|G_1 u\|^2 + \|G_2 b\|^2$, precisely the two gauge weights used by the hierarchical Gaussian integral. Apply eq. 5.cv to these nondegenerate gauge-fixed forms, explicitly taking

$$T = B_{\mathrm{tot}} + G_1^* G_1 + M^* G_2^* G_2 M.$$

Corollary 5.7. On an admitted homogeneous physical background graph, the normalized Gaussian logarithms obey

$$\Psi_j = \Phi_j + \Psi_{j-1} \circ p_j, \tag{5.cviii}$$

where p_j is the actual preceding critical background map and Φ_j is the actual one-step Gaussian logarithm. All constraint-curvature terms are included before the Gaussian integration. Field-independent measure constants cancel in the normalization. ■□

Proof. Use the preceding Hessian decomposition at each stage and integrate first in u, then in b. The first factor in eq. 5.cv is the earlier Gaussian normalizer evaluated at $p_j(V)$; the second is the new step normalizer. Normalize both at the trivial coarse field and take their real logarithms. This gives eq. 5.cviii. □

5.3.7. *The physical multiplier correction has zero coefficient.* The statement that a current correction is of third order in external momentum concerns its determinant functional. The matrix $-\langle \mu, q'' \rangle$ itself need not have that order. We prove the required functional statement on the actual background domain.

Fix a homogeneous depth j, and work near a flat reference with trivial coarse field for the coefficient extraction. For the following argument assume the actual critical background graph and its first two derivatives are exponentially local on this neighborhood. The weighted construction in Prop. 3.183, with eq. 3.mccxcv and eq. 3.mccxcvi, supplies this property on the constructed flat-reference neighborhood; no estimate uniform in j for the determinants in this argument will be required. Let

$$T(V) = A''(U(V)) + D(1 - R^*R)D^*.$$

Introduce an independent coarse bond covector ν, with the same coordinate normalization as μ, and put

$$\begin{aligned} L_j(V, \nu) = & -\tfrac{1}{2} \log \det \mathbb{S}(T(V) - \langle \nu, q_V'' \rangle, Q_V) \\ & + \tfrac{1}{2} \log \det \mathbb{S}(T(V), Q_V). \end{aligned} \tag{5.cix}$$

Here and below the logarithms are coherent local branches; their difference is zero at $\nu = 0$. The actual multiplier correction to the physical saddle logarithm is

$$C_j(V) = L_j(V, DS_c(V)).$$

Proposition 5.8. The bulk Hessian of C_j has symbol

$$\widehat{\pi}^{C_j}(p) = O_j(|p|^3) \qquad (p \to 0). \tag{5.cx}$$

Consequently $b[C_j] = 0$. The statement is exact at every admitted depth. It does not assert a pointwise $O(|p|^3)$ bound for the multiplier matrix. ∎

Proof. We first justify the local trace jets used here. At a fixed fine mesh, the flat background-gauge vector form restricted to $\ker Q$ is nondegenerate. A zero of its sum of nonnegative squares would satisfy

$$\mathrm{d}v = 0, \qquad Qv = 0, \qquad P_0 D^* v = 0, \quad P_0 = 1 - q^* q.$$

In each Bloch fibre a closed field is a gradient, apart from the parallel constant modes at zero frequency. The actual average detects those constant vector modes, so they vanish. For the gradient part $v = D\lambda$, the identity $QD = \mathrm{d}_c q$ gives $\mathrm{d}_c q\lambda = 0$. Subtract a parallel constant from λ if needed; it then has $q\lambda = 0$. Pairing $P_0 D^* D\lambda = 0$ with λ gives $D\lambda = 0$. Thus $v = 0$.

The finite Bloch matrices and their constraint maps are continuous on the compact Brillouin torus. Surjectivity of Q, supplied by the actual row seeds, and the preceding kernel argument imply invertibility of the full saddle matrix in every fibre. At this fixed mesh, its inverse is uniformly bounded over that torus. It extends to a small complex momentum strip by the resolvent identity. Fourier contour shifting therefore gives exponential decay of its coarse-cell kernels, with constants which may depend on j.

All other coefficients in eq. 5.cix have fixed physical carriers before the background is substituted. The exponentially local background derivatives and the resolvent identity show that its two trace derivatives have absolutely summable exponential moments. For example, differentiating a logarithm twice gives $\mathrm{Tr}(S^{-1}S'' - S^{-1}S'S^{-1}S')$; each differentiated coefficient has its declared local carrier or the exponentially decreasing background response. Products of these kernels retain an exponential moment after decreasing its rate. There are finitely many fine coordinates per cell at fixed j, so their internal trace is finite. The same estimates make finite-volume winding terms vanish exponentially. This proves existence of the bulk Hessian symbols and their analyticity in a momentum neighborhood of zero. It also justifies the Ward identities below by first using finitely supported gauge parameters and then taking these absolutely convergent Fourier sums.

The function L_j is invariant under simultaneous coarse gauge transformation of V and the covector ν. Indeed, the background orbit is gauge covariant, all fine and coarse tangent spaces transform by their adjoint rotations, and the actual constraint second derivative transforms with its covector pairing. Both saddle determinants are conjugated by these rotations, whose determinants are one. In addition,

$$L_j(V, 0) = 0, \qquad DL_j(1, 0) = 0. \tag{5.cxi}$$

The first equality is its definition. For the derivative in ν, invariance under constant colour rotations makes each coefficient an invariant linear functional on the adjoint colour space, hence zero. The derivative in V vanishes by the first equality.

Let K_j be the mixed V, ν Hessian kernel at $(1, 0)$. Differentiate the joint gauge identity in a gauge parameter and in ν. The term from transforming ν is multiplied by the zero first derivative in eq. 5.cxi. Thus

$$D^2_{V,\nu} L_j(1, 0)[\mathrm{d}_c\chi, \nu] = 0.$$

Translation covariance gives, in Fourier coordinates,

$$\widehat{\mathrm{d}}_c(-p)^{\mathsf{T}} \widehat{K_j}(p) = 0. \tag{5.cxii}$$

Since $\widehat{\mathrm{d}}_{c,\mu}(p) = -ip_\mu + O(|p|^2)$, its linear Taylor term forces $\widehat{K_j}(0) = 0$: every column is annihilated by every row vector p^{T}. Analyticity then gives

$$\widehat{K_j}(p) = O_j(|p|). \tag{5.cxiii}$$

The actual multiplier is $\mu(V) = DS_c(V)$, and $\mu(1) = 0$. Let P_j be the symbol of its derivative, that is the Hessian of S_c at the trivial field. Gauge invariance gives $P_j(0) = 0$ by the same zero-momentum Ward argument. In midpoint coordinates, inversion sends both bond variations to their negatives and p to $-p$. The Hessian symbol in those coordinates is therefore even. Its linear Taylor term vanishes, and the endpoint-to-midpoint phase does not change this conclusion after $P_j(0) = 0$. Hence

$$P_j(p) = O_j(|p|^2). \tag{5.cxiv}$$

These are the actual symmetries of the symmetric contour construction and its critical orbit.

Apply the second-order chain rule to C_j. The pure V, V Hessian of $L_j(V, 0)$ is zero. The term involving $D^2\mu$ is multiplied by $D_\nu L_j(1, 0) = 0$. The remaining terms are the two mixed kernels composed with P_j, and the ν, ν kernel composed with P_j on both sides. Their orders are respectively at least $|p|^3$ and $|p|^4$, by eq. 5.cxiii and eq. 5.cxiv. This proves eq. 5.cx. The quadratic Maxwell coefficient is therefore zero. □

The coefficient identity $\sum_{l\le j} b_l^0 = b[\Psi_j]$ additionally uses invariance of the coefficient under the actual map p_j. The saddle formula and the recursion alone do not supply that response estimate. Likewise, identification of the physical Hessian here does not give localization or common complex-current domains for a chosen off-shell completion. These analytic requirements remain distinct from the finite gauge-change and composition identities.

5.4. **The massive Wilson determinant in a constant field.** We compute the logarithmic coefficient directly on the unit lattice. This is a component of the small-field Gaussian renormalization method of [B87]. This calculation concerns the Wilson Hessian and the covariant site Laplacian, before an averaging constraint is introduced. It includes the neutral colour, the charged colours, and the order of the volume, field, and mass limits. The comparison with a constrained determinant is a separate step.

Write t_a for the Pauli matrices, so that $\frac{1}{2}\,\mathrm{tr}(t_a t_b) = \delta_{ab}$. A real bond variation is written $e^{ita_b}U_b$, with $a_b = \sum_a a_b^a t_a$. The Wilson action and its Hessian have the normalization

$$A(U) = \sum_p (1 - \tfrac{1}{2}\,\mathrm{tr}\,U_p), \qquad A''(1)[a, a] = \sum_p |(\mathrm{d}a)_p|^2.$$

Adjoints below use counting measure on the unit lattice and this Euclidean colour inner product. Put

$$(D_U\lambda)_\mu(x) = \lambda(x) - \mathrm{Ad}_{U_\mu(x)}\,\lambda(x + e_\mu), \qquad \Delta_U = D_U^* D_U, \qquad K_U = A''(U) + D_U D_U^*.$$

The opposite sign for both occurrences of D_U gives the same operators. We use a star for the real Hilbert adjoint and for its complexification in this calculation.

For $f \in \mathbb{R}$, fix the Abelian field

$$U_{f,1}(x) = e^{-ifx_2 t_3}, \qquad U_{f,\mu}(x) = 1 \quad (\mu \neq 1). \tag{5.cxv}$$

Its positively oriented $(1, 2)$-plaquettes are e^{ift_3}; all its other plaquettes are the identity. The connection itself grows in a logarithmic coordinate as $|x_2|$, whereas every plaquette is constant. We therefore define the determinant density by finite compressions, rather than by placing arbitrary flux on a periodic torus.

Let $\Lambda_R = [-R, R]^4 \cap \mathbb{Z}^4$. Site operators are compressed to sites in Λ_R; vector operators are compressed to positive bonds with both endpoints there. Thus, for example, $K_{f,R} = P_R K_{U_f} P_R^*$. Compression is taken after the full lattice operator has been formed. This is the Hessian for

variations extended by zero outside the indicated coordinates. It does not discard plaquettes meeting the boundary. For $z > 0$, define

$$\begin{aligned}\mathcal{L}_R(f,z) &= \log\det(\Delta_{f,R}+z) - \tfrac{1}{2}\log\det(K_{f,R}+z),\\ \mathcal{D}_R(f,z) &= |\Lambda_R|^{-1}\big(\mathcal{L}_R(f,z)-\mathcal{L}_R(0,z)\big).\end{aligned} \tag{5.cxvi}$$

The determinants here are over all three real colours. For each fixed positive z, the matrices in this formula are positive when $|f|$ is sufficiently small in terms of z.

Proposition 5.9. The functions $\mathcal{D}_R(\cdot,z)$ and their first three derivatives at zero have limits as $R\to\infty$, locally uniformly for z in compact subsets of $(0,\infty)$. The limiting density $\mathcal{D}(f,z)$ is a real, even, smooth function of real f near zero. Let

$$\widetilde{\beta}(z) = \partial_f^2 \mathcal{D}(0,z).$$

Then

$$\widetilde{\beta}(z) = \frac{11}{6\pi^2}\log\frac{1}{z} + C_* + E(z), \qquad |E(z)| + |zE'(z)| + |z^2E''(z)| \le C\sqrt{z}, \quad 0<z\le 1, \tag{5.cxvii}$$

for finite constants C_* and C. In particular,

$$\sup_{0<z\le 1}\left\{\left|\widetilde{\beta}(z) - \frac{11}{6\pi^2}\log\frac{1}{z}\right| + |z\widetilde{\beta}'(z)| + |z^2\widetilde{\beta}''(z)|\right\} < \infty. \tag{5.cxviii}$$

The same limits hold for any lattice Følner exhaustion, using the same zero-extension compression convention. ∎

The proof will give an exact Brillouin-zone formula at every positive mass. The coefficient is therefore obtained from the actual lattice Hessian, without replacing it by a continuum vector operator.

5.4.1. *Charged coordinates and magnetic translations.* The neutral coordinate is a^3. For the other two real coordinates put $w = a^1 - ia^2$. Direct multiplication of Pauli matrices gives

$$\mathrm{Ad}_{e^{i\theta t_3}}\, w = e^{2i\theta} w.$$

Consequently the charged covariant shifts in the background eq. 5.cxv are

$$(u_1 w)(x) = e^{-i\varphi x_2} w(x+e_1), \qquad (u_\mu w)(x) = w(x+e_\mu) \quad (\mu\neq 1), \qquad \varphi = 2f.$$

They are unitary, and

$$u_1 u_2 = e^{i\varphi} u_2 u_1, \qquad u_\mu u_\nu = u_\nu u_\mu \quad \text{if } \{\mu,\nu\}\neq\{1,2\}. \tag{5.cxix}$$

For $m\in\mathbb{Z}^4$ define

$$W_m = e^{-i\varphi m_1 m_2/2} u_1^{m_1} u_2^{m_2} u_3^{m_3} u_4^{m_4}.$$

The commutation relation proves, including negative powers,

$$W_m W_n = e^{i\varphi(m_1 n_2 - m_2 n_1)/2} W_{m+n}, \qquad W_m^* = W_{-m}. \tag{5.cxx}$$

If $a(q) = \sum_m a_m e^{im\cdot q}$, write $\mathrm{Op}_\varphi(a) = \sum_m a_m W_m$. This definition also applies to matrix coefficients, with the matrix acting on the vector index. Absolute Fourier convergence is sufficient.

Let $\mathbb{B} = [-\pi,\pi]^4$, with opposite faces identified, and write

$$\int_{\mathbb{B}} h(q)\, d\bar{q} = (2\pi)^{-4}\int_{[-\pi,\pi]^4} h(q)\, dq.$$

The normalized trace of a finite Weyl polynomial is

$$\tau\big(\mathrm{Op}_\varphi(a)\big) = \mathrm{tr}\, a_0 = \int_{\mathbb{B}} \mathrm{tr}\, a(q)\, d\bar{q}.$$

Indeed, W_m has a zero diagonal unless $m = 0$, and $W_0 = 1$. The same formula holds for absolutely summable coefficients by approximation. For two such symbols the zero Fourier coefficient of their product involves only $n = -m$. The phase in eq. 5.cxx is then one. Hence

$$\tau(\operatorname{Op}_\varphi(a)\operatorname{Op}_\varphi(b)) = \int_{\mathbb{B}} \operatorname{tr}(ab)\, d\bar{q}. \tag{5.cxxi}$$

In particular this trace is cyclic, also for matrix-valued symbols. It is a trace per lattice site, with the ordinary matrix trace retained on the fibre.

For later remainder estimates, use

$$\|a\|_s = \sum_{m\in\mathbb{Z}^4} (1+|m|)^s \|a_m\|, \qquad s = 0, 1, \dots.$$

For real φ, the phase in eq. 5.cxx has modulus one, so $\|a \star_\varphi b\|_0 \le \|a\|_0\|b\|_0$. The same argument and $(1+|m+n|)^s \le (1+|m|)^s(1+|n|)^s$ give the corresponding weighted product bound. The operator norm is at most $\|a\|_0$. These estimates are uniform in the real magnetic field. They do not assert holomorphy in a complex constant flux.

Taylor expansion of the phase in eq. 5.cxx gives

$$a \star_\varphi b = ab - \frac{i\varphi}{2}\{a,b\} - \frac{\varphi^2}{8}\{\{a,b\}\} + \mathcal{R}_3(a,b;\varphi), \tag{5.cxxii}$$

where subscripts denote ordinary momentum derivatives and

$$\{a,b\} = a_1 b_2 - a_2 b_1, \qquad \{\{a,b\}\} = a_{11}b_{22} - 2a_{12}b_{12} + a_{22}b_{11}.$$

For example,

$$\|\mathcal{R}_3(a,b;\varphi)\|_0 \le C|\varphi|^3 \|a\|_3\|b\|_3.$$

To check the signs, the product of $e^{im\cdot q}$ and $e^{in\cdot q}$ acquires the positive phase in eq. 5.cxx, while each pair of momentum derivatives contributes $i^2 = -1$. The remainder bound follows from the third-order Taylor remainder of a real phase and $|m_1 n_2 - m_2 n_1| \le |m||n|$. Weighted versions follow by the same summation.

5.4.2. *The exact charged Wilson Hessian.* We first derive the finite Weyl polynomial that is needed in the calculation. This also fixes the spin normalization. Let $p = (x;\mu,\nu)$ be a positive plaquette and let its background holonomy be $P = e^{if_{\mu\nu}t_3}$, where $f_{12} = f$ and the other $f_{\mu\nu}$ vanish. Put $\lambda = e^{2if_{\mu\nu}}$. Moving the four varied factors to the base point gives

$$P(t) = e^{itX_1}e^{itX_2}e^{itX_3}e^{itX_4}P,$$

where

$$\begin{aligned} X_1 &= a_\mu(x),\\ X_2 &= \operatorname{Ad}_{U_\mu(x)} a_\nu(x+e_\mu),\\ X_3 &= -\operatorname{Ad}_{PU_\nu(x)} a_\mu(x+e_\nu),\\ X_4 &= -\operatorname{Ad}_P a_\nu(x). \end{aligned}$$

The inverses on the third and fourth edges are responsible for both minus signs and both occurrences of P. In charged coordinates the four rows acting on $(w_1,\dots,w_4)$ are

$$C_1 w = w_\mu, \qquad C_2 w = u_\mu w_\nu, \qquad C_3 w = -\lambda u_\nu w_\mu, \qquad C_4 w = -\lambda w_\nu. \tag{5.cxxiii}$$

These are rows of operators; their adjoints reverse the order of operator multiplication.

For real three-vectors x, y, the Pauli product is $(x\cdot t)(y\cdot t) = (x\cdot y)1 + i(x\times y)\cdot t$. Differentiating $1 - \frac{1}{2}\operatorname{tr} P(t)$ twice gives

$$\cos f_{\mu\nu}\left|\sum_r X_r\right|^2 - 2\sin f_{\mu\nu}\sum_{r<s}(X_r\times X_s)_3.$$

For charged vectors, $(x \times y)_3 = -\operatorname{Im}(\overline{w}_x w_y)$. Thus the charged plaquette Hessian is the Hermitian form

$$H_{\mu\nu} = \cos f_{\mu\nu}\, S^*_{\mu\nu} S_{\mu\nu} + \frac{\sin f_{\mu\nu}}{i} \sum_{r<s} (C_r^* C_s - C_s^* C_r), \qquad S_{\mu\nu} = \sum_{r=1}^{4} C_r. \tag{5.cxxiv}$$

For example, the second summand evaluated on w is $2 \sin f_{\mu\nu} \sum_{r<s} \operatorname{Im}\langle C_r w, C_s w\rangle$, as required. There is no continuum approximation in eq. 5.cxxiv.

Put $D_\mu = 1 - u_\mu$. The exact charged vector operator is

$$K_\varphi = DD^* + \sum_{\mu<\nu} H_{\mu\nu} = \mathrm{Op}_\varphi(\sigma_\varphi), \qquad \Delta_\varphi = \sum_\mu D_\mu^* D_\mu = \mathrm{Op}_\varphi(\psi), \tag{5.cxxv}$$

where

$$\psi(q) = \sum_{\mu=1}^{4} (2 - 2\cos q_\mu).$$

Each entry of σ_φ is a finite sum of terms $c e^{i\varphi p/2} e^{im\cdot q}$, with integer p. At zero flux the ordinary curl–divergence identity gives

$$\sigma_0(q) = \psi(q) I_4. \tag{5.cxxvi}$$

This identity can also be checked entry by entry: the diagonal curl terms supply all $D_\nu^* D_\nu$ with $\nu \neq \mu$, the divergence term supplies the missing direction, and their off-diagonal entries cancel when the shifts commute.

We record the short computation that determines the first flux coefficient. Only the $(1,2)$ plane can change the flat cancellation. To evaluate the Weyl symbol at $q = 0$, one must first put each product into the order eq. 5.cxx; setting the shifts to one beforehand would lose the magnetic phase. For example the full off-diagonal entry is

$$\begin{aligned}\sigma_\varphi^{12}(q) = 1 - e^{-iq_2} - e^{iq_1} - e^{i(q_1-q_2)} \\ + e^{-i\varphi/2}\big(e^{i(q_1-q_2)} + e^{iq_1} + e^{-iq_2}\big) - e^{i\varphi/2}.\end{aligned}$$

The phases in the second line arise from putting products of the two noncommuting shifts into Weyl order. Its combined coefficient at $q = 0$ is

half-phase p	-1	0	1
$\sum_m c^{12}_{m,p}$	3	-2	$-1.$

Here the contribution of DD^* is combined with the two terms in eq. 5.cxxiv. These three numbers can be obtained by substituting the four rows eq. 5.cxxiii, using $\lambda = e^{i\varphi}$, and applying $W_m W_n = e^{i\varphi(m_1 n_2 - m_2 n_1)/2} W_{m+n}$ to each pair. The diagonal sums vanish, and the opposite off-diagonal entry is the complex conjugate. Hence

$$\sigma_\varphi(0) = \big(3e^{-i\varphi/2} - e^{i\varphi/2} - 2\big) E_{12} + \big(3e^{i\varphi/2} - e^{-i\varphi/2} - 2\big) E_{21}. \tag{5.cxxvii}$$

The entries with indices outside $\{1,2\}$ are zero in this formula. Write

$$\sigma_\varphi = \psi I_4 + \varphi \Sigma_1 + \varphi^2 \Sigma_2 + O(\varphi^3). \tag{5.cxxviii}$$

The remainder and all its momentum derivatives are bounded by a constant times $|\varphi|^3$. In particular,

$$\Sigma_1(0) = -2i(E_{12} - E_{21}), \qquad \operatorname{tr} \Sigma_1(0)^2 = 8, \qquad \Sigma_2(0) = -\tfrac{1}{4}(E_{12} + E_{21}). \tag{5.cxxix}$$

The finite Fourier expressions also give

$$\|\Sigma_1(q) - \Sigma_1(0)\| \le C|q|, \qquad \|\Sigma_2(q)\| \le C, \qquad q \in \mathbb{B}. \tag{5.cxxx}$$

Representatives in $[-\pi, \pi]^4$ are used in the first bound.

There is a useful independent identity for this normalization. The field eq. 5.cxv is critical under compactly supported variations: on each bond the two adjacent $(1,2)$-plaquettes contribute opposite copies of $\sin f\, t_3$, and the remaining plaquettes contribute zero. Gauge invariance, differentiated at this critical field, gives $A''(U_f)D_{U_f} = 0$. Consequently

$$K_\varphi D = D\Delta_\varphi. \tag{5.cxxxi}$$

It also follows by multiplication of the finite Weyl polynomials above. The spin value in eq. 5.cxxix was computed from the Hessian itself; it was not inferred from the Ward identity alone.

5.4.3. *The neutral sector and positivity at fixed mass.* In the third colour all adjoint phases disappear. The four insertions commute, so the only changed plaquette Hessian is the factor $\cos f$ in the $(1,2)$ curl. With ordinary commuting shifts let

$$c_{12}(q)a = (1 - e^{iq_2})a_1 + (e^{iq_1} - 1)a_2.$$

The neutral site and vector symbols are exactly

$$\Delta^0 = \psi, \qquad K_\varphi^0 = \psi I_4 + (\cos(\varphi/2) - 1)c_{12}^* c_{12} = \psi I_4 + \varphi^2 N_2 + O(\varphi^4), \quad N_2 = -\tfrac{1}{8} c_{12}^* c_{12}. \tag{5.cxxxii}$$

In particular

$$\mathrm{tr}\, N_2(q) = -\tfrac{1}{8}(|1 - e^{iq_1}|^2 + |1 - e^{iq_2}|^2). \tag{5.cxxxiii}$$

This term is bounded and vanishes quadratically at zero momentum. It is retained in the exact coefficient formula below.

We next justify that the logarithms used in the calculation exist. By eq. 5.cxxvi and the finite Fourier description, the coefficient norm of $\sigma_\varphi - \psi I_4$ is at most $C|\varphi|$. This is a comparison with the magnetic scalar Laplacian, not with the nonmagnetic operator in a globally small potential. Since $\Delta_\varphi \geq 0$,

$$K_\varphi \geq -C|\varphi|, \qquad K_\varphi + z \geq z/2 \quad \text{if } |\varphi| \leq cz. \tag{5.cxxxiv}$$

The same lower bound holds for every compression. In the neutral sector, for $\cos f \geq 0$, the sum of the weighted curl squares and the divergence square is nonnegative. Thus $K_\varphi^0 + z \geq z$. These observations prove positivity of all finite determinants in eq. 5.cxvi in a common real interval about zero, for each fixed $z > 0$.

5.4.4. *Volume limits and differentiation in the field.* Here is a trace argument that deals with the linearly growing potential. It will also justify differentiation of the determinant density without a complex constant-field continuation.

Lemma 5.10. Let $T_\varphi = \mathrm{Op}_\varphi(t_\varphi)$ be a Hermitian finite Weyl polynomial on d components. Suppose $t_0 = \psi I_d$, and its finite Fourier coefficients are smooth functions of real φ. For fixed $z > 0$, the normalized logarithms of the zero-extension compressions of $T_\varphi + z$ converge near $\varphi = 0$, together with any fixed finite number of real flux derivatives. Their limits are the cyclic trace of the logarithm defined by its convergent power series. The convergence is locally uniform in positive z. ∎

Proof. First restrict z to a compact positive interval. Choose $a > 8 + z$ throughout that interval and put

$$B_\varphi = I - a^{-1}(T_\varphi + z).$$

At zero flux the sum of the norms of its combined Fourier coefficients is

$$1 - (8 + z)/a + 8/a = 1 - z/a < 1.$$

Coefficients with the same lattice shift are combined before this norm is taken. Their smoothness and their finite number give, on a sufficiently small real interval, $\|b_\varphi\|_0 \leq r < 1$, uniformly in the restricted masses. Consequently

$$\log(T_\varphi + z) = (\log a)I - \sum_{n \geq 1} \frac{B_\varphi^n}{n} \tag{5.cxxxv}$$

converges in operator norm and in the absolutely summable coefficient algebra. The same series holds for each compressed matrix, with the same norm bound.

Expand the trace of a power as a sum over walks. A term has steps $m_1, \dots, m_n$ in a fixed finite set. It contributes to the trace only if $\sum_j m_j = 0$. For such a closed word, the product formula eq. 5.cxx gives a scalar phase depending on the word and φ, but not on its starting site. Its phase exponent has absolute value at most Cn^2. A finite compression keeps precisely the words whose intermediate coordinates remain in the compression. A fixed word is therefore lost only when its starting site lies within distance Cn of the boundary. The proportion of such sites tends to zero in a Følner exhaustion. The normalized trace of each fixed power tends to its zero-coefficient trace. For vector compressions with both endpoints in the box, the omitted boundary bonds also have zero density. Their omission changes only the same boundary set for each fixed word. The constant term in the normalized logarithm tends to $d \log a$, because the number of retained vector coordinates divided by the number of sites tends to d.

For completeness, the flux derivative estimates must use the combined coefficients of b_φ; expanding separately terms which cancel at zero flux would lose the bound $r < 1$. For a derivative of order j, differentiating coefficient factors gives at most j exceptional factors, with uniformly bounded coefficient norms. Differentiating the closed-word phase gives a factor at most $C_j n^{2j}$. Summing the other factors in absolute value gives, after increasing the constant,

$$\left| \frac{1}{|\Lambda_R|} \partial_\varphi^j \operatorname{Tr}(P_R B_\varphi P_R^*)^n \right| \le C_j (1+n)^{3j} r^{\max\{n-j,0\}}.$$

The same bound holds for the limiting zero-coefficient trace. The sum of these bounds divided by n converges. It justifies termwise differentiation, passage to the volume limit, and their interchange. The argument is uniform on compact positive mass intervals. It proves the assertion for each finite number of derivatives. □

The proof applies to the charged vector polynomial by eq. 5.cxxvi, and to the charged scalar polynomial directly. The neutral polynomial is an ordinary finite Fourier polynomial with the same flat symbol, so it satisfies the same conclusion. A constant colour rotation by it_1 takes U_f to U_{-f}, preserves the compression coordinates, and conjugates both real operators orthogonally. Hence every finite density $\mathcal{D}_R(f, z)$, and its limit, is even.

The cyclic trace in eq. 5.cxxxv will be denoted by $\tau \log(T_\varphi + z)$. This notation means the convergent series with its scalar $d \log a$ term. It is independent of a, since it is the limit of the finite logarithms. It also satisfies

$$\partial_z \tau \log(T_\varphi + z) = \tau (T_\varphi + z)^{-1}. \tag{5.cxxxvi}$$

One may differentiate the locally uniformly convergent series to prove this identity; cyclicity combines the n positions of a differentiated factor. The same argument proves the Jacobi identity for any bounded differentiable perturbation which preserves a positive gap.

5.4.5. *The scalar orbital coefficient.* Let

$$u(q, z) = (\psi(q) + z)^{-1}, \qquad a(q) = \psi_{11}(q) = 2 \cos q_1, \qquad b(q) = \psi_{22}(q) = 2 \cos q_2.$$

For each fixed $z > 0$, u and all its momentum derivatives have absolutely summable Fourier coefficients. For instance, $\psi + z$ stays away from zero on a sufficiently small complex momentum strip, so the Fourier coefficients decrease exponentially by shifting each integration contour. The strip may depend on z. Uniformity of that strip as $z \downarrow 0$ is neither asserted nor needed here.

Lemma 5.11. If $s_2(z)$ is the coefficient of φ^2 in $\tau \log(\Delta_\varphi + z)$, then exactly

$$s_2(z) = \frac{1}{24} \int_{\mathbb{B}} a(q) b(q) u(q, z)^2 \, d\bar{q}. \tag{5.cxxxvii}$$

■

Proof. The Poisson bracket $\{\psi, u\}$ is zero, because u is a function of ψ. The product expansion eq. 5.cxxii therefore gives a second-order parametrix for the scalar resolvent with symbols

$$r_0 = u, \qquad r_1 = 0, \qquad r_2 = \frac{1}{8} u\{\{\psi, u\}\}.$$

More explicitly,

$$(\psi + z) \star_\varphi (u + \varphi^2 r_2) = 1 + O_z(|\varphi|^3) \tag{5.cxxxviii}$$

in the absolutely summable coefficient norm. All required weighted norms are finite at fixed z, so the remainder estimate follows from eq. 5.cxxii.

This parametrix determines the actual inverse coefficient. Indeed, $\Delta_\varphi + z$ has a convergent inverse series in the same coefficient algebra, obtained from eq. 5.cxxxv by the geometric series. Its coefficient norm is locally bounded at fixed z. Multiplying eq. 5.cxxxviii by that inverse shows that the symbol of the actual resolvent differs from $u + \varphi^2 r_2$ by $O_z(|\varphi|^3)$. Thus no formal inverse is being substituted for the lattice resolvent.

Since $\psi_{12} = 0$, differentiation of u gives

$$r_2 = \frac{1}{4}\left\{u^4(a\psi_2^2 + b\psi_1^2) - u^3 ab\right\}.$$

Integration by parts on the momentum torus yields

$$0 = \int_{\mathbb{B}} \partial_2(a\psi_2 u^3)\, d\bar{q} = \int_{\mathbb{B}} (abu^3 - 3a\psi_2^2 u^4)\, d\bar{q},$$

and the same formula with indices exchanged. Consequently

$$\tau \operatorname{Op}_\varphi(r_2) = \int_{\mathbb{B}} r_2\, d\bar{q} = -\frac{1}{12}\int_{\mathbb{B}} abu^3\, d\bar{q}. \tag{5.cxxxix}$$

By eq. 5.cxxxvi, the right side is $s_2'(z)$. The derivative in z of the right side of eq. 5.cxxxvii is the same expression.

Both candidate coefficients tend to zero as $z \to \infty$. For the exact logarithm this follows from the series $\log(\Delta_\varphi + z) = \log z + \log(1 + z^{-1}\Delta_\varphi)$, whose flux derivatives converge uniformly for large z. For the integral it follows from boundedness of a, b and $u \le z^{-1}$. Equality of their derivatives and of their limits at infinity proves eq. 5.cxxxvii. □

The term s_2 is the orbital contribution of one charged scalar determinant. In particular it is already nonzero before the vector spin term is included. Its sign and factor come from the second magnetic bracket, not from a pointwise Taylor expansion of the symbol ψ.

5.4.6. *The vector logarithm and colour multiplicities.* We give the trace calculation with its non-commuting factors. It prevents a scalar logarithm expansion from inadvertently discarding the magnetic contribution. Put

$$B_\varphi = (\Delta_\varphi + z)I_4, \qquad \delta_\varphi = K_\varphi - \Delta_\varphi I_4 = \operatorname{Op}_\varphi(\varphi\Sigma_1 + \varphi^2\Sigma_2 + O(\varphi^3)).$$

At fixed positive z, the segment $B_\varphi + t\delta_\varphi$, $0 \le t \le 1$, has a positive gap for small real φ. The trace Jacobi identity gives

$$\tau \log(B_\varphi + \delta_\varphi) - \tau \log B_\varphi = \int_0^1 \tau\big((B_\varphi + t\delta_\varphi)^{-1}\delta_\varphi\big)\, dt.$$

The exact twice-iterated resolvent identity and cyclicity then give

$$\tau \log(B_\varphi + \delta_\varphi) - \tau \log B_\varphi = \tau(B_\varphi^{-1}\delta_\varphi) - \frac{1}{2}\tau(B_\varphi^{-1}\delta_\varphi B_\varphi^{-1}\delta_\varphi) + O_z(|\varphi|^3). \tag{5.cxl}$$

For example, the remaining resolvent term contains three copies of δ_φ, bounded inverse factors, and a trace on four components per site, so its absolute value is at most $C_z\|\delta_\varphi\|_0^3$.

The scalar inverse has first flux coefficient zero by Lem. 5.11. The exact two-factor identity eq. 5.cxxi therefore shows that the quadratic coefficient of the first term on the right of eq. 5.cxl

is $\int u \operatorname{tr} \Sigma_2 \, d\bar{q}$. The quadratic coefficient of the second term is obtained at zero flux, and equals $-\frac{1}{2} \int u^2 \operatorname{tr} \Sigma_1^2 \, d\bar{q}$. No first magnetic bracket contributes an additional cross term: the scalar inverse has no linear symbol correction, and the trace of a two-factor star product is the ordinary integral exactly. If $v_2(z)$ denotes the quadratic flux coefficient of the charged vector logarithm, we have proved

$$v_2(z) = 4s_2(z) + \int_{\mathbb{B}} u \operatorname{tr} \Sigma_2 \, d\bar{q} - \frac{1}{2} \int_{\mathbb{B}} u^2 \operatorname{tr} \Sigma_1^2 \, d\bar{q}. \tag{5.cxli}$$

For the neutral vector logarithm the corresponding coefficient is simply

$$v_2^0(z) = \int_{\mathbb{B}} u \operatorname{tr} N_2 \, d\bar{q}. \tag{5.cxlii}$$

There are two real charged colours. Equivalently, complexifying the real two-colour space gives sectors with fluxes φ and $-\varphi$. The real determinant of a positive complex-linear charged matrix is the square of its complex determinant. Thus the scalar charged contribution to the real logarithm is twice the one-sector scalar logarithm, and likewise for the charged vector. The neutral scalar logarithm is independent of f. The coefficient of φ^2 in the combination $\log\det\Delta - \frac{1}{2}\log\det K$ is therefore

$$2s_2 - v_2 - \tfrac{1}{2}v_2^0 = -2s_2 - \int u \operatorname{tr} \Sigma_2 \, d\bar{q} + \tfrac{1}{2} \int u^2 \operatorname{tr} \Sigma_1^2 \, d\bar{q} - \tfrac{1}{2} \int u \operatorname{tr} N_2 \, d\bar{q}.$$

Finally $\varphi = 2f$, and a quadratic φ coefficient is multiplied by eight when it is differentiated twice in f. Combining this fact with eq. 5.cxxxvii proves the exact formula

$$\boxed{\widetilde{\beta}(z) = 8 \int_{\mathbb{B}} \left\{ \frac{1}{2} u^2 \operatorname{tr} \Sigma_1^2 - \frac{1}{12} abu^2 - u \operatorname{tr} \Sigma_2 - \frac{1}{2} u \operatorname{tr} N_2 \right\} d\bar{q}.} \tag{5.cxliii}$$

All four functions of momentum in this formula are independent of z. The last term is the neutral-colour correction.

5.4.7. *Infrared integrals and mass derivatives.* We now estimate eq. 5.cxliii uniformly as the mass decreases. On the chosen representatives of the momentum torus,

$$c|q|^2 \le \psi(q) \le |q|^2, \qquad \psi(q) = |q|^2 + O(|q|^4) \quad (q \to 0). \tag{5.cxliv}$$

The lower bound follows, for example, by applying $|\sin(t/2)| \ge |t|/\pi$ on $[-\pi, \pi]$ to each term $2 - 2\cos t$.

Lemma 5.12. Put $I_2(z) = \int_{\mathbb{B}} (\psi + z)^{-2} \, d\bar{q}$. There is a finite c_2 such that

$$I_2(z) = \frac{1}{16\pi^2} \log \frac{1}{z} + c_2 + e_2(z), \qquad |e_2(z)| + |z e_2'(z)| + |z^2 e_2''(z)| \le C\sqrt{z}. \tag{5.cxlv}$$

If h is smooth on $\mathbb{B}$ and $h(0) = 0$, then $R_h(z) = \int h(\psi + z)^{-2} \, d\bar{q}$ has a finite limit at zero and

$$|R_h(z) - R_h(0)| + |z R_h'(z)| + |z^2 R_h''(z)| \le C_h \sqrt{z}. \tag{5.cxlvi}$$

For bounded smooth h, the same conclusion holds for $\int h(\psi + z)^{-1} \, d\bar{q}$. ∎

Proof. Choose a fixed ball $|q| < \rho < \pi$. Outside this ball the integrands and their first two mass derivatives are uniformly bounded. Inside the ball, subtract $(|q|^2 + z)^{-2}$ from $(\psi + z)^{-2}$. The difference is bounded by

$$C \frac{|q|^4}{(|q|^2 + z)^3}.$$

Its first and second mass derivatives are bounded respectively by $C|q|^4(|q|^2 + z)^{-4}$ and $C|q|^4(|q|^2 + z)^{-5}$. Radial integration in four dimensions gives an integrable limit for the difference, a bound $C(1 + |\log z|)$ for the integral of its first derivative, and C/z for that of its second derivative. For instance the first derivative is bounded by a constant times $\int_0^\rho r^7 (r^2 + z)^{-4} \, dr$; splitting at

$r = \sqrt{z}$ gives the asserted logarithm. The second is handled by the same split. Integrating the first derivative from zero to z bounds the difference from its limiting constant by $Cz(1 + |\log z|)$.

The remaining continuum radial integral is exact:

$$\int_{|q|<\rho} (|q|^2 + z)^{-2}\, d\bar{q} = \frac{1}{16\pi^2} \left\{ \log \frac{\rho^2 + z}{z} + \frac{z}{\rho^2 + z} - 1 \right\}.$$

Its nonsingular part has a finite limit and bounded first two derivatives on a sufficiently small positive interval. This proves eq. 5.cxlv, with the slightly weaker but convenient error $C\sqrt{z}$, since $z(1 + |\log z|) \le C\sqrt{z}$ for $0 < z \le 1$.

For the second assertion, smoothness and $h(0) = 0$ give $|h(q)| \le C_h|q|$ near zero. This makes the zero-mass integral absolutely convergent. The first derivative has absolute integral at most

$$C_h \int_0^\rho \frac{r^4}{(r^2 + z)^3}\, dr \le C_h z^{-1/2},$$

and the second at most $C_h \int_0^\rho r^4(r^2 + z)^{-4}\, dr \le C_h z^{-3/2}$. The estimates follow by scaling $r = \sqrt{z}\, s$, extending the resulting integrals to infinity, and using their integrable large-s tails. Their weighted bounds are therefore $C_h\sqrt{z}$. Integration of the first derivative from zero to z proves the remaining difference bound.

For the last assertion the zero-mass integrand is bounded by $C|q|^{-2}$, which is integrable in four dimensions. The first derivative has integral at most $C(1 + |\log z|)$, and the second at most C/z. The same argument again gives the stated, weaker $C\sqrt{z}$ error and weighted derivative bounds. □

Proof of Prop. 5.9. The volume and field-differentiation assertions follow from Lem. 5.10. Positivity and evenness were established above. Formula eq. 5.cxliii identifies the second field derivative exactly.

By eq. 5.cxxix, $\frac{1}{2} \operatorname{tr} \Sigma_1(0)^2 = 4$, whereas $a(0)b(0)/12 = 1/3$. Thus the coefficient of the only logarithmically divergent integral in eq. 5.cxliii is

$$8(4 - \tfrac{1}{3}) I_2(z) = \frac{88}{3} I_2(z).$$

The remaining numerator in front of u^2 vanishes at $q = 0$, by eq. 5.cxxx and continuity of a, b. Its contribution is covered by eq. 5.cxlvi. The terms with one factor of u have bounded smooth numerators and are covered by the last assertion of Lem. 5.12. This includes the neutral term; discarding it would change the finite constant, though not the logarithm.

All these remainders have finite zero-mass limits and the weighted derivative bounds in that lemma. Since

$$\frac{88}{3} \frac{1}{16\pi^2} = \frac{11}{6\pi^2},$$

equation eq. 5.cxlv proves eq. 5.cxvii. Differentiating its logarithmic term and using the weighted error estimates proves eq. 5.cxviii. □

5.4.8. *The second-order mass subtraction.* The mass comparison uses a Taylor polynomial evaluated at zero mass, not merely the determinant at the comparison mass. The preceding proof controls the two derivative terms as well. Define

$$\widetilde{\beta}^\sharp(z) = \widetilde{\beta}(z) - z\widetilde{\beta}'(z) + \tfrac{1}{2} z^2 \widetilde{\beta}''(z).$$

Corollary 5.13. For $c = 11/(6\pi^2)$,

$$\widetilde{\beta}^\sharp(z) = c \log(1/z) + C_* + \tfrac{3}{2} c + O(\sqrt{z}). \tag{5.cxlvii}$$

In particular, for fixed $L > 1$,

$$\widetilde{\beta}^\sharp(L^{-2k}) = \frac{11}{3\pi^2} k \log L + O(1), \qquad k \ge 0. \tag{5.cxlviii}$$

The successive differences of these bare massive coefficients converge to $11\log L/(3\pi^2)$ with error $O(L^{-k})$. ■□

Proof. For $c\log(1/z)$ the first derivative is $-c/z$ and the second is c/z^2. Its two subtraction terms thus add $c + c/2$. The constant contributes only itself, and eq. 5.cxvii bounds the error and both subtracted derivatives by $C\sqrt{z}$. This proves eq. 5.cxlvii. Substitution of $z = L^{-2k}$ proves eq. 5.cxlviii; subtraction at consecutive values of k gives the last assertion. □

The successive differences in this corollary are defined by the bare massive determinant. To identify them, up to a uniformly bounded total error, with a sum of constrained Gaussian increments requires the gauge-change identity, the Schur-complement composition, and the uniform comparison between the averaging regulator and the scalar mass regulator. The present calculation supplies the lattice logarithm and the mass-derivative estimates in that comparison. It does not replace those three identifications. Nor does it imply geometric convergence of the actual renormalization increments from a bounded cumulative comparison alone.

5.5. **The diagonal anisotropy of the massive Wilson coefficient.** The scalar logarithm does not determine the response to a traceless change of the four coordinate weights. We compute that response from the weighted lattice Hessian. The computation retains the lattice symbol until its infrared estimate. In particular it differentiates an actual family of Gaussian operators, rather than differentiating a previously extracted scalar asymptotic without a parameter bound.

Let $a = (a_1, \dots, a_4)$, initially real and close to $(1, 1, 1, 1)$, with all $a_\mu > 0$. Write $\mathsf{A} = \operatorname{diag}(a_\mu)$ on the vector index, and put

$$A_a(U) = \sum_{\mu<\nu} \sum_x a_\mu a_\nu \left(1 - \tfrac{1}{2}\operatorname{tr} U_{\mu\nu}(x)\right), \qquad \Delta_{a,U} = D_U^\sharp \mathsf{A} D_U. \tag{5.cxlix}$$

The colour inner product, covariant shifts, and physical normalization are those in § 5.4. The symbol A_a denotes an action; A is its constant diagonal weight. Set

$$\begin{aligned} K_{a,U} &= A_a''(U) + \mathsf{A} D_U D_U^\sharp \mathsf{A}, \\ \widetilde{K}_{a,U} &= \mathsf{A}^{-1/2} K_{a,U} \mathsf{A}^{-1/2}, \qquad \widetilde{D}_{a,U} = \mathsf{A}^{1/2} D_U. \end{aligned} \tag{5.cl}$$

Square roots are positive for real a; near $a = 1$ their analytic branches are fixed by that choice.

For a chosen coordinate plane $\{\mu, \nu\}$, use the constant Abelian field of eq. 5.cxv, with the axes renamed if necessary. Compress the full operators after they have been formed, exactly as in Prop. 5.9. Define the vacuum-subtracted determinant density from

$$\mathcal{L}_{a,R}(f, z) = \log\det(\Delta_{a,f,R} + z) - \tfrac{1}{2}\log\det(\widetilde{K}_{a,f,R} + z), \qquad z > 0, \tag{5.cli}$$

and let $\widetilde{\beta}_a^{\mu\nu}(z)$ be its second f-derivative per lattice site in the exhaustion limit. All three real colours are included.

Proposition 5.14. There is $\delta > 0$ such that $\widetilde{\beta}_a^{\mu\nu}(z)$ extends holomorphically to $\max_\lambda |a_\lambda - 1| < \delta$. On every fixed smaller polydisc,

$$\widetilde{\beta}_a^{\mu\nu}(z) = c\, d(a) a_\mu a_\nu \log(1/z) + C_{\mu\nu}(a) + E_{\mu\nu}(a, z), \qquad c = \frac{11}{6\pi^2}, \quad d(a) = \prod_{\lambda=1}^{4} a_\lambda^{-1/2}, \tag{5.clii}$$

where $C_{\mu\nu}$ is holomorphic. For every fixed multi-index I,

$$\sup_a \sum_{j=0}^{2} \left| z^j \partial_z^j \partial_a^I E_{\mu\nu}(a, z) \right| \le C_I \sqrt{z}, \qquad 0 < z \le 1. \tag{5.cliii}$$

For real a, this is the coefficient of the actual real weighted Wilson determinant. The field variable f is differentiated as a real variable at fixed $z > 0$. No holomorphic constant-flux family is asserted. ■

5.5.1. *The gauge and the field-coordinate change.* The additional term in eq. 5.cl is the square of the weighted divergence $D_U^\sharp \mathsf{A} v$. Its Faddeev–Popov operator is $D_U^\sharp \mathsf{A} D_U = \Delta_{a,U}$. For real a, change vector coordinates by $v = \mathsf{A}^{-1/2} w$. The Hessian and its gauge square become

$$\widetilde{K}_{a,U} = \mathsf{A}^{-1/2} A_a''(U) \mathsf{A}^{-1/2} + \widetilde{D}_{a,U} \widetilde{D}_{a,U}^\sharp. \tag{5.cliv}$$

The constant Jacobian of this field-coordinate change is independent of U. It disappears from the vacuum-subtracted density. Equivalently the vector mass in the original coordinates is $z\mathsf{A}$:

$$K_{a,U} + z\mathsf{A} = \mathsf{A}^{1/2} (\widetilde{K}_{a,U} + z) \mathsf{A}^{1/2}.$$

This equality also holds for the declared zero-extension compressions. It specifies the regulator used here; comparison with an averaging regulator must retain this choice.

Every constant Abelian field used here is critical for A_a under compactly supported variations. On a bond, the two adjacent plaquettes in each plane contribute opposite copies of the same weighted $\sin f_{\mu\nu}\, t_3$. Gauge invariance therefore gives

$$A_a''(U_f) D_{U_f} = 0, \qquad \widetilde{K}_{a,U_f} \widetilde{D}_{a,U_f} = \widetilde{D}_{a,U_f} \Delta_{a,U_f}. \tag{5.clv}$$

The second identity is also obtained directly from eq. 5.cliv. The spin coefficient below is computed from the Hessian; the Ward identity is an independent check on the chosen gauge.

5.5.2. *An exact weighted symbol.* It suffices to use the plane $(1,2)$. Keep the magnetic shifts and the Weyl product of eq. 5.cxx, with $\varphi = 2f$. Let $H_{\rho\sigma}$ be the exact charged plaquette Hessian in eq. 5.cxxiv. The actual charged operators are

$$\begin{aligned} \widetilde{K}_{a,\varphi} &= \mathsf{A}^{-1/2} \left(\sum_{\rho<\sigma} a_\rho a_\sigma H_{\rho\sigma} \right) \mathsf{A}^{-1/2} + \mathsf{A}^{1/2} D D^\sharp \mathsf{A}^{1/2}, \\ \Delta_{a,\varphi} &= \mathrm{Op}_\varphi(\psi_a), \qquad \psi_a(q) = \sum_{\rho=1}^{4} a_\rho (2 - 2\cos q_\rho). \end{aligned} \tag{5.clvi}$$

Both sides are finite Weyl polynomials. At zero flux, their curl and divergence terms cancel off the diagonal and supply the same missing diagonal direction. Thus

$$\widetilde{\sigma}_{a,0}(q) = \psi_a(q) I_4. \tag{5.clvii}$$

For example the μ-component of the weighted curl square contains $\sum_{\rho\neq\mu} a_\rho D_\rho^\sharp D_\rho$; the divergence square supplies $a_\mu D_\mu D_\mu^\sharp$. This verifies the diagonal identity as well as the off-diagonal cancellation.

Write the actual flux expansion as

$$\widetilde{\sigma}_{a,\varphi} = \psi_a I_4 + \varphi \Sigma_{a,1} + \varphi^2 \Sigma_{a,2} + O(\varphi^3). \tag{5.clviii}$$

Its coefficients are holomorphic in a, with uniformly bounded momentum derivatives on a small complex polydisc. Only the $(1,2)$ plaquette can change the flat cancellation. Relative to the unweighted calculation, its diagonal corrections in the 11 and 22 entries have multipliers a_2 and a_1; its off-diagonal corrections have multiplier $\sqrt{a_1 a_2}$. All other corrections vanish. This follows entry by entry from eq. 5.clvi: congruence divides the 11 entry of $a_1 a_2 H_{12}$ by a_1, and its 12 entry by $\sqrt{a_1 a_2}$. The weighted divergence has exactly the same factors in its corresponding entries. Consequently

$$\Sigma_{a,1}(0) = -2i\sqrt{a_1 a_2}(E_{12} - E_{21}), \qquad \mathrm{tr}\, \Sigma_{a,1}(0)^2 = 8 a_1 a_2, \tag{5.clix}$$

and

$$\|\Sigma_{a,1}(q) - \Sigma_{a,1}(0)\| \le C|q|, \qquad \|\Sigma_{a,2}(q)\| \le C. \tag{5.clx}$$

The same bounds hold after any fixed number of a-derivatives. The neutral colour has expansion

$$\widetilde{K}^0_{a,\varphi} = \psi_a I_4 + \varphi^2 N_{a,2} + O(\varphi^4),$$

where $N_{a,2}$ is a bounded finite Fourier polynomial, holomorphic in a. Its 11 and 22 corrections have the same respective weights a_2, a_1. This neutral term is retained in the finite part of the coefficient.

5.5.3. *The weighted orbital and spin terms.* For $z > 0$, put

$$u_a(q,z) = (\psi_a(q) + z)^{-1}, \qquad A_1(q) = 2a_1 \cos q_1, \quad A_2(q) = 2a_2 \cos q_2.$$

The scalar Weyl calculation in Lem. 5.11 applies with ψ replaced by ψ_a. Its mixed second derivative is still zero. The integration by parts has, for example, the exact form

$$0 = \int_{\mathbb{B}} \partial_2(A_1\, \partial_2\psi_a\, u_a^3)\, d\bar{q} = \int_{\mathbb{B}} (A_1 A_2 u_a^3 - 3A_1(\partial_2\psi_a)^2 u_a^4)\, d\bar{q}.$$

There is no change of magnetic phase, and no approximation of the lattice dispersion in this identity. The scalar quadratic flux coefficient is therefore

$$s_{a,2}(z) = \frac{1}{24} \int_{\mathbb{B}} A_1 A_2 u_a^2\, d\bar{q}. \tag{5.clxi}$$

The trace logarithm is handled by the same twice-iterated resolvent identity as eq. 5.cxl. At fixed real positive a, z, the segment between the scalar diagonal operator and the full vector operator is positive for sufficiently small real flux. Its quadratic term is

$$4s_{a,2} + \int u_a \operatorname{tr} \Sigma_{a,2}\, d\bar{q} - \tfrac{1}{2} \int u_a^2 \operatorname{tr} \Sigma_{a,1}^2\, d\bar{q}.$$

The scalar inverse has no first flux coefficient. The exact trace of a two-factor Weyl product is its ordinary momentum integral, so no first magnetic bracket has been omitted here. The two real charged colours and $\varphi = 2f$ give the same multiplicity eight as in eq. 5.cxliii. We obtain the exact formula

$$\begin{aligned} \widetilde{\beta}_a^{12}(z) = 8 \int_{\mathbb{B}} \{ &\tfrac{1}{2} u_a^2 \operatorname{tr} \Sigma_{a,1}^2 - \tfrac{1}{12} A_1 A_2 u_a^2 \\ &- u_a \operatorname{tr} \Sigma_{a,2} - \tfrac{1}{2} u_a \operatorname{tr} N_{a,2} \}\, d\bar{q}. \end{aligned} \tag{5.clxii}$$

Its existence as a real exhaustion limit follows from the closed-walk proof in Lem. 5.10. All step ranges remain fixed. The coefficients and their parameter derivatives are uniformly bounded on compact sets of positive a, z. Every fixed number of flux and parameter derivatives therefore has the same dominated closed-walk limit. For example a derivative of a finite power inserts at most a polynomial in its length, while the fixed-mass resolvent series has geometric decay. Boundary walks occupy a vanishing fraction of any declared Følner exhaustion. This justifies taking the real field derivative before the exhaustion limit.

For complex a close to one, $\operatorname{Re} \psi_a(q) \geq c|q|^2$ on the standard momentum representatives. The right side of eq. 5.clxii is consequently holomorphic in a at each $z > 0$. It defines the claimed extension from its real values. This extension concerns the weight parameters; it does not complexify the constant flux used in the closed-walk argument.

5.5.4. *A uniform anisotropic infrared integral.* We prove the parameter estimate needed to differentiate the logarithm. For a in a small complex polydisc put

$$I_{2,a}(z) = \int_{\mathbb{B}} (\psi_a + z)^{-2}\, d\bar{q}, \qquad H_a(t) = \int_{\mathbb{B}} e^{-t\psi_a(q)}\, d\bar{q}.$$

For $t \geq 1$, uniformly on that polydisc,

$$H_a(t) = \frac{d(a)}{16\pi^2 t^2} + O(t^{-3}). \tag{5.clxiii}$$

To verify the remainder, take a fixed small momentum ball. On it,

$$\psi_a(q) = Q_a(q) + O(|q|^4), \quad Q_a(q) = \sum_{\lambda} a_\lambda q_\lambda^2, \quad \operatorname{Re} Q_a(q) \geq c|q|^2.$$

The difference of the two exponentials is bounded by $Ct|q|^4 e^{-ct|q|^2}$. Its four-dimensional integral is $O(t^{-3})$. Outside the ball the lattice integral is exponentially small, and extending the Gaussian integral to $\mathbb{R}^4$ costs the same type of error. The latter integral is

$$(2\pi)^{-4}\int_{\mathbb{R}^4} e^{-tQ_a(q)}\,dq = \frac{d(a)}{16\pi^2 t^2}.$$

For complex a, this identity follows from the one-dimensional Gaussian integrals on their branches near the positive real axis. Every estimate is uniform on a slightly larger polydisc than the one on which derivatives will be taken.

Since $\mathrm{Re}(\psi_a + z) > 0$, Fubini gives

$$I_{2,a}(z) = \int_0^\infty te^{-tz}H_a(t)\,dt. \tag{5.clxiv}$$

Let $c_a = d(a)/(16\pi^2)$. Subtract $c_a t^{-2}$ only for $t \geq 1$. The remaining integrand $tH_a(t)$ is bounded near zero and is $O(t^{-2})$ at infinity. Thus

$$I_{2,a}(z) = c_a\log(1/z) + C_I(a) + R_I(a,z), \qquad \sum_{j=0}^{2}|z^j\partial_z^j R_I(a,z)| \leq C\sqrt{z}. \tag{5.clxv}$$

Here is an explicit control of the limit and its derivatives. For the subtracted remainder $r_a(t)$, $|r_a(t)| \leq C\min(t, t^{-2})$. Replacing e^{-zt} by one costs

$$\int_0^\infty |e^{-zt}-1|\,|r_a(t)|\,dt \leq Cz\{1+\log(1/z)\}.$$

After one or two z-derivatives, the corresponding estimates are

$$z\int_0^\infty te^{-zt}|r_a(t)|\,dt \leq Cz\{1+\log(1/z)\}, \qquad z^2\int_0^\infty t^2e^{-zt}|r_a(t)|\,dt \leq Cz.$$

The subtracted leading term uses $\int_1^\infty e^{-zt}dt/t$. Its difference from $\log(1/z)$ has a finite limit, an error $O(z)$, and weighted first and second derivative errors $O(z)$. These estimates prove eq. 5.clxv. The constant $C_I(a)$ is a normally convergent integral plus a holomorphic multiple of a fixed number, and is holomorphic. Cauchy's estimate on the larger polydisc proves all fixed a-derivative versions of eq. 5.clxv.

Two elementary remainder estimates complete the calculation. If $h_a(q)$ is holomorphic in a and $|h_a(q)| \leq C|q|$, then

$$\int_{\mathbb{B}} h_a(q)u_a(q,z)^2\,d\bar{q} = C_h(a) + R_h(a,z), \qquad \sum_{j=0}^{2}|z^j\partial_z^j R_h(a,z)| \leq C\sqrt{z}. \tag{5.clxvi}$$

The limit at zero is integrable. Split its difference from the positive-mass integral at $|q| = \sqrt{z}$. The inner radial bound is $C\int_0^{\sqrt{z}}dr = C\sqrt{z}$; the outer bound is $Cz\int_{\sqrt{z}}^1 r^{-2}dr \leq C\sqrt{z}$. For the weighted first derivative, use $Cz\int_0^1 r^4(r^2+z)^{-3}dr$; for the second use $Cz^2\int_0^1 r^4(r^2+z)^{-4}dr$. Both are $O(\sqrt{z})$. The region outside the unit ball has a uniform positive dispersion and obeys the same bound. Normal convergence makes C_h holomorphic. Cauchy again gives its parameter derivative versions.

If the numerator is merely bounded and there is one factor u_a, the zero-mass limit is also finite. Its error is bounded by $Cz\{1+\log(1/z)\}$, its weighted first derivative by the same quantity, and its weighted second derivative by Cz. These follow from the radial integrals with numerator r^3. They too imply the bound $C\sqrt{z}$. This includes the neutral term and the second vector-symbol jet.

Proof of Prop. 5.14. At $q = 0$, the combined numerator of u_a^2 in eq. 5.clxii is

$$8\left(4a_1a_2 - \frac{1}{3}a_1a_2\right) = \frac{88}{3}a_1a_2.$$

After this constant is subtracted, the numerator vanishes at least linearly in $|q|$, by eq. 5.clx. Apply eq. 5.clxv to its constant part, eq. 5.clxvi to its vanishing part, and the single-resolvent estimate to the remaining two terms. The only logarithm is therefore

$$\frac{88}{3}a_1a_2\frac{d(a)}{16\pi^2}\log(1/z) = c\,d(a)a_1a_2\log(1/z).$$

All finite constants are holomorphic in a, and all remainders have the stated mass and parameter derivative bounds. Renaming the two axes proves every plane case. □

5.5.5. *The actual tracefree diagonal response.* Let $e = (e_1, \dots, e_4)$, and put $a_\lambda(t) = 1 + te_\lambda$. The weight of the (μ, ν) plaquette is

$$a_\mu(t)a_\nu(t) = 1 + t(e_\mu + e_\nu) + O(t^2).$$

Thus its derivative at zero is exactly the prescribed diagonal anisotropy; the harmless quadratic choice of the weight family does not change that derivative. Define

$$\dot\beta_e^{\mu\nu}(z) = \frac{d}{dt}\Big|_{t=0}\widetilde\beta_{a(t)}^{\mu\nu}(z).$$

The derivative of the logarithmic weight is

$$\frac{d}{dt}\Big|_0 d(a(t))a_\mu(t)a_\nu(t) = e_\mu + e_\nu - \frac{1}{2}\sum_{\lambda=1}^{4} e_\lambda. \tag{5.clxvii}$$

Consequently, if $\sum_\lambda e_\lambda = 0$,

$$\dot\beta_e^{\mu\nu}(z) = c(e_\mu + e_\nu)\log(1/z) + \dot C_e^{\mu\nu} + O(|e|\sqrt{z}), \tag{5.clxviii}$$

with the same two weighted mass derivative estimates for the error. For an isotropic direction $e_\lambda = s$, the logarithmic derivative vanishes. This verifies directly that the tracefree diagonal channel and the scalar weight channel have different one-loop responses.

Apply the second-order mass subtraction to the weighted family:

$$\widetilde\beta_a^{\mu\nu,\sharp}(z) = \left(1 - z\partial_z + \tfrac{1}{2}z^2\partial_z^2\right)\widetilde\beta_a^{\mu\nu}(z).$$

Parameter differentiation commutes with this finite differential operator. By eq. 5.cliii,

$$\widetilde\beta_a^{\mu\nu,\sharp}(z) = c\,d(a)a_\mu a_\nu\log(1/z) + C_{\mu\nu}(a) + \tfrac{3}{2}c\,d(a)a_\mu a_\nu + O_a(\sqrt{z}), \tag{5.clxix}$$

uniformly with any fixed number of parameter derivatives.

Corollary 5.15. Let $h_k = L^{-k}$, with the fixed blocking integer L. In the tracefree diagonal direction,

$$\frac{d}{dt}\Big|_0 \widetilde\beta_{1+te}^{\mu\nu,\sharp}(h_k^2) = \frac{11}{3\pi^2}(e_\mu + e_\nu)k\log L + C_e^{\mu\nu} + O(|e|L^{-k}). \tag{5.clxx}$$

Its consecutive differences converge geometrically to $11(e_\mu + e_\nu)\log L/(3\pi^2)$. The analogous cumulative coefficient in the isotropic weight direction is bounded. ■□

Proof. Substitute $z = h_k^2$ in eq. 5.clxix, differentiate, and use eq. 5.clxvii. The two errors at consecutive depths are each bounded by a constant times L^{-k}. The coefficient of the logarithm is zero in the isotropic direction, so only its finite limit and the bounded error remain there. □

This corollary concerns the bare massive determinants just defined. For the actual blocked anisotropic increment one must also compare the weighted constrained determinant, its classical background, and its regulator uniformly in the weight parameter. The uniform parameter estimate here is the input that permits that comparison to be differentiated. A bounded scalar comparison without such a parameter domain would not suffice.

5.6. **Affine response and preservation of the coupling coefficient.** The coefficient of the action can be read from an affine field of constant curvature. The nonlinear background map is defined on a bounded field ball, so this readout uses the polynomial extension of its linear response. We construct that extension from the actual exponentially localized inverse and compute its value. No nonlinear background is evaluated at an unbounded affine field.

Use the homogeneous construction of Prop. 3.183 at the trivial flat reference. The coarse spacing is one and $h = L^{-j}$, with $j \geq 0$. The fixed flat fine gradient is D, its curl is d, and the actual straightened derivative is Q. The derivative of the constructed strong-gauge representative will be denoted by H_h. The derivative of the literal physical representative will be denoted by $\widehat{H}_h$. Gauge covariance relates them, but they are not identified as coordinate maps.

5.6.1. *Polynomial extension of the actual inverse.* Group fine coordinates into unit coarse cells. At a fixed depth, each cell has finitely many fine coordinates. The exponential kernel estimates for the joint inverse and its coarse multiplier imply that its matrix entries have every polynomial spatial moment. The following observation makes the uniqueness argument precise.

Lemma 5.16. Suppose a cell operator $\mathcal{L}$ and a two-sided inverse $\mathcal{G}$ have absolutely summable exponentially weighted row kernels, uniformly in the row. Then both act on fields of any fixed polynomial growth, their products agree with their usual matrix products there, and $\mathcal{L}\mathcal{G} = \mathcal{G}\mathcal{L} = 1$ on that space. In particular a polynomial-growth solution of $\mathcal{L}u = 0$ is zero. ■

Proof. For a field with $|u(z)| \leq C(1 + |z|)^m$, use

$$(1 + |z|)^m \leq (1 + |x|)^m (1 + |z - x|)^m$$

in the row defining the output at x. The exponential moment dominates the last polynomial, so the row converges absolutely. In a product of two kernels the corresponding double sum converges absolutely by the same inequality applied twice. Fubini therefore identifies it with the matrix product, whose identity was already known on finitely supported fields. □

Apply this lemma to the actual flat joint operator

$$\mathcal{L}_h(A, \omega) = \big((\mathrm{d}^\sharp \mathrm{d} + DRD^\sharp)A - Q^\sharp \omega,\, QA\big).$$

The site smoothing in R has exponential cell kernels, as do its first derivatives; the remaining coefficients have fixed physical carriers. The operator and its inverse therefore satisfy the lemma at each fixed h. Their physical weighted estimates also show that the extensions of their fixed-degree jets have constants independent of depth. The finite-dimensional coordinate count inside a cell is not used as a uniform bound.

5.6.2. *The actual response to constant curvature.* Fix a real antisymmetric tensor $F = (F_{\mu\nu})_{\mu,\nu=1}^4$, and one constant colour t, with $\frac{1}{2}\,\mathrm{tr}\, t^2 = 1$. On the physical fine and coarse lattices set

$$a_\mu(x) = \tfrac{1}{2} \sum_\nu F_{\nu\mu} x_\nu t, \qquad b_\mu(y) = \tfrac{1}{2} \sum_\nu F_{\nu\mu} y_\nu t. \tag{5.clxxi}$$

Their fine curl is the constant tensor $F_{\mu\nu} t$. Their fine divergence is zero, since $F_{\mu\mu} = 0$. In particular

$$\mathrm{d}^\sharp \mathrm{d} a = 0, \qquad D^\sharp a = 0.$$

Lemma 5.17. For every homogeneous depth, the actual straightened linear average satisfies $Qa = b$. ■

Proof. Write $n = h^{-1}$, which is odd. In the parallel frame, the actual row is eq. 3.mccxxiv:

$$(Qa)_\mu(y) = h^5 \sum_{x \in B_n(y)} \sum_{\ell=0}^{n-1} a_\mu(x + \ell h e_\mu).$$

The centred block has coordinate mean y. The line average shifts only the μ-coordinate, by $(1-h)/2$. Its coefficient in a_μ is $F_{\mu\mu}/2 = 0$. The normalization of the block and line weights is $h^5 n^5 = 1$. These facts give $Qa = b$ exactly.

The formula for the row also follows directly by composing the actual one-step flat derivatives. Balanced base-L digits run once through the centred block of n sites in each direction, while ordinary digits $0, \dots, L-1$ run once through the n successive longitudinal steps. Thus no replacement of the composed average by a continuum mean has occurred. □

Proposition 5.18. The polynomial extension of the actual strong-gauge linear response satisfies

$$H_h b = a, \qquad D\omega(0)b = 0. \tag{5.clxxii}$$

The literal physical response has the form

$$\widehat{H}_h b = a + D\lambda_b, \tag{5.clxxiii}$$

for a polynomial-growth fine gauge parameter λ_b. Its degree is bounded independently of depth. ■

Proof. Differentiate the actual joint fixed-point equations at zero. Their nonlinear residuals have zero first derivative, so $(H_h b, D\omega(0)b)$ solves

$$(\mathrm{d}^\sharp \mathrm{d} + DRD^\sharp)H_h b - Q^\sharp D\omega(0)b = 0, \qquad QH_h b = b.$$

The pair $(a, 0)$ solves these same equations by Lem. 5.17 and the zero divergence and curl-divergence identities above. It also satisfies the fixed Landau condition. Both pairs have polynomial growth. Their difference vanishes by Lem. 5.16, which proves eq. 5.clxxii.

The actual literal representative is obtained from the strong-gauge one by the specified fine gauge in eq. 3.mcclxxxiv. Differentiate that identity at zero. The derivative of a fine gauge is a fine gradient, giving eq. 5.clxxiii. Its gauge parameter is the composition of the derivative of the actual node factor, the local node extension, and the response H_h. The node factor has a fixed physical carrier and bounded analytic derivatives, while H_h has exponential cell kernels. These operators map an affine input to a polynomial-growth output of bounded degree. This argument extends the linear jets only. □

For a single $(1,2)$ curvature component, the symmetric potential in eq. 5.clxxi differs from the potential $a_1 = -F_{12}x_2 t,\ a_2 = 0$ by the gradient of a quadratic polynomial, with sign determined by the convention for D. Thus either potential gives the same gauge-invariant quadratic readout.

5.6.3. *The coefficient readout after substitution.* Use the pointed density convention of eq. 4.ii and eq. 4.v. Thus write $\mathcal{F}_h = \sum_z \mathcal{F}_{h,z}$, where each localized scalar density is gauge invariant and is normalized at the trivial field. Its Hessian kernel at an anchor z satisfies, at each fixed mesh,

$$\sum_{b,c} e^{m(\mathrm{dist}(b,z)+\mathrm{dist}(c,z))} \left\| D^2\mathcal{F}_{h,z}(1)[\delta_b, \delta_c] \right\| < \infty \tag{5.clxxiv}$$

for some $m > 0$. The anchors, physical volume normalization and compatible pointing are part of this convention. A sum of already localized members with the same absolute moment has the same meaning here.

Constant colour rotations force the first derivative of each density to vanish. Its Hessian annihilates fine gradients by the differentiated local gauge Ward identity. The two-leg moment eq. 5.clxxiv extends that identity to polynomial gauge parameters and polynomial second arguments. In particular the affine readout is taken in a density anchored at z, then summed with the prescribed density of anchors per physical volume. It is not the formal extensive pairing $\langle a, Ka\rangle$ of a translation-invariant bulk kernel with an unbounded affine field.

For each localized density, the second derivative of $\mathcal{F}_{h,z}(\widehat{U}(B))$ has no term involving the second derivative of the background: that term is multiplied by $D\mathcal{F}_{h,z}(1) = 0$. Its affine quadratic readout is consequently the rooted Hessian applied to $\widehat{H}_h b$ twice. Equation eq. 5.clxxiii and the polynomial

Ward identity replace both arguments by a. Sum the resulting density identities with the actual anchor weights; their partition of unity preserves the physical density. The action itself has density $\frac{1}{2}\sum_{\mu<\nu}|F_{\mu\nu}|^2$ in this normalization. We have proved

$$b[\mathcal{F}_h \circ \widehat{U}] = b_h[\mathcal{F}_h]. \tag{5.clxxv}$$

The subscript on the right specifies physical fine spacing h. In four dimensions this coefficient has no extra power of the blocking scale.

For a successive map this also requires the actual nested criticality identity, rather than an identification of that map with a direct Wilson lift. We give the argument explicitly. Work first in common physical units. Write $\widehat{U}^{(j)}$ for the full Wilson critical lift to the original fine lattice, $\widehat{U}^{(j-1)}$ for the preceding lift, and p_j for the one-step critical map of the actual effective action S_{j-1}. The common-chart semigroup identity proved in § 4.9.6 says

$$\widehat{U}^{(j)}(B) \sim \widehat{U}^{(j-1)}(p_j(B)),$$

where the equivalence is a fine gauge equal to one at the final coarse nodes. Apply the literal $(j-1)$-step mean. The right side is $p_j(B)$. The gauge on the left induces a gauge on the intermediate coarse lattice. Consequently, at the trivial field,

$$Dp_j(0)b = Q_{\mathrm{lit}}^{(j-1)}\widehat{H}^{(j)}b + \mathrm{d}\chi = a_{\mathrm{intermediate}} + d\widetilde{\chi}. \tag{5.clxxvi}$$

Here b is an affine final coarse potential with constant antisymmetric curvature. The symbol $a_{\mathrm{intermediate}}$ denotes its link variation in the same convention as p_j: it is ξa_{phys} at intermediate bond centres for raw link-log coordinates, where $\xi = 1/L$ in final coarse units, and it is a_{phys} for variations normalized per unit length. For the second equality, the direct fine response is the affine fine potential modulo a gradient by eq. 5.clxxiii. The straightened block-line mean reproduces that affine potential at its intermediate bond centres, with this length factor; see also eq. 5.24. Its literal mean differs by the coarse frame gauge of the exact plain-mean recursion. The linearized gauge covariance of the literal mean takes a fine gradient to an intermediate gradient. These observations give exactly the last term in eq. 5.clxxvi, without claiming that the literal derivative equals the straightened average.

The same polynomial-growth extension used in the direct affine response justifies these linear identities on the infinite lattice. In particular, for any compatible complete pointed gauge-invariant density $\mathcal{F}$, its vanished first jet removes D^2p_j, and its two-leg Ward identity removes both gradients in eq. 5.clxxvi. Thus

$$b[\mathcal{F} \circ p_j] = b[\mathcal{F}]. \tag{5.clxxvii}$$

This applies to the physical cumulative Gaussian density in its successive-depth identity. It concerns complete invariant densities, rather than arbitrary fixed-reference Taylor pieces.

Finally change physical units between the successive lattices. Two factors L^{-1} from the one-form variation and a factor L^4 from the volume convert its quadratic Hessian to $L^2\hat{\pi}(p/L)$; the two powers of momentum remove that L^2. Equation eq. 5.clxxv is the coordinate-free affine version of this cancellation. It establishes preservation of the coefficient; it does not require equality of full polarization symbols at nonzero momentum.

5.6.4. *Physical mass and the bare lattice formula.* For a physical mass parameter $s > 0$, let

$$\mathcal{L}_h(s, U) = \log\det(\Delta_{h,U} + s) - \tfrac{1}{2}\log\det(K_{h,U} + s),$$

with its trivial-field value subtracted and with the bulk trace convention of § 5.4. These are unconstrained site and Wilson-vector operators. The fine physical variations and inner products give

$$\Delta_{h,U} = h^{-2}\Delta_{\mathrm{bare},U}, \qquad K_{h,U} = h^{-2}K_{\mathrm{bare},U}, \qquad z = h^2 s. \tag{5.clxxviii}$$

The scalar factors h^{-2} in their determinants are field independent and disappear from the normalized logarithm.

In a constant physical curvature tF, the angle of a fine plaquette in bare units is h^2tF. There are h^{-4} bare sites per unit physical volume. Hence the coefficient per physical volume is obtained by multiplying $\frac{1}{2}\widetilde{\beta}(h^2s)(h^2tF)^2$ by h^{-4}. The two powers of plaquette area cancel this density exactly. Thus

$$b[\mathcal{L}_h(s,\widehat{U}(\cdot))] = \widetilde{\beta}(h^2s). \tag{5.clxxix}$$

For the constant field, the symmetric and linear potentials are related by an exact Abelian gauge. Each finite compression of the massive bare operators is conjugated by its unitary adjoint matrices. Their determinant densities therefore agree. Equivalently their quadratic jets agree by the polynomial Ward identity.

At a fixed positive mass, the massive resolvent and its mass derivatives have exponential kernels, locally uniformly in that mass. Differentiation therefore commutes with the second-moment coefficient readout. Applying it once and twice to eq. 5.clxxix, define

$$\mathcal{L}_h^\sharp = \mathcal{L}_h(1) - \partial_s\mathcal{L}_h(1) + \tfrac{1}{2}\partial_s^2\mathcal{L}_h(1).$$

Then

$$b[\mathcal{L}_h^\sharp \circ \widehat{U}] = \widetilde{\beta}(h^2) - h^2\widetilde{\beta}'(h^2) + \tfrac{1}{2}h^4\widetilde{\beta}''(h^2). \tag{5.clxxx}$$

This identity supplies the scale and normalization needed to use Cor. 5.13 in the physical Gaussian comparison.

5.7. **Uniform comparison of the averaging and mass regulators.** The massive coefficient and the finite gauge-change identity have different regulators. We now compare them at the actual homogeneous background, uniformly in the fine depth. The comparison includes the constraint Schur determinants. Its ultraviolet remainder contains three free resolvents, which are trace summable in four dimensions. The few averaging directions are controlled by rank, rather than by pretending that the averaging regulator is a scalar mass.

We use the background of Prop. 3.183 on a smaller fixed coarse ball. Fine scalar and vector spaces have physical measure h^4, where $h = L^{-j}$; coarse spaces have counting measure. At each actual background $U = \widehat{U}(B)$, re-center the fine coordinate as $e^{iha}U$. Write $D = D_U$, $\Delta = D^\sharp D$, and let $q = q_U$, $Q = Q_U$ be the actual site and straightened field derivatives at this re-centered zero. Thus $qq^\sharp = 1$ and $QD = \mathrm{d}_c q$. They are not the effective τ_A of the fixed-flat chart at a nonzero A. Let $A''_W(U)$ denote the actual physical Wilson Hessian and put

$$K = A''_W(U) + DD^\sharp, \qquad V_s = q^\sharp q, \qquad V_v = Q^\sharp Q - Dq^\sharp qD^\sharp. \tag{5.clxxxi}$$

The two averaging precisions are $\Delta + V_s$ and $K + V_v$. The latter is the background-gauge precision with its field-row penalty, rather than the Landau precision used to construct the background. Its gap therefore requires a separate proof.

5.7.1. *A uniform gap for the flat background gauge.* All operators in this subsection are at a flat reference. Put $P_0 = 1 - q^\sharp q$, and retain R_L for the previously proved Landau projector. Define

$$\Xi_0 = \mathrm{d}^\sharp\mathrm{d} + DP_0D^\sharp + Q^\sharp Q. \tag{5.clxxxii}$$

Lemma 5.19 (The projected scalar Poisson equation)**.** For $f \in \ker q$, the equations

$$q\lambda = 0, \qquad P_0\Delta\lambda = f \tag{5.clxxxiii}$$

have a unique solution and

$$\|\lambda\|_2 + \|D\lambda\|_2 + \|D^2\lambda\|_2 \le C\|f\|_2. \tag{5.clxxxiv}$$

The constants are uniform in mesh, volume and real flat holonomy. ∎

Proof. The actual site Poincaré inequality on $\ker q$ makes $\langle D\lambda, D\lambda\rangle$ coercive there. Its finite variational equation gives existence, uniqueness and $\|\lambda\|_{H^1} \le C\|f\|_2$. The missing site component is a multiplier: $\Delta\lambda = f + q^\sharp\zeta$. Read it with the smooth exact site lift E_q of Lem. 3.180. For every coarse b,

$$\langle \zeta, b\rangle = \langle D\lambda, DE_q b\rangle - \langle f, E_q b\rangle.$$

The physical seed energy yields $\|\zeta\|_2 \le C\|f\|_2$. Since $q^\sharp$ is an isometry, $\|\Delta\lambda\|_2 \le C\|f\|_2$. In the flat parallel frame the Fourier identity $\sum_{\mu,\nu}\|D_\mu D_\nu\lambda\|_2^2 = \|\Delta\lambda\|_2^2$ proves the last estimate. Twisted periodic phases do not change this identity. No point readout of a fine energy function is used. □

Proposition 5.20 (Uniform background-gauge gap)**.** There are $c, C > 0$ such that

$$c\|v\|_{H^1}^2 \le \langle v, \Xi_0 v\rangle \le C\|v\|_{H^1}^2. \tag{5.clxxxv}$$

On a fixed smaller ball of real actual backgrounds the same comparison holds for $K + V_v$ and for $\Delta + V_s$, relative to their free physical H^1 norms. All constants are independent of j, M. On its smaller complex continuation, the normalized precisions have uniform relative-form Neumann inverses; no Hermitian inequality is asserted at a complex background. ■

Proof. Use the proved flat Landau restoration to write $v = s + D\lambda$, where $R_L D^\sharp s = 0$ and $q\lambda = 0$. Its intertwining gives $Qs = Qv$ and its flat curl gives $\mathrm{d}s = \mathrm{d}v$. The Landau gap therefore implies

$$\|s\|_{H^1} \le C(\|\mathrm{d}v\|_2 + \|Qv\|_2).$$

The remaining scalar function satisfies $P_0\Delta\lambda = P_0 D^\sharp v - P_0 D^\sharp s$. Apply Lem. 5.19 to obtain

$$\|D\lambda\|_{H^1} \le C(\|P_0 D^\sharp v\|_2 + \|s\|_{H^1}).$$

Together these inequalities prove the lower bound. The upper bound follows from the actual flat row bounds and $\|P_0\| \le 1$.

For the actual background, its literal normal coordinate has fixed small X_α norm. The actual coefficient comparisons give $D_U - D_0 = O(r)$ as a zero-order L^2 operator and $q_U - q_0, Q_U - Q_0 = O(r)$ in physical L^2 row norms. For the site map this follows directly by summing its disjoint transported pillar averages; path lengths are bounded in physical units and its transport errors are $O(r)$. For the field map use the actual row/column density estimates. The exact Wilson Hessian comparison bounds its form error by $Cr\|v\|_{H^1}^2$. Expanding $D_U(1 - q_U^\sharp q_U)D_U^\sharp$ as a form gives the same error. Thus $K + V_v$ is a small form perturbation of Ξ_0. The scalar statement is the actual site gap, or the identical comparison with $\Delta_0 + q_0^\sharp q_0$. A fixed smaller r preserves both gaps uniformly. □

The gaps hold throughout the interpolation

$$M = K_* + 1, \qquad S_t = M + t(V - 1), \qquad 0 \le t \le 1, \quad (K_*, V) = (\Delta, V_s) \text{ or } (K, V_v). \tag{5.clxxxvi}$$

Indeed its form is the convex combination of $K_* + 1$ and $K_* + V$. At the flat reference both are uniformly comparable to $L + 1$; the just proved coefficient perturbation preserves this fact. This observation also supplies coherent logarithm branches near the real positive precisions.

5.7.2. *Fixed free normalization and the actual low-rank factors.* Set $G_0 = (L+1)^{-1}$ on the flat fine scalar space, with identity on colours and, for vectors, on components. All normalizations below use this fixed free operator, independent of the background. Define

$$B = G_0^{1/2} M G_0^{1/2}, \quad B_t = G_0^{1/2} S_t G_0^{1/2}, \quad A = G_0^{1/2} V G_0^{1/2}, \quad X = A - G_0. \tag{5.clxxxvii}$$

The gaps prove uniform bounds for B, B_t and their inverses; they continue to a fixed smaller complex physical background ball by their relative form Neumann series.

The actual rank factorization is explicit. In the scalar case $A = (qG_0^{1/2})^\sharp (qG_0^{1/2})$. In the vector case it is

$$A = (QG_0^{1/2})^\sharp (QG_0^{1/2}) - (qD^\sharp G_0^{1/2})^\sharp (qD^\sharp G_0^{1/2}). \tag{5.clxxxviii}$$

At a flat coarse Bloch fibre its rank is at most 3 in the scalar case and $12+3=15$ in the vector case. Its norm is uniformly bounded. Indeed Q, q have the actual physical row bounds, and $D_U^\sharp G_0^{1/2}$ is bounded since its flat part is a normalized derivative and its remaining part is zero order $O(r)$. The negative sign in the vector regulator causes no problem for this norm/rank assertion or for the interpolation gap.

We record why these bounds retain two actual background derivatives. The site transport has physical path length bounded by a geometric sum of scales. Its complex adjoint matrices and all fixed parameter derivatives have bounded norm. Summation over disjoint pillars gives bounded physical q row norms on a fixed complex fine potential ball. The actual straightened recursion gives bounded physical Q row norms on the same joint reference/increment ball. To check that this joint ball is uniform after re-centering, truncate the construction at scale s. Its formulas give both $\|a_s\|_\infty \le Cr\xi_s$ and $\|v_s - 1\|_\infty \le Cr\sum_{r'<s}\xi_{r'} \le Cr\xi_s$. Thus the plain reference $W_s = M^s U$ has raw logarithm of size $Cr\xi_s$ in the flat frame. The joint one-step reference/increment estimates therefore have summable errors at every remaining scale. Their actual row/column products give the physical Q bound on a fixed ball, even for a complex reference. This does not assume that the fixed-reference effective gauge derivative is a site average. Banach-valued Cauchy differentiation in the reference potential therefore bounds the first two derivatives of these row operators; it does not infer absolute entry sums from a general bilinear infinity-norm estimate. The fine derivative D_U has first parameter variation of zero order $O(\|\delta A\|_\infty)$ and second variation $O(h\|\delta A_1\|_\infty\|\delta A_2\|_\infty)$, directly from the exponential link.

The physical Wilson Hessian can be checked without an unspecified coefficient theorem. In one plaquette put

$$\mathcal{C}_U a(p) = h^{-1}\sum_{b\in\partial p}\epsilon_{p,b}\,\mathrm{Ad}(T_{p,b}(U))a_b,$$

where $T_{p,b}$ is the ordered prefix which moves that link insertion to the plaquette base. In a reversed edge its inverse-link insertion is included in that prefix. Thus $\delta U(p)U(p)^{-1} = ih^2\mathcal{C}_U a(p)$ and $\mathcal{C}_0 = d$. Differentiating the four link factors a second time splits their Hessian into a quadratic form in $\mathcal{C}_U a, \mathcal{C}_U b$, with bounded analytic plaquette coefficient, and a remainder with physical bound $Ch^4|F_p|\sum_{b\in\partial p}|a_b|\sum_{b\in\partial p}|b_b|$. To see the power, the two link insertions supply h^2; the part not in their squared total insertion pairs with the antisymmetric plaquette defect, of size h^2F_p. At the identity this part is zero. The symmetric total-insertion coefficient is the bounded matrix obtained from $U(p)+U(p)^{-1}$.

Every prefix contains at most four links. Consequently $\mathcal{C}_U - d$ is zero order of size $C\|A\|_\infty$, its first parameter derivative is zero order of size $C\|\delta A\|_\infty$, and its second derivative has bound $Ch\|\delta A_1\|_\infty\|\delta A_2\|_\infty$. The curvature formula $F = \mathrm{d}A + E_h(A)$ bounds its first two parameter jets by the corresponding X_α background norms. Differentiate the preceding finite plaquette decomposition. Since $\mathrm{d}G_0^{1/2}$ is bounded, it proves uniform bounds on the first two derivatives of $G_0^{1/2}A''_W(U)G_0^{1/2}$. The same statement for $DD^\sharp$ follows from the already stated zero-order parameter derivatives of D. If these calculations are instead performed in the fixed A chart, the extra second coordinate differential contains hJ; it is also bounded because $h\|\mathrm{d}^\sharp\mathrm{d}\delta A\|_\infty \le C\|D\delta A\|_\infty$ and the complete Wilson residual is uniformly analytic. We have therefore obtained the first two normalized M jets from the actual Wilson formula, without assuming the desired inverse. The localized response estimates eq. 3.mccxcv and eq. 3.mccxcvi supply exactly those directions after the physical background is substituted.

5.7.3. *The exact resolvent subtraction.* The following identity is finite dimensional and retains the full regulator V, which need not be positive. Put $G = M^{-1}$ and $W = V - 1$. The resolvent identity applied twice gives

$$S_t^{-1} = G - tGWG + t^2GWGWS_t^{-1}.$$

Integrate $\partial_t \log\det S_t = \mathrm{Tr}(S_t^{-1}W)$, then expand $W = V - 1$. One obtains exactly

$$\begin{aligned}&\log\det(K_* + V) - \log\det(K_* + 1) + \mathrm{Tr}\, G + \tfrac{1}{2}\,\mathrm{Tr}\, G^2\\ &\quad = \mathrm{Tr}(GV) + \mathrm{Tr}(G^2V) - \tfrac{1}{2}\,\mathrm{Tr}(GVGV)\\ &\qquad + \int_0^1 t^2\,\mathrm{Tr}(GWGWS_t^{-1}W)\,dt.\end{aligned} \tag{5.clxxxix}$$

With the fixed normalization eq. 5.clxxxvii, its last trace is

$$\mathrm{Tr}(B^{-1}XB^{-1}XB_t^{-1}X). \tag{5.cxc}$$

The three earlier terms become respectively $\mathrm{Tr}(B^{-1}A)$, $\mathrm{Tr}(B^{-1}G_0B^{-1}A)$ and $\mathrm{Tr}(B^{-1}AB^{-1}A)$. Every such term contains an actual finite coarse-rank factor. Expand the three $X = A - G_0$ factors in eq. 5.cxc. All terms except the pure G_0 term again contain A, and are bounded by its rank times the product of the already bounded operator norms. The remaining term is bounded by Schatten Hölder:

$$|\,\mathrm{Tr}(B^{-1}G_0B^{-1}G_0B_t^{-1}G_0)| \le C\|G_0\|_{\mathcal{S}_3}^3. \tag{5.cxci}$$

One must apply this reasoning per physical coarse cell, not with the rank of a full finite-volume matrix. The next argument does so and proves the two external momentum derivatives needed for the coefficient.

5.7.4. *Two external jets without an unbounded complex plane wave.* Work at the trivial background for the bulk Hessian. Coarse Bloch momentum is $\kappa \in [-\pi,\pi]^4$. At fine spacing $h = 1/n$ the free aliases in one cell have momenta $q = \kappa + 2\pi m$, with m in n consecutive centered integer values per coordinate. Their Laplacian symbol is

$$\lambda_h(q) = 4h^{-2}\sum_\mu \sin^2(hq_\mu/2). \tag{5.cxcii}$$

At real κ, $\lambda_h(q) \ge c|q|^2$ on the fine Brillouin cube. A fixed small complex shift z obeys

$$\mathrm{Re}(1 + \lambda_h(q+z)) \ge c(1 + |q|^2), \qquad |z| < s_1, \tag{5.cxciii}$$

after a uniform decrease of s_1. To verify it, the imaginary shift changes the real symbol by at most $C|\,\mathrm{Im}\, z|^2$; the real shift remains in a fixed slightly enlarged Brillouin cube, where the same sine lower bound holds. Thus the principal square root of $G_0(\kappa + z)$ is analytic on a fixed strip. In particular

$$\int_{[-\pi,\pi]^4} \|G_0(\kappa+z)\|_{\mathcal{S}_3}^3 \frac{d\kappa}{(2\pi)^4} \le C\int_{\mathbb{R}^4} (1 + c|q|^2)^{-3}\,dq < \infty. \tag{5.cxciv}$$

The sum over the aliases simply partitions the fine Brillouin cube. The fixed colour/component multiplicities are included in C.

Let two external coarse variations have momenta p and $-p$. At first take p real, and use the formal coefficient ring $\mathbb{C}[\varepsilon_1,\varepsilon_2]/(\varepsilon_1^2,\varepsilon_2^2)$. Substituting $B = \varepsilon_1 be^{ipx} + \varepsilon_2 ce^{-ipx}$ records the zeroth, two first and mixed second jets of each actual operator. This is a jet computation at zero, not an assertion that a complex plane-wave field lies in a globally bounded background domain.

Represent the jets on four graded fine-cell spaces indexed by $\varnothing, \{1\}, \{2\}, \{1,2\}$. Their momenta are $\kappa, \kappa+p, \kappa-p, \kappa$. A jet block from grade T to grade S is zero unless $T \subset S$, and otherwise is the derivative with the external indices in $S \setminus T$. Operator multiplication and inversion of these finite triangular matrices are exactly the product rule and inverse rule for the mixed two-jet. The free matrix $\mathbf{G}_0$ is diagonal in these four grades, with the four shifted free symbols just specified. Use it on both sides to normalize every jet matrix.

All normalized jet blocks of $\mathbf{B}, \mathbf{B}_t, \mathbf{A}$ are bounded uniformly in h, κ, t, on a fixed complex neighborhood of $p = 0$. Here are the details of this assertion. The localized first and second background jets yield absolutely convergent Fourier sums for their cell profiles when $|\,\mathrm{Im}\, p| < s/4$. Their strong

norms are uniformly bounded by eq. 3.mccxcvi: the exponential kernel bound dominates both external factors, after decreasing its rate. Applying the finite-carrier transport and plaquette formulas proved above gives bounded normalized q, Q, D, K jets. Every factor comparing two fine momenta is also bounded by eq. 5.cxciii. Thus all off-diagonal normalized blocks are bounded without a fine-volume factor.

For the diagonal inverses, the actual flat precision gaps give a uniform relative form inverse. Conjugation by a small physical exponential changes each local derivative form by $O(s)$ in the H^1, H^{-1} pairing, and changes each averaging row form by $O(s)$ because its physical carrier is bounded. Consequently the flat interpolation inverse remains bounded for the shifted complex Bloch momenta in a fixed strip. This proves uniform bounds for the diagonal blocks of $\mathbf{B}_t^{-1}$; the corresponding statement for $\mathbf{B}^{-1}$ is immediate from the free massive operator. Inverting a four-grade triangular matrix then uses a finite sum with at most two nontrivial jet steps. The inverses of the full jet matrices are therefore bounded uniformly as well.

The rank statement also survives with no derivative-count problem. Apply the jet functor to eq. 5.clxxxviii. It still factors through four copies of the coarse site/field spaces. The rank of $\mathbf{A}$ is at most 12 in the scalar case and 60 in the vector case. In this statement the jet of $Q^\sharp$ is the analytic derivative of that operator; it is not the ordinary transpose of the four-grade jet matrix, which would reverse grades. The actual factorization, and hence this finite-rank bound, remains valid for complex external momentum.

Apply eq. 5.clxxxix in the jet algebra. The mixed trace is the trace of its $(\{1,2\},\varnothing)$ block, not the ordinary trace of the entire triangular matrix. For real p, cyclic permutation of trace factors is valid after integrating in κ: it only reindexes κ by one of the real external momenta, and the coarse Brillouin torus and its fibre identifications are periodic. Thus the displayed normalized trace identities give the desired mixed bulk Hessian.

Each term containing $\mathbf{A}$ has uniformly bounded trace norm by its rank and the operator bounds. For the pure free term apply Schatten Hölder to its three diagonal free factors, and Hölder once more in κ if their momenta are different. Equation eq. 5.cxciv bounds the resulting integral uniformly. Projection onto one graded block cannot increase trace norm, so it also bounds the required mixed trace. Integration over $0 \le t \le 1$ preserves that bound.

Every expression just obtained is holomorphic in a fixed complex neighborhood of $p = 0$, by the same integrable bounds and analytic inverse formulas. The equalities first proved for real p extend there by the identity theorem. This orders the steps correctly: real cyclic reindexing is performed before analytic continuation; there is no unproved change of a complex Bloch integration contour. We have proved a uniform holomorphic bound for the mixed bulk polarization of the entire remainder in eq. 5.clxxxix. Cauchy's formula bounds each second external momentum derivative by a uniform constant.

For completeness the same construction justifies the bulk limit. At fixed h the gapped fine and coarse Bloch inverses have exponential cell kernels. Finite torus kernels are their periodic sums, and every differentiated trace above is a sum of products with absolutely convergent spatial moments. Terms winding around the torus vanish when its side tends to infinity. The bulk polarization is the Bloch integral used above. Its bounds are uniform in h, because rank and eq. 5.cxciv were uniform before taking this limit. A full finite-volume trace was never bounded by a fixed rank.

5.7.5. *The constraint Schur determinants.* Let $T_v = K - Dq^\sharp qD^\sharp$ and $T_s = \Delta$. For either $C = Q$ or $C = q$, elementary block elimination gives

$$|\det \mathbb{S}(T_*, C)| = \det(T_* + C^\sharp C)\, \det\{C(T_* + C^\sharp C)^{-1} C^\sharp\}. \tag{5.cxcv}$$

It can also be checked in orthogonal $\ker C$ coordinates. The field/site constraint is onto, and the first precision has the uniform gap proved above. Its coarse Schur matrix has uniform positive lower and upper bounds. For the lower bound use the actual exact smooth row lift E_C and its physical

energy:

$$\|b\|_2^2 = \langle (T_* + C^\sharp C)(T_* + C^\sharp C)^{-1} C^\sharp b, E_C b\rangle \le C\langle b, C(T_* + C^\sharp C)^{-1} C^\sharp b\rangle^{1/2} \|b\|_2.$$

The upper bound follows from the gap and the bounded row form. The actual nonflat lift is obtained from the flat smooth seeds by the row comparison and its coarse Neumann inverse; its energy bound is uniform on the present physical strong ball.

The Schur matrix and its inverse have a fixed holomorphic momentum strip. This follows either by weighted relative conjugation of the precision and its fixed-carrier rows, or directly by its normalized jet formula. Its mixed logarithmic trace derivative is $\mathrm{Tr}(S^{-1}S_{12} - S^{-1}S_1 S^{-1} S_2)$, with the appropriate shifted momenta and integrated cyclic convention. The fine inverses in these coefficients have already been bounded. There are only 12 coarse vector colours and 3 coarse site colours per cell. Hence the mixed Schur-log polarization is bounded holomorphically, uniformly in h. Cauchy's formula again bounds its second momentum coefficient. Coherent branches are fixed by the positive real Schur matrices; only the displayed real saddle identity uses absolute values.

5.7.6. *The uniform physical coefficient comparison.* Let

$$\mathcal{L}_h(s,U) = \log\det(\Delta_U + s) - \tfrac{1}{2}\log\det(K_U + s), \qquad \mathcal{L}_h^\sharp = \mathcal{L}_h(1) - \partial_s \mathcal{L}_h(1) + \tfrac{1}{2}\partial_s^2 \mathcal{L}_h(1), \tag{5.cxcvi}$$

with trivial-field values subtracted and bulk trace per physical coarse volume. Let Ψ_j be the actual physical homogeneous Gaussian logarithm of eq. 5.civ.

Proposition 5.21 (Averaging versus mass with uniform two-jet error)**.** On the constructed homogeneous background domain,

$$\left| b[\Psi_j] - b[\mathcal{L}_h^\sharp \circ \widehat{U}] \right| \le C, \qquad h = L^{-j}, \quad j \ge 0, \tag{5.cxcvii}$$

where C is independent of j. More precisely, the difference after removal of the physical multiplier term has a bulk Hessian bounded holomorphically on a fixed external momentum neighborhood. ■

Proof. Apply eq. 5.clxxxix to the scalar and vector precisions, with coefficients 1 and $-1/2$. Their left sides combine as the averaging logarithm minus $\mathcal{L}_h(1) - \partial_s \mathcal{L}_h(1) + \frac{1}{2}\partial_s^2 \mathcal{L}_h(1)$. Indeed the two added trace terms on that left side combine to $\partial_s \mathcal{L}_h(1) - \frac{1}{2}\partial_s^2 \mathcal{L}_h(1)$, since the first log-determinant derivative is the resolvent trace and the second is minus the square trace. Moving them to the right gives precisely eq. 5.cxcvi. The uniform jet argument bounds the second-momentum coefficient of both remainder terms. Equation eq. 5.cxcv adds only the two coarse Schur logarithms, whose coefficients were uniformly bounded. Finally Prop. 5.8 proves that the actual physical multiplier correction has coefficient zero. This is a statement about its determinant functional; no false pointwise third-order claim for the matrix $-\mu q''$ is used. The finite-dimensional coefficient readout b is a fixed linear combination of these second momentum derivatives. The Cauchy bounds therefore prove eq. 5.cxcvii. □

The actual affine-response identity and physical mass rescaling in eq. 5.clxxx identify the massive term:

$$b[\Psi_j] = \widetilde{\beta}(h^2) - h^2 \widetilde{\beta}'(h^2) + \tfrac{1}{2} h^4 \widetilde{\beta}''(h^2) + O(1). \tag{5.cxcviii}$$

This uses the actual coefficient-preserving background pullback, not an arbitrary smooth coarse interpolation. Combining the massive lattice coefficient eq. 5.clxviii yields the cumulative physical law

$$b[\Psi_j] = \frac{11}{3\pi^2} j \log L + O(1). \tag{5.cxcix}$$

By the exact physical Gaussian stage composition and coefficient preservation eq. 5.clxxv, its one-step increments $b_\ell^0 = b[\Phi_\ell]$ therefore satisfy

$$\sum_{\ell=1}^{j} b_\ell^0 = \frac{11}{3\pi^2} j \log L + O(1). \tag{5.cc}$$

The bounded error here is a cumulative comparison. It does not imply geometric convergence, or even convergence, of the actual individual increments: a difference of two bounded comparison errors need not tend to zero. The geometric error in the bare massive coefficient is a separate, stronger property of that particular regulator.

5.8. **Interpolation and consistency of the actual lattice mean.** To compare the classical effective actions at successive fine depths, we need trial fields on both meshes with controlled curvature and controlled coarse mean. The trial field must use the actual group average. This subsection supplies the interpolation and consistency estimates for that comparison.

Work at the trivial flat reference on the periodic physical torus $\mathbb{T}^4_M$, $M \geq 2$. This is the reference used to extract the Taylor coefficients. Put $h = L^{-j}$, with odd $L \geq 3$, and fix $0 < \beta < 1$. Constants can depend on L, β and the fixed small coordinate ball, but not on j or M. A fine bond field $a_\mu(x)$ is regarded as data at its physical midpoint $x + \frac{h}{2}e_\mu$. Write $\|a\|_{X_\beta}$ for the physical first-difference and local Hölder norm in eq. 3.mccxxiii. At the trivial reference all differences are ordinary differences. Every continuous connection below is periodic.

5.8.1. *An exact interpolation with one Hölder derivative.* We first give the scalar interpolation; apply it to each colour component on each of the four shifted midpoint grids. On a grid of spacing h, let a_x be the values and put

$$g_x = (D_1^+ a(x), \dots, D_4^+ a(x)).$$

Suppose $\|a\|_\infty + \|g\|_\infty + [g]_{\beta,\mathrm{loc}} \leq K$. For grid points x, y with $h \leq |x-y| \leq 1$, a coordinate path and telescoping give

$$|g_x - g_y| \leq CK|x-y|^\beta, \qquad |a_y - a_x - g_x \cdot (y-x)| \leq CK|x-y|^{1+\beta}. \tag{5.cci}$$

For the second inequality, each directed path increment is its forward grid difference. Compare that difference with its value at x; all intervening points are within $C|x-y|$ of x. There are at most $C|x-y|/h$ increments, each with an error $CKh|x-y|^\beta$. Negative increments use the forward difference at their other endpoint and obey the same estimate. For fixed multiples of the unit radius the supremum terms give the analogous bound after increasing C.

Choose a smooth nonnegative product bump ρ, supported in $(-1,1)^4$, positive on $[-3/4, 3/4]^4$, with $\rho(0) = 1$. On the periodic lift of the grid define

$$\eta_x(X) = \frac{\rho((X-x)/h)}{\sum_z \rho((X-z)/h)}, \qquad P_x(X) = a_x + g_x \cdot (X-x), \qquad \mathcal{I}_h a(X) = \sum_x \eta_x(X) P_x(X).$$

Only a fixed number of terms occur at each X. The denominator has positive lower and finite upper bounds, because a nearest grid point is at coordinate distance at most $h/2$. Consequently

$$\sum_x \eta_x = 1, \qquad |\partial^\ell \eta_x| \leq C_\ell h^{-|\ell|}.$$

At a grid point y, the only nonzero bump is the one at y. All derivatives of bumps centered at its neighboring grid points vanish there, since their arguments are on the boundary of the open support. Hence

$$\mathcal{I}_h a(y) = a_y, \qquad \nabla \mathcal{I}_h a(y) = g_y. \tag{5.ccii}$$

The periodic lift makes these definitions independent of a fundamental cube. A componentwise shifted grid is treated by the same formula.

Proposition 5.22 (Uniform interpolation of the fine connection)**.** There is a linear periodic interpolation $\mathcal{I}_h$ from midpoint bond data to smooth continuous connections such that

$$(\mathcal{I}_h a)_\mu(x + \tfrac{h}{2}e_\mu) = a_\mu(x), \qquad \|\mathcal{I}_h a\|_{C^{1,\beta}} \leq C_\beta \|a\|_{X_\beta}. \tag{5.cciii}$$

For a continuous $C^{1,\beta}$ connection A, its midpoint samples

$$(\mathcal{S}_h A)_\mu(x) = A_\mu(x + \tfrac{h}{2}e_\mu)$$

satisfy

$$\|\mathcal{S}_h A\|_{X_\beta} \le C_\beta \|A\|_{C^{1,\beta}}. \tag{5.cciv}$$

Both constants are independent of the physical volume and the number of fine sites in a unit cell. ■

Proof. For X within Ch of a grid point x, compare each polynomial in the interpolation formula with P_x. Equation eq. 5.cci gives

$$|P_y(X) - P_x(X)| \le CKh^{1+\beta}, \qquad |g_y - g_x| \le CKh^\beta$$

whenever $\eta_y(X) \neq 0$. Differentiating the partition formula once and twice therefore gives

$$|\nabla \mathcal{I}_h a(X) - g_x| \le CKh^\beta, \qquad |\nabla^2 \mathcal{I}_h a(X)| \le CKh^{\beta-1}. \tag{5.ccv}$$

The second bound is not a uniform second-derivative estimate; only its consequence for the first-derivative Hölder norm will be used.

If $|X - Y| \le h$, integrate the second bound to obtain

$$|\nabla \mathcal{I}_h a(X) - \nabla \mathcal{I}_h a(Y)| \le CKh^{\beta-1}|X - Y| \le CK|X - Y|^\beta.$$

If $h \le |X - Y| \le 1$, compare the two gradients with g_x, g_y at their nearest grid points and use eq. 5.cci. The same Hölder bound follows. Zeroth and first suprema follow directly from the local formula, proving eq. 5.cciii. For vector fields use the appropriate shifted grid for each component. This preserves reality of the colour coordinates.

For sampling, a forward difference is an average of the corresponding continuous derivative on a segment of length h. Its supremum and its translated Hölder difference are bounded by the continuous $C^{1,\beta}$ norm. This proves eq. 5.cciv. □

5.8.2. *Wilson action consistency at this regularity.* For a continuous Hermitian connection A, put

$$U_h(A)_\mu(x) = \exp(ihA_\mu(x + \tfrac{h}{2}e_\mu)), \qquad F_{\mu\nu}(A) = \partial_\mu A_\nu - \partial_\nu A_\mu + i[A_\mu, A_\nu].$$

The norm of a Hermitian colour matrix is the one with $|X|^2 = \frac{1}{2}\operatorname{tr} X^2$. Let

$$\mathscr{E}(A) = \frac{1}{2}\int_{\mathbb{T}^4_M} \sum_{\mu<\nu} |F_{\mu\nu}(A)(x)|^2 \, dx.$$

Proposition 5.23 (Consistency of the Wilson energy)**.** On a fixed sufficiently small $C^{1,\beta}$ ball,

$$|A_h(U_h(A)) - \mathscr{E}(A)| \le C_\beta h^\beta M^4. \tag{5.ccvi}$$

Here A_h is the actual Wilson sum over fine positive plaquettes. In particular, for the same interpolated connection,

$$|A_{h/L}(U_{h/L}(A)) - A_h(U_h(A))| \le C_\beta h^\beta M^4. \tag{5.ccvii}$$

The constants are uniform in the two meshes. ■

Proof. Let c_p be the plaquette center. Write the four edge values of A as their affine Taylor polynomials at c_p plus errors bounded by $C_\beta h^{1+\beta}$. The signed sum of the four link exponents is then

$$ih^2(\partial_\mu A_\nu - \partial_\nu A_\mu)(c_p) + O(h^{2+\beta}).$$

The quadratic Baker–Campbell–Hausdorff term for constant edge values is $-h^2[A_\mu, A_\nu]$. Replacing those constant values by the edge Taylor values changes that term by $O(h^3)$. The cubic and higher terms are also $O(h^3)$, uniformly on the fixed connection ball. All four-factor logarithms are

on the small branch. Consequently, with the actual plaquette logarithm defined by $U_h(A)(p) = \exp(ih^2 F_{h,p})$,

$$|F_{h,p} - F(A)(c_p)| \le C_\beta h^\beta. \tag{5.ccviii}$$

This argument uses one Hölder derivative, not a bounded second derivative of A.

The exact Pauli trace gives

$$1 - \tfrac{1}{2}\operatorname{tr} e^{ih^2 F_{h,p}} = \tfrac{1}{2}h^4 |F_{h,p}|^2 + O(h^8 |F_{h,p}|^4).$$

The plaquette fields are uniformly bounded. Equation eq. 5.ccviii changes this value by at most $C_\beta h^{4+\beta}$ when $F_{h,p}$ is replaced by $F(A)(c_p)$. There are $6M^4 h^{-4}$ plaquettes. Finally $|F(A)|^2$ has a uniform C^β modulus, so its midpoint Riemann sum has error at most $C_\beta h^\beta M^4$. These estimates prove eq. 5.ccvi. Apply it on both meshes and subtract to obtain eq. 5.ccvii. □

5.8.3. *The first two actual mean vertices.* Consider one step from fine spacing H/L to spacing H, with $0 < H \le 1$. At the identity write its output raw bond logarithm as

$$m_L(a) = m_{L,1}a + m_{L,2}[a,a] + R_{L,3}(a), \qquad |R_{L,3}(a)| \le C_L \|a\|_\infty^3.$$

The formula is on the finite double-block carrier of an output row. Its coefficients and the remainder bounds are the actual analytic coefficients of the symmetric contour mean. The finite dimension depends on L; there is no fine-depth dependence in this one-step statement.

Lemma 5.24 (Midpoint affine reproduction and quadratic cancellation)**.** The actual linear mean applied to midpoint samples of an affine connection is its coarse midpoint value multiplied by H. The quadratic map $m_{L,2}$ vanishes on every constant connection. ■

Proof. At the identity, the derivative of a group mean is the arithmetic mean of its Lie-algebra inputs. Let $T_{y,x}$ be the internal transport from the coarse node y to a fine starting point x in its centered block, and let $t_{y,x}$ be its first logarithmic variation. The positively oriented row has linear variation

$$\frac{1}{L^4}\sum_{x\in B(y)} \left\{ t_{y,x} + \sum_{\ell=0}^{L-1} a_\mu(x + \ell H e_\mu/L) - t_{y+He_\mu, x+He_\mu} \right\}. \tag{5.ccix}$$

The entries a_μ here are fine link angles, sampled at their fine bond midpoints.

For an affine continuous connection, midpoint sums along each coordinate path integrate that affine connection exactly. Translating such a path by He_μ changes its integral by

$$H\sum_\nu (\partial_\mu A_\nu)(x_\nu - y_\nu),$$

independently of the order of its coordinate edges. The mean of $x - y$ over the centered odd block is zero. Thus the two internal transport contributions in eq. 5.ccix cancel after averaging. The remaining straight line samples have mean position $y + \frac{H}{2}e_\mu$: the starting block is centered at y, and the average of its L fine bond midpoints is the midpoint of the coarse edge. They therefore give exactly $HA_\mu(y + \frac{H}{2}e_\mu)$. This proves the linear assertion, including the plain transport factors.

For the second assertion set a_μ to a constant matrix in each direction. The input and output connections are then translation invariant. Central inversion of the lattice takes these constant fine links to their inverses. The actual symmetric contour mean commutes with this inversion, including reversal of the coarse bond. Its admitted output logarithm therefore satisfies

$$m_L(-a) = -m_L(a).$$

Its quadratic coefficient on a constant connection is zero. Polarization gives zero for two different constant connections as well. This is an exact symmetry of the actual mean, not a continuum replacement of its quadratic vertex. □

5.8.4. *One-step consistency for the nonlinear mean.*

Proposition 5.25. For a continuous connection A in a fixed small $C^{1,\beta}$ ball, one actual averaging step obeys

$$\left\| \frac{1}{i} \log \mathcal{M}(U_{H/L}(A)) - H\mathcal{S}_H A \right\|_\infty \le C_\beta H^{2+\beta}. \tag{5.ccx}$$

The logarithm is the small raw logarithm at the identity. The estimate is local on each actual double block and uniform in the volume. ■

Proof. Fix a coarse bond. Expand the continuous connection to first order at its midpoint. Over its double block, the remainder in A is $O(H^{1+\beta})$; the remainder in a fine link angle is consequently $O(H^{2+\beta})$, with L fixed. By Lem. 5.24, the linear vertex applied to the affine part gives precisely the coarse midpoint angle. It has a bounded finite row sum, so its Taylor remainder has the asserted size.

Split the fine angles as $a = a_{\mathrm{const}} + a_{\mathrm{var}}$, where $\|a_{\mathrm{const}}\| \le C_L H \|A\|_\infty$ and $\|a_{\mathrm{var}}\| \le C_L H^2 \|\nabla A\|_\infty$. The constant–constant quadratic term is zero. All other quadratic terms have size $O(H^3)$. The cubic analytic remainder has size $O(H^3)$ as well. Since $H^3 \le H^{2+\beta}$ for $0 < H \le 1$, these estimates prove eq. 5.ccx. The fixed small connection ball keeps every path mean and raw logarithm on its admitted branch. □

5.8.5. *Uniform propagation through the remaining levels.* The plain derivative of one step contains internal transport terms. Iterating a crude bound on that derivative could lose a factor at each level. We instead use the exact node factorization to control the full plain mean in fine physical coordinates.

Lemma 5.26. There are $r_0, C > 0$, independent of $h = L^{-j}$ and volume, such that

$$\mathscr{P}_h(a) = \frac{1}{i} \log \mathcal{M}^j(e^{iha})$$

is holomorphic on $\|a\|_\infty < r_0$ and

$$\|\mathscr{P}_h(a) - \mathscr{P}_h(\widetilde{a})\|_\infty \le C \|a - \widetilde{a}\|_\infty \tag{5.ccxi}$$

on its half ball. This statement uses no derivative bound for the fine potentials. ■

Proof. Use the actual recursion and node factors in eq. 3.mccliii. Its first-exit estimate uses only $\|a\|_\infty$, and gives

$$\|a_s\|_\infty \le C\xi_s \|a\|_\infty, \qquad \|v_s - 1\|_\infty \le C\xi_s \|a\|_\infty, \quad \xi_s = hL^s.$$

The geometric sum of the intermediate ξ_s's bounds the second expression. At the final level, eq. 3.mccliv writes the plain mean as a product of $e^{iq_h(a)}$ and the two node factors at its endpoints. Both have norm and distance from the identity bounded uniformly on this fine supremum ball. Reduce r_0 so their output has its small logarithm. This proves a uniform bound for the holomorphic map $\mathscr{P}_h$ on a slightly larger fixed ball.

For a fine direction b, apply the one-variable Banach-valued Cauchy estimate to $\mathscr{P}_h(a + zb)$ on that larger ball. It gives a dimension-independent bound $\|D\mathscr{P}_h(a)b\|_\infty \le C\|b\|_\infty$ on the half ball. Integrate it along the segment from a to $\widetilde{a}$ to obtain eq. 5.ccxi. □

Proposition 5.27 (Consistency of the full actual coarse mean)**.** For a continuous $C^{1,\beta}$ connection in a fixed sufficiently small ball,

$$\left\| \frac{1}{i} \log \mathcal{M}^{j+1}(U_{h/L}(A)) - \frac{1}{i} \log \mathcal{M}^j(U_h(A)) \right\|_\infty \le C_\beta h^{1+\beta}, \qquad h = L^{-j}. \tag{5.ccxii}$$

The two coarse outputs have spacing one, and both logarithms are raw logarithms near the trivial coarse field. ■

Proof. After the first step from h/L to h, write its actual output as $e^{ih\widetilde{a}_h}$. Equation eq. 5.ccx gives

$$\|\widetilde{a}_h - \mathcal{S}_h A\|_\infty \le C_\beta h^{1+\beta}.$$

Both potentials lie in the half ball of Lem. 5.26 after the initial continuous ball is reduced once. The remaining j steps are exactly the same actual mean on the two fine-h fields. Applying eq. 5.ccxi proves eq. 5.ccxii. For $j = 0$ the remaining mean is the identity and the argument is unchanged. □

Together, Props. 5.22, 5.23 and 5.27 give actual real trial connections for comparing successive effective actions. They require only the first Hölder derivative supplied by the homogeneous background construction. The exact repair of their small coarse-mean error, the variational comparison, and the passage from real action differences to localized Taylor kernels are the next steps.

5.9. **Geometric convergence of the actual classical Taylor vertices.** The comparison in this section concerns the actual minimized Wilson action, rather than a postulated continuum minimizer. Interpolation is used only to transfer a real trial field between two adjacent meshes. Analyticity then transfers a real energy comparison to the second, third and fourth Taylor vertices. This last passage needs a real-to-complex argument: Cauchy's inequality alone cannot turn a small bound on a real cube into a small complex derivative.

Work near the trivial flat reference, at physical coarse spacing one. Put $h_j = L^{-j}$, let $\widehat{U}_j(B)$ be the actual literal background of Prop. 3.183, and write

$$S_j(B) = A_{h_j}(\widehat{U}_j(B)), \qquad \mathcal{V}_{j,m} = D^m S_j(0), \quad m = 2, 3, 4. \tag{5.ccxiii}$$

The coarse torus has side $M \ge 2$ and physical volume $\mathcal{V} = M^4$. Its real coarse field coordinates are traceless Hermitian bond logarithms. A complex ball always means their holomorphic continuation. Fix an exponent $0 < \beta < 1$ and use the preceding background construction with X_β. Its coarse radius may be decreased by a fixed amount below.

We use the proved mesh-consistency facts in Props. 5.22, 5.23, 5.25 and 5.27: a periodic fine potential in X_β admits a periodic $C^{1,\beta}$ interpolation with the same midpoint values and a uniform norm bound; its sampled Wilson energy differs from $\frac{1}{2}\int \sum_{\mu<\nu} |F_{\mu\nu}|^2$ by $Ch^\beta \mathcal{V}$; and the actual one-step mean applied to the refined midpoint samples differs from the coarser midpoint link by $Ch^{2+\beta}$ in raw relative logarithm. All these constants are uniform in M, j on the fixed small norm ball. These are consistency estimates for the actual mean and Wilson action, not assumptions about a continuum critical field.

5.9.1. *Repairing a transferred trial field without losing derivatives.*

Lemma 5.28 (An exact repair of a small coarse mean error)**.** Let $U = e^{ihA}$ be a real fine trial with small X_β norm, and suppose its literal mean is $e^{i(B+e)}$, where $\|e\|_\infty$ is small. There is a literal trial U^{rep} with mean e^{iB} and

$$|A_h(U^{\mathrm{rep}}) - A_h(U)| \le C\|e\|_\infty \mathcal{V}. \tag{5.ccxiv}$$

The trial and its repair stay in a fixed small strong chart. All constants are uniform in mesh and volume. ■

Proof. Apply the actual mean-gauge slice map eq. 3.mcclxxxvii to the literal trial. Its result $\overline{A}$ has $q_h(\overline{A}) = B + e$ and $RD^\sharp \overline{A} = 0$, with $\|\overline{A}\|_{X_\beta} \le C\|A\|_{X_\beta}$. It has exactly the same action as U.

Use the fixed smooth exact field seed E_Q and solve

$$z = -e - \{C_h(\overline{A} + E_Q z) - C_h(\overline{A})\}, \qquad C_h = q_h - Q. \tag{5.ccxv}$$

The actual nonlinear row Lipschitz estimate makes its right side a contraction on a ball of radius $2\|e\|_\infty$ when the strong chart is fixed sufficiently small. It gives $q_h(\overline{A} + E_Q z) = B$ and $\|E_Q z\|_{Y_\beta} \le C\|e\|_\infty$. The specified node-gauge extension in eq. 3.mcclxxxiv converts this into a literal field U^{rep} with the desired mean, preserving action.

To estimate the change, integrate the first variation along $\overline{A}+tE_Qz$. Its curvature is uniformly bounded on the small strong chart. Equation eq. 3.mccxc uses only that curvature bound and the physical $W^{1,1}$ norm of E_Qz, not a second derivative of $\overline{A}$. The smooth seeds have bounded overlap, amplitude and first differences, so $\|E_Qz\|_{1,h}+\|DE_Qz\|_{1,h}\le C\mathcal{V}\|z\|_\infty$. The normal-to-left differential has the same estimate, by its explicit bounded coefficients and their first differences. This proves eq. 5.ccxiv. The actual gauge and seed bounds also keep the repaired field inside the strong chart. □

The correction E_Qz need not be horizontal. When comparing its energy with the minimum, apply the literal-to-mean slice once more. It preserves the action and puts the trial in $q_h=B$ and $RD^\sharp A=0$, where the proved chord minimum applies.

Proposition 5.29 (Real adjacent-mesh action comparison)**.** On a fixed sufficiently small real coarse ball,

$$\sup_{\|B\|_\infty<\rho}\frac{|S_{j+1}(B)-S_j(B)|}{\mathcal{V}}\le C_\beta h_j^\beta. \tag{5.ccxvi}$$

The constants are independent of M,j. ■

Proof. Interpolate the literal real background potential at spacing $h=h_j$ by the proved periodic $C^{1,\beta}$ interpolation, and sample that same potential at spacing h/L. The refined trial has a uniformly small X_β norm. The two Wilson energies differ by at most $Ch^\beta\mathcal{V}$, since each differs from the energy of this common continuous interpolation by that bound.

The one-step mean of the refined trial differs from the original spacing-h field by $Ch^{2+\beta}$ in raw link logarithm. In physical spacing-h potential coordinates this is $Ch^{1+\beta}$. Apply Lem. 5.26 to the remaining j actual mean steps. Their final logarithms therefore differ by at most $Ch^{1+\beta}$. Thus the refined trial has literal final mean $e^{i(B+e)}$ with $\|e\|_\infty\le Ch^{1+\beta}$. Repair it by Lem. 5.28 and compare its action with the actual spacing-h/L minimum. This gives $S_{j+1}(B)\le S_j(B)+Ch^\beta\mathcal{V}$.

For the reverse inequality interpolate the spacing-h/L background, and sample its interpolation on the spacing-h grid. One-step consistency compares its actual fine first mean with that coarse sample. The remaining j means again produce an error $Ch^{1+\beta}$. The same energy and repair estimates give $S_j(B)\le S_{j+1}(B)+Ch^\beta\mathcal{V}$.

All transferred potentials have norm at most $C_\beta\rho$. The plain-mean Lipschitz bound at zero also gives $\|e\|_\infty\le C_\beta\rho$, in addition to its mesh-dependent bound. This ensures uniform admission even for the initial coarse meshes, where $h^{1+\beta}$ need not be small by itself. Choose the real ball once so this bound, and its slice and repair images, lie inside the fixed minimum chart. The local minimum is then applicable in both directions; no global minimizer or continuum critical field is invoked. □

The uniform complex bound needed below is simpler. For the actual holomorphic background, $\|F\|_\infty\le C\rho$ and a plaquette action is at most $Ch^4\rho^2$ in absolute value. There are $O(h^{-4}\mathcal{V})$ plaquettes. Consequently on a fixed complex coarse ball,

$$|S_j(B)|/\mathcal{V}\le C,\qquad j\ge 0. \tag{5.ccxvii}$$

5.9.2. *Small real values imply small fixed-order Taylor jets.*

Lemma 5.30 (A quantitative real-to-jet estimate)**.** Fix $m\ge 1$ and a complex polydisc. Suppose f is holomorphic there with $|f|\le C$, and $|f|\le\varepsilon$ on a fixed smaller real cube centered at zero. Then

$$|\partial_1\cdots\partial_m f(0)|\le C_m\varepsilon(1+\log(1/\varepsilon))^{2m},\qquad 0<\varepsilon<\tfrac12. \tag{5.ccxviii}$$

The constant depends only on the two radii, m and C. ■

Proof. Rescale the real cube to $[-1,1]^m$ and choose $R>1$ so that the product of closed Bernstein ellipses of parameter R lies inside the holomorphy domain. Expand in product Chebyshev polynomials: $f(t)=\sum_{n\in\mathbb{N}^m}c_n\prod_i T_{n_i}(t_i)$. Real orthogonality gives $|c_n|\le 2^m\varepsilon$. Analyticity on the

ellipses gives $|c_n| \le C_m R^{-|n|_1}$: write $t_i = (w_i + w_i^{-1})/2$ and apply the Laurent coefficient estimate on $|w_i| = R$ in each variable.

The derivative at zero has weight $\prod_i |T'_{n_i}(0)| \le \prod_i n_i \le (1 + |n|_1)^m$. For $|n|_1 \le N$, the real bound therefore gives at most $C_m \varepsilon (1+N)^{2m}$ after counting the multi-indices. The tail is at most $C_m R^{-N}(1+N)^{2m-1}$, by summing the geometric series with this fixed polynomial weight. Choose N to be the smallest integer at least $\log(1/\varepsilon)/\log R$. Restore the fixed rescaling of the cube to prove the lemma. The differentiated series is absolutely convergent. No Cauchy estimate has been applied to a real-only supremum bound. □

Take real coarse profiles $b_1, \dots, b_m$ with supremum norm at most one and apply the lemma to

$$f(z) = \mathcal{V}^{-1}(S_{j+1} - S_j)\left(\sum_{i=1}^{m} z_i b_i\right).$$

The complex polydisc and real cube can be chosen independently of profiles, depth and volume, by taking $m \max_i |z_i|$ smaller than the fixed action ball. Equations eq. 5.ccxvi and eq. 5.ccxvii give, for $2 \le m \le 4$,

$$\frac{|D^m(S_{j+1} - S_j)(0)[b_1, \dots, b_m]|}{\mathcal{V}} \le C_m h_j^{\beta} (1+j)^{2m}. \tag{5.ccxix}$$

The finitely many initial j for which the smallness parameter exceeds $1/2$ are covered by the uniform complex Cauchy bound. Complex Fourier profiles are permitted as well: expand each e^{ipx} into its real cosine and sine profiles and use complex multilinearity, at a fixed cost at most 2^m.

5.9.3. *Uniform analytic strips for the actual action vertices.* We spell out the locality assertion needed to pass from a small symbol to a small kernel. Resolve a coarse bond into its cell location and one of its twelve component-colour indices. In the infinite-volume translation-covariant notation write the m-vertex as $V_{j,m}(x_1, \dots, x_m)$, retaining these finite indices. Fix the first location at zero and define its star-weighted norm by

$$\|V\|_{m,\sigma} = \max_{\text{component-colour indices}} \sum_{x_2,\dots,x_m} e^{\sigma \sum_{i=2}^{m} |x_i|_1} |V(0, x_2, \dots, x_m)|. \tag{5.ccxx}$$

Here infinite-volume notation refers to kernels of compactly supported variations, obtained from their local periodic limits. No finite total action on a nondecaying infinite field is assigned. One may sum the finite index maximum instead, changing only a fixed constant. On a torus use periodic distance. This norm also controls any weight given by the length of a shortest tree connecting the inputs, since that length is no larger than the displayed star.

Lemma 5.31 (Uniform exponential moments at fixed Taylor order)**.** For $m = 2, 3, 4$ there are $\sigma_0 > 0$ and C_m, independent of j, M, such that

$$\|V_{j,m}\|_{m,\sigma_0} \le C_m. \tag{5.ccxxi}$$

The infinite-volume kernels exist, and finite-torus kernels are their periodic sums in the $m-1$ relative input variables. Their symbols are consequently bounded holomorphic functions on a fixed polystrip in $4(m-1)$ complex momentum variables. ■

Proof. Split the Wilson action into unit-cell densities, assigning a plaquette by its base point. Each density is uniformly analytic in a small local X_β ball and has bounded analytic norm: the fine plaquette factor is $O(h^4 \|A\|^2_{X_\beta})$, and only $O(h^{-4})$ plaquettes lie in one physical cell. Its derivatives of every fixed order are therefore bounded multilinear local maps, uniformly in h. Their carriers have bounded physical diameter.

For a background jet with unit inputs at $y_1, \dots, y_a$, eq. 3.mccxcvi bounds its cell-X_β norm at z by $C_a e^{-s \max_i |z - y_i|_1}$. This holds also for the literal background, as proved there. In the chain rule for an order-m cell-action jet, each partition of the m inputs contributes a product of such bounds.

For each block of size a, its maximum is at least a^{-1} times its sum. Since $a \le m$, every term is bounded by $C_m e^{-(s/m)\sum_i |z-y_i|_1}$, with a fixed change of the constant for the bounded action carrier. Summing action cells gives

$$|V_{j,m}(y_1,\dots,y_m)| \le C_m \sum_z e^{-(s/m)\sum_i |z-y_i|_1}. \tag{5.ccxxii}$$

With $y_1 = 0$, the triangle inequality implies $\sum_{i=2}^m |y_i|_1 \le (m-1)\sum_i |z-y_i|_1$. Split the exponent into two halves. One half pays a star weight of any size below $s/(2m(m-1))$; the other is summable in z and all relative inputs after a further fixed decrease of that weight. For example choose $\sigma_0 < s/(4m(m-1))$ and sum first in each y_i and then in z. This proves the moment bound, uniformly on periodic tori as well.

We justify the infinite-volume and periodization assertions at the level of these actual jets. At zero field the joint inverse has its translation-covariant Bloch representation and exponential cell kernels. Its finite periodic kernel is the periodic sum of the infinite one. Differentiate the actual fixed-point equation at order a. Its order-a unknown is the same linear joint inverse applied to a finite sum of products of lower-order jets and the finite-carrier derivatives of the actual residual. Induction for $a \le m$ shows that each such jet is an absolutely convergent rooted-tree kernel expression. Its leaves are the distinct external differentiation slots. Once a lift of an internal vertex is chosen, the images of the input slots in each child subtree are independent. Expanding a periodic propagator chooses the lift of its child vertex; continuing down the tree then gives the independent periodic images of all external slots. There is no closed internal cycle imposing an extra image constraint. Thus periodic summation commutes with these multilinear contractions; this is not the generally false identity that periodization commutes with an ordinary pointwise product in one shared argument. The exponential bounds justify all changes of summation order.

Apply the same finite-order chain rule to the cell action and sum its cells. Its action root joins those child trees, still without a closed cycle. Fixing the first external input lift removes the common translation; the remaining $m-1$ external images are independent. This proves existence of the infinite-volume action vertex and exact periodization in each relative input, not just a subsequential compactness claim.

Finally Fourier series are absolutely convergent when the imaginary parts of the $m-1$ independent external momenta are sufficiently small. The moment bound gives a uniform bound on a smaller closed polystrip. Cell positions rather than bond midpoints can be used in this Fourier convention; changing that convention introduces only fixed bounded analytic phases. □

Translation covariance now turns eq. 5.ccxix into a pointwise bound for the difference of vertex symbols. Choose complex unit component- colour profiles with allowed momenta $p_1,\dots,p_m$ whose sum is zero. The volume-normalized m-linear functional is exactly its vertex symbol at those momenta. It follows that

$$\sup_{p_2,\dots,p_m \text{ real}} |\widehat{V}_{j+1,m}(p_2,\dots,p_m) - \widehat{V}_{j,m}(p_2,\dots,p_m)| \le C_m h_j^{\beta} (1+j)^{2m}. \tag{5.ccxxiii}$$

Initially the momenta are on a finite-torus grid. Pass to arbitrarily large tori using the just proved periodization, then use continuity and density of the grids. This establishes the bound for every real momentum, with no volume-dependent Fourier inversion loss.

5.9.4. *Interpolation into a smaller complex momentum strip.* We need an elementary several-variable refinement of the three-lines principle. Let F be periodic and holomorphic in $|\operatorname{Im} p_i| < a_0$, $1 \le i \le d$, and bounded by C there. Suppose $|F| \le \varepsilon$ on the real torus. Choose $0 < a < a_0' < a_0$. Apply the three-lines bound in one variable, keeping the remaining variables real, between its real axis and the line of imaginary part a_0' or $-a_0'$. This gives $C^{1-\theta}\varepsilon^{\theta}$ for $|\operatorname{Im} p_1| \le a$, where $\theta = 1 - a/a_0'$. Periodicity permits the argument on a bounded cylinder, or equivalently by the annulus maximum principle. Keeping this first variable in its reduced strip, repeat in the second

variable. Its real-axis bound is now the improved preceding bound, whereas its outer-line bound is still C. After all d variables,

$$\sup_{|\operatorname{Im} p_i|\le a} |F(p)| \le C^{1-\Theta}\varepsilon^{\Theta}, \qquad \Theta = (1-a/a_0')^d. \tag{5.ccxxiv}$$

This argument uses the uniform bound on the full larger polystrip at each step. Smallness on the real torus alone is not assumed to imply the same smallness throughout that larger strip.

Apply eq. 5.ccxxiv to the vertex-symbol difference. The larger-strip bound is supplied by Lem. 5.31; the real bound is eq. 5.ccxxiii. Since $d = 4(m-1)$,

$$\sup_{|\operatorname{Im} p_i|\le a} |\Delta\widehat{V}_{j,m}(p)| \le C_m\{h_j^{\beta}(1+j)^{2m}\}^{(1-a/a_0')^{4(m-1)}}. \tag{5.ccxxv}$$

Again the finitely many initial indices are absorbed into C_m. Fourier contour shifting on this reduced polystrip gives

$$|\Delta V_{j,m}(0,x_2,\dots,x_m)| \le C_m\{h_j^{\beta}(1+j)^{2m}\}^{\Theta_m} e^{-a\sum_{i=2}^m |x_i|_1}, \quad \Theta_m = (1-a/a_0')^{4(m-1)}. \tag{5.ccxxvi}$$

Shift each scalar momentum coordinate with the sign prescribed by the corresponding relative lattice coordinate. Periodicity makes the opposite contour faces cancel. The fixed analytic midpoint phases, if used, change only C_m.

Proposition 5.32 (Convergence of the actual classical Taylor triple)**.** For every $0<\alpha<1$ there are $\sigma_\alpha>0$ and C_α such that, for $m=2,3,4$,

$$\|V_{j+1,m} - V_{j,m}\|_{m,\sigma_\alpha} \le C_\alpha L^{-\alpha j}. \tag{5.ccxxvii}$$

The limits $V_{\infty,m}$ exist in these weighted kernel norms and

$$\|V_{\infty,m} - V_{j,m}\|_{m,\sigma_\alpha} \le C_\alpha L^{-\alpha j}. \tag{5.ccxxviii}$$

The bounds hold uniformly on compatible finite tori by periodic summation. They concern the actual Wilson background Taylor vertices; no continuum minimizing field has been assumed. ■

Proof. Choose $\alpha<\beta<1$, and then choose the reduced strip $a>0$ so small that $\beta(1-a/a_0')^{12}>\alpha$. This gives $\beta\Theta_m>\alpha$ for every $m=2,3,4$. Take $\sigma_\alpha = a/2$. Summing eq. 5.ccxxvi with this weight costs only the convergent geometric lattice sum $\sum_{x_2,\dots,x_m} e^{-(a/2)\sum|x_i|_1}$. Its remaining polynomial in j is absorbed by the strict exponent margin $\beta\Theta_m-\alpha>0$. This proves eq. 5.ccxxvii. The geometric series in j converges in the Banach kernel norm, proving eq. 5.ccxxviii.

The periodization proved above preserves the weighted bound: periodic relative distances are no larger than their lifted distances, and the absolute value of a periodic sum is bounded by the sum of absolute values. Thus no finite-volume factor enters the result. □

The classical Taylor triple now has a genuine geometric mesh comparison. Passing this estimate through a Gaussian polarization requires a uniform Lipschitz estimate for that polarization in the same kernel norms. That is a separate analytic step. The cumulative one-loop comparison alone did not prove it, and no convergence of individual Gaussian increments is asserted here.

5.10. **The actual one-step Gaussian polarization.** The Gaussian coefficient of a step depends only on the second, third and fourth Taylor forms of its input effective action. Here the constraint is the actual plain group average and the gauge is the actual symmetric contour gauge. We derive this dependence, including the Haar and coarea factors, and prove a volume-independent Lipschitz bound. The resulting implication from convergence of the actual Taylor triples to convergence of the actual increments is quantitative.

Fix an odd step size L. The input lattice has unit spacing; it is not the original fine lattice of spacing L^{-k}. There are finitely many input coordinates, depending only on L, in one outer

coarse cell. Use orthonormal Pauli colour coordinates and product Lebesgue measures for group logarithms. Write

$$S(B) = S_k(e^{iB}), \qquad m(B) = i^{-1}\log \mathcal{M}(e^{iB}), \qquad m(0) = 0, \quad Q = Dm(0).$$

The background for all Taylor forms in this section is the trivial field. Let $\ell_x(B)$ be the actual contour coordinate from the node of a block to its nonnode site x, and put

$$\begin{aligned} F_g(B) &= \sum_x \left(1 - \tfrac{1}{2}\operatorname{tr} T_x(e^{iB})\right) \\ &= \sum_x \left(1 - \cos|\ell_x(B)|\right). \end{aligned} \tag{5.ccxxix}$$

This is the canonical $\tau = 1$ Gaussian gauge convention. The proof also permits fixed gauge weights in a fixed positive compact interval. Coupling powers and field-independent reference-gauge constants have been factored out; the two-coupling mismatch is a separate term. On complex coordinates the trace formula is its analytic continuation; the cosine expression is its power series in the bilinear colour square of ℓ_x.

5.10.1. *The actual free effective action supplies the gap.* We first record why the free input of every homogeneous depth has the lower bound used below. In the physical fine spacing $h = 1/n$, the actual straight derivative is

$$(Q_h a)_\mu(y) = h^5 \sum_{x\in B_n(y)} \sum_{r=0}^{n-1} a_\mu(x + rhe_\mu).$$

Telescoping the two coarse differences gives

$$(\mathrm{d}_c Q_h a)_{\mu\nu}(y) = h^6 \sum_{x\in B_n(y)} \sum_{r,s=0}^{n-1} (\mathrm{d}_h a)_{\mu\nu}(x + rhe_\mu + she_\nu) =: (T_h d_h a)_{\mu\nu}(y). \tag{5.ccxxx}$$

These weights are positive. A row sum is $h^6 n^6 = 1$. A fixed fine plaquette has n^2 choices of (r, s), each with exactly one starting block, so its column sum is $h^6 n^2 = h^4$. Jensen's inequality therefore proves $\|T_h F\|_2 \le \|F\|_{2,h}$, with constant one.

The plain derivative differs from this straight derivative by the actual coarse gradient of the linear node factor. Their curls agree. The physical derivative of the actual background minimizes fine curl energy at its fixed mean: its stationarity gives zero energy cross term against every zero-mean variation. A literal fine node gauge preserves this energy. The exact smooth row lift of Lem. 3.180, followed by the specified node gauge when passing to the plain mean, has uniform physical gradient energy. Consequently

$$\mathrm{d}^\sharp \mathrm{d} \ \le T_2 := S_k''(0) \ \le CI. \tag{5.ccxxxi}$$

The lower bound is the actual flux contraction applied to the minimizing lift. The upper bound inserts the exact smooth trial. It is uniform in the inner homogeneous depth, including depth zero. No continuum coercivity estimate is substituted for these actual averaging identities.

Lemma 5.33 (The fixed one-step contour gap)**.** Let $K_g = D^2 F_g(0)$. On compatible tori, uniformly in volume,

$$\mathrm{d}^\sharp \mathrm{d} + K_g + Q^\sharp Q \ge c_L I. \tag{5.ccxxxii}$$

The actual plain row Q is onto with a bounded right inverse depending only on L. Thus, whenever $\mathrm{d}^\sharp \mathrm{d} \le T_2$ and $\|T_2\| \le M$,

$$\mathbb{L}(T_2) = \begin{pmatrix} T_2 + K_g & Q^\sharp \\ Q & 0 \end{pmatrix} \tag{5.ccxxxiii}$$

has a uniformly bounded inverse. Only positivity on $\ker Q$ is required. ∎

Proof. The actual pivot chart supplies the onto row and its bounded local pivot right inverse at the trivial field. All its coefficients and inverse pivot coefficients belong to one fixed L-block geometry. For the gap use the Bloch decomposition by these blocks. The finite matrices of d, K_g, Q are continuous on the compact Bloch torus.

Suppose the three squared terms vanish in one fibre. A closed fine field is a gradient, except for constant vector modes at zero Bloch frequency. This follows also from the fine Fourier modes $p = (\theta + 2\pi r)/L$: at every nonzero mode the closedness equation says its vector is parallel to the fine gradient symbol. At zero frequency write the field as $D\lambda + c$. The actual plain average of its gradient is the coarse gradient of the node values, and its average of c is Lc. In that zero-frequency block the former gradient is zero, so $Qu = 0$ gives $c = 0$.

For the remaining gradient, contour covariance gives

$$D\ell(0)D\lambda(x) = \lambda(y) - \lambda(x).$$

The contour term therefore forces λ to be constant inside each block. Its plain row is the coarse gradient of that block value. Zero coarse gradient makes the field itself zero, at both zero and nonzero Bloch frequencies. Every Bloch matrix has zero kernel, so compactness proves eq. 5.ccxxxii. In particular $T_2 + K_g$ is uniformly coercive on $\ker Q$. The right inverse and the kernel equation prove the bounded full saddle inverse, by lifting the datum and recovering the multiplier from the remaining functional. □

5.10.2. *The global group-coordinate normalizer.* Define the actual Lagrangian in full input group coordinates and coarse multiplier coordinates by

$$\Lambda_C(B, v) = S(B) + F_g(B) + \langle v, m(B) - C\rangle. \tag{5.ccxxxiv}$$

Its stationary branch is $z(C) = (B(C), v(C))$, with $z(0) = 0$. Its Hessian at zero is $\mathbb{L}(T_2)$. The implicit function theorem therefore gives the actual local branch; the already constructed homogeneous background is this branch after its specified residual contour gauge. One can see the gauge removal directly: along a fine gauge equal to one at coarse nodes both S and m are constant. The derivative of ℓ_x in those gauge directions is an invertible endpoint map near zero. Stationarity of eq. 5.ccxxxiv thus implies $\ell(B(C)) = 0$: the derivative of the actual trace weight in its ℓ_x variable is $(\sin|\ell_x|/|\ell_x|)\ell_x$, whose scalar factor is nonzero on the chosen small branch. Hence $F_g = DF_g = 0$ at the centre, and this branch is physically constrained critical for S. At every such centre its gauge Hessian is $D\ell^\sharp D\ell$, also the Hessian of the quadratic logarithmic gauge. Thus their Gaussian log normalizers, after subtraction at zero, agree along this physical branch. All vertices below use the literal trace function eq. 5.ccxxix.

Let $j_f(B)$ and $j_c(C)$ be the products of the actual SU(2) exponential Haar densities. Factor out the classical weight $e^{-S(B(C))}$. The Gaussian log normalizer in these global coordinates is

$$\begin{aligned}\Phi(C) = {} & \log j_f(B(C)) - \log j_c(C) \\ & - \tfrac{1}{2}\log\left|\det D_z^2\Lambda_C(z(C))\right| - (\text{the same at } C = 0).\end{aligned} \tag{5.ccxxxv}$$

The omitted Gaussian powers and contour normalization are independent of C. At real C the saddle determinant has a fixed nonzero sign. Its local analytic logarithm means the logarithm of its ratio to the value at zero, continued from one.

Here is why this formula is the actual constrained Gaussian. In global logarithms the exact conditional measure has density

$$j_f(B)\, j_c(C)^{-1}\delta(m(B) - C)\, dB.$$

Its tangent constraint is $Dm(B(C))v = 0$. The quadratic form is the complete Lagrangian Hessian, including $v(C)D^2m$, plus the actual contour Hessian. The constrained Gaussian identity Lem. 5.4 replaces its quadratic integral and its coarea determinant by the full saddle determinant

in eq. 5.ccxxxv. In particular a coordinate-dependent coarea factor has not been discarded. Using left exponential fluctuation coordinates instead would transfer the centre Haar factor into this determinant; retaining just one of these changes would alter the answer.

5.10.3. *All vertices and the colour cancellation.* Put

$$\mathbb{G} = \mathbb{L}(T_2)^{-1}, \quad ZC = \mathbb{G}(0, C), \quad HC = (ZC)_B, \quad V_r = D_z^r \Lambda_0(0) \quad (r = 3, 4). \tag{5.ccxxxvi}$$

Differentiating stationarity gives

$$z'(0)C = ZC = (HC, -\Delta_{\mathrm{next}} C).$$

The sign of the multiplier follows from the plus sign in eq. 5.ccxxxiv. More explicitly, set $S_{\mathrm{next}}(C) = S(B(C))$. Its Hessian is $\Delta_{\mathrm{next}} = H^\sharp T_2 H$. Differentiating the zero contour coordinate gives $K_g H = 0$; pairing the linear stationary equation with HC' then gives $\upsilon'(0)C = -\Delta_{\mathrm{next}} C$.

For clarity, if $z_i = (a_i, \alpha_i)$, the full vertices are

$$\begin{aligned} V_3[z_1, z_2, z_3] &= (D^3 S + D^3 F_g)[a_1, a_2, a_3] + \sum_{i=1}^{3} \langle \alpha_i, D^2 m[a_j, a_l] \rangle, \\ V_4[z_1, z_2, z_3, z_4] &= (D^4 S + D^4 F_g)[a_1, a_2, a_3, a_4] + \sum_{i=1}^{4} \langle \alpha_i, D^3 m[a_1, \dots, \widehat{a}_i, \dots, a_4] \rangle. \end{aligned} \tag{5.ccxxxvii}$$

In the first sum $\{j, l\}$ is the complement of $\{i\}$. The constraint and gauge terms are fixed one-step terms; they are present before taking a Gaussian. There is no multiplier at zero, so no additional $D^4 m$ term occurs.

The scalar

$$z \longmapsto \log |\det D_z^2 \Lambda_0(z)|$$

is invariant under every constant colour rotation. Indeed S, F_g, m have their actual covariance, and the simultaneous adjoint rotation of all field and multiplier coordinates is orthogonal with determinant one. Its differential at zero is an invariant linear functional on a direct sum of adjoint colour copies. Each copy has no invariant linear functional. Therefore, in every field and multiplier direction v,

$$\mathrm{Tr}(\mathbb{G} V_3[v]) = 0. \tag{5.ccxxxviii}$$

This is a finite-volume identity, before any trace per volume or infinite-volume limit.

Proposition 5.34 (Actual Gaussian Hessian formula)**.** The Hessian of eq. 5.ccxxxv is

$$\begin{aligned} \Phi''(0)[C, C'] = {} & \tfrac{2}{3} \langle C, C' \rangle - \tfrac{2}{3} \langle HC, HC' \rangle \\ & - \tfrac{1}{2} \mathrm{Tr}(\mathbb{G} V_4[ZC, ZC']) \\ & + \tfrac{1}{2} \mathrm{Tr}(\mathbb{G} V_3[ZC] \mathbb{G} V_3[ZC']). \end{aligned} \tag{5.ccxxxix}$$

It depends on S only through $(D^2 S(0), D^3 S(0), D^4 S(0))$. ∎

Proof. The second derivative of a matrix logarithm is the trace of its inverse times its second derivative, minus the trace of the two first derivatives separated by inverse factors. Along $z(C)$, the first matrix derivative is $V_3[ZC]$; the second is $V_4[ZC, ZC'] + V_3[z''(0)[C, C']]$. The last term has zero trace by eq. 5.ccxxxviii, in its full augmented direction. Thus no unknown second background response survives.

In the present Pauli normalization the exact one-bond Haar density is

$$j(B) = \left(\frac{\sin |B|}{|B|} \right)^2, \qquad \log j(B) = -|B|^2/3 + O(|B|^4).$$

Its first derivative is zero and its second derivative is $-2/3$ times the colour inner product. This gives the two Haar terms in eq. 5.ccxxxix, including their signs. The complete saddle contains

all the constraint and contour contributions in eq. 5.ccxxxvii. Combining the terms proves the formula. □

5.10.4. *A norm for the actual Taylor triple.* Assign input bonds, contour coordinates and coarse multipliers to their outer L-cells. The number of coordinates per cell is $N_L < \infty$. For a scalar symmetric r-tensor W, define

$$\|W\|_{s,r} = \max_{1\le j\le r} \sup_{i_j} \sum_{(i_l)_{l\neq j}} e^{s\,\mathfrak{t}(i_1,\dots,i_r)} |W(i_1,\dots,i_r)|. \tag{5.ccxl}$$

Here $\mathfrak{t}$ is the least cell-tree length joining the indicated cells, and sums include bond and colour indices. For $r = 2$ this is the usual maximum absolute weighted row and column Schur norm. On a torus the least torus tree length is used; retained lifted kernels can instead use their cover tree lengths.

Use the derivative triple $\mathfrak{J} = (T_2, T_3, T_4)$, with $T_r = D^r S(0)$, and norm

$$\|\mathfrak{J}\|_s = \sum_{r=2}^{4} \|T_r\|_{s,r}. \tag{5.ccxli}$$

If S_3, S_4 denote the homogeneous Taylor forms, their polarizations have the additional fixed factors 3! and 4! in T_3, T_4. This fixes the convention without changing the asserted Lipschitz property.

Assume $\|\mathfrak{J}\|_s \le M$. The actual action-tree expansion supplies such norms on its smaller fixed ball. The fixed one-step constraint and gauge vertices have finite carriers and bounded norms of every fixed order. Thus the augmented V_3, V_4 satisfy the same kind of bounds, depending only on M, L, s.

Lemma 5.35 (Inverse kernels uniformly over the input triples)**.** On the class $\|\mathfrak{J}\|_s \le M$, $T_2 \ge \mathrm{d}^\sharp\mathrm{d}$, there is a fixed $t > 0$ such that $\mathbb{G}$ and Z have bounded weighted Schur norms at rate t. For two such triples,

$$\|\mathbb{G} - \mathbb{G}'\|_{t,2} + \|Z - Z'\|_{t,2} \le C\|T_2 - T_2'\|_{s,2}. \tag{5.ccxlii}$$

Constants are independent of the torus volume and the inner homogeneous depth. ■

Proof. The unweighted inverse is uniform by Lem. 5.33. For a bounded one-Lipschitz cell function ψ, the weighted Schur norm of the coefficients gives

$$\|e^{a\psi}\mathbb{L}(T_2)e^{-a\psi} - \mathbb{L}(T_2)\| \le C(M, L, s)|a|$$

for $|a| \le s/2$. A normalized Neumann series gives uniformly bounded inverses for a fixed nonzero a. Truncated distance weights yield exponential cell entries of $\mathbb{G}$. At a fixed smaller rate their row and column sums are bounded: cell growth is polynomial of degree four, with N_L internal coordinates. This also proves the bounds on Z, a fixed column inclusion of $\mathbb{G}$.

Only the field-field T_2 block differs between the two full saddle matrices. The exact resolvent identity is

$$\mathbb{G} - \mathbb{G}' = -\mathbb{G}\begin{pmatrix} T_2 - T_2' & 0 \\ 0 & 0 \end{pmatrix}\mathbb{G}'.$$

Weighted Schur norms are submultiplicative. This proves eq. 5.ccxlii and its column statement for Z. □

5.10.5. *Rooted trace contractions have no volume cost.* Let $\Pi(\mathfrak{J})$ be the coarse kernel of eq. 5.ccxxxix. All statements below concern absolute coordinate sums; an operator norm alone would not suffice.

For the quartic trace, fix one external coarse coordinate c. Sum first its response column Z_{ic}, then the quartic vertex rooted at i, then the second external response row. The internal loop kernel is bounded by its Schur norm. The distance from c to the other external coordinate is no greater

than the first response distance, the vertex tree length and the last response distance combined. Hence, at a common smaller rate,

$$\|\mathrm{Tr}(\mathbb{G}V_4[Z\,\cdot, Z\,\cdot])\|_{t,2} \le \|\mathbb{G}\|_{t,2}\|V_4\|_{t,4}\|Z\|_{t,2}^2. \tag{5.ccxliii}$$

For the pair of cubic vertices, root the first vertex at that first response index. Sum one intervening Green kernel, then the second cubic vertex rooted at its endpoint, then the second external response. The other loop kernel is bounded pointwise by its Schur norm. This gives

$$\|\mathrm{Tr}(\mathbb{G}V_3[Z\,\cdot]\mathbb{G}V_3[Z\,\cdot])\|_{t,2} \le \|\mathbb{G}\|_{t,2}^2\|V_3\|_{t,3}^2\|Z\|_{t,2}^2. \tag{5.ccxliv}$$

The scalar tensor norms already sum all internal coordinate indices. No free vacuum component remains once the first external coordinate is fixed. In particular neither estimate has a volume factor. The Haar contraction is a direct weighted matrix product of $H^\sharp$ and H.

Proposition 5.36 (Lipschitz Gaussian polarization)**.** For actual input actions whose Taylor triples satisfy the preceding boundedness and lower bound, there are $t > 0$ and $C < \infty$, independent of depth and volume, such that

$$\|\Pi(\mathfrak{J}) - \Pi(\mathfrak{J}')\|_{t,2} \le C\|\mathfrak{J} - \mathfrak{J}'\|_s. \tag{5.ccxlv}$$

Each polarization itself has bounded weighted norm. The full constraint and gauge vertices in the formula are fixed actual one-step vertices. ■

Proof. The augmented differences of V_3, V_4 are precisely the field vertices $T_3 - T_3'$, $T_4 - T_4'$. All other vertex terms are fixed. Subtract the two formulas eq. 5.ccxxxix by replacing one factor at a time. For a propagator or response difference use eq. 5.ccxlii. For a vertex difference use its rooted tensor norm. Each remaining contraction is bounded by eq. 5.ccxliii or eq. 5.ccxliv. The Haar difference uses the same weighted product bound. These are finitely many terms with fixed degrees, which proves the assertion. □

These estimates also pass to compatible bulk kernels: every rooted contraction has an absolute exponential majorant. Period images are summed with that same majorant, and winding contributions tend to zero along a growing compatible volume. Thus eq. 5.ccxlv holds for the common infinite-lattice companions whenever the input triples have those actual companions.

5.10.6. *The implication for actual increments.* For the invariant physical total, the colour-averaged second-moment readout of the coefficient is continuous in this norm. Explicitly its standard off-diagonal form is

$$b(\Pi) = \sum_{u\in\mathbb{Z}^4} u_\mu u_\nu\, \overline{\Pi}_{\mu\nu}(u), \qquad \mu \ne \nu,$$

after the actual Ward and lattice symmetries have identified this form. The bar here denotes the orthonormal colour average, not complex conjugation. Since $|u|^2 \le C_t e^{t|u|}$, absolute moments give

$$|b(\Pi(\mathfrak{J})) - b(\Pi(\mathfrak{J}'))| \le C_t\|\mathfrak{J} - \mathfrak{J}'\|_s. \tag{5.ccxlvi}$$

The coefficient convention is the physical one, with the outer coarse lattice rescaled to unit spacing.

Corollary 5.37. The actual homogeneous Taylor triples have common bulk companions and, by Prop. 5.32, for each $0 < \alpha < 1$ obey the following bound at some fixed positive rate s_α:

$$\|\mathfrak{J}_{k+1} - \mathfrak{J}_k\|_{s_\alpha} \le C_\alpha L^{-\alpha k}, \qquad 0 < \alpha < 1. \tag{5.ccxlvii}$$

Then their actual Gaussian increments $b_{k+1}^0 = b[\Phi_{k+1}]$ satisfy, with a fixed index shift absorbed into the constant,

$$|b_{k+1}^0 - b_k^0| \le C_\alpha L^{-\alpha k}, \qquad |b_k^0 - c_0| \le C_\alpha L^{-\alpha k}, \qquad c_0 = \frac{11}{3\pi^2}\log L. \tag{5.ccxlviii}$$

■□

Proof. The difference bound follows from eq. 5.ccxlvi. Its tail is a geometric series, so the increments converge with the displayed rate to some constant. The exact physical stage composition and the proved massive lattice comparison give eq. 5.cc. Dividing that cumulative identity by the number of steps and taking the Cesaro limit identifies the constant as $11 \log L/(3\pi^2)$. This last argument uses the lattice coefficient, not a quoted continuum beta coefficient. □

The actual formula and its uniform Taylor-triple Lipschitz estimate complete the geometric increment argument on the homogeneous physical germ. The rooted star norm of Prop. 5.32 dominates eq. 5.ccxl, after the fixed L-cell grouping and the fixed Taylor-factor conventions, and therefore supplies eq. 5.ccxlvii. A formal response expansion alone does not establish that mesh comparison. A bounded cumulative determinant error alone would likewise not give geometric successive-increment convergence.

5.11. **The nonflat effective curl bound and the outer Gaussian gap.** The positive massive row Schur matrix does not, by itself, give a gap after its artificial row mass is subtracted. We prove the needed physical comparison. It gives the actual outer contour-gauge gap near a regular nonflat critical reference, uniformly in the inner fine depth.

This subsection uses a homogeneous inner torus, with fine spacing $h = L^{-k}$ and intermediate coarse spacing one. The real fine reference U is an actual constrained-critical field of literal mean $V = M^k U$, with

$$\|F(U)\|_\infty \le \kappa, \qquad \|j_U\|_\infty \le \gamma. \tag{5.ccxlix}$$

The current is the physical Wilson current in these units. The actual hierarchical means are on their regular branches. All ceilings below are fixed sufficiently small. Nontrivial holonomies are allowed. We construct statements on the critical germ provided by Prop. 3.117. We do not infer existence of this reference from coarse curvature alone.

Let Q be its re-centered, straightened, per-length field derivative. Let ω be its physical multiplier, so $j_U = Q^\sharp \omega$. The actual readout gives $\|\omega\|_\infty \le C\gamma$. Write S for the local physical critical action as a function of the intermediate coarse field. The straightened datum and literal datum differ by their admitted node gauge. The action is invariant under that gauge, so their scalar action germs coincide in the declared coarse normal coordinates.

5.11.1. *The flat flux row with its physical norm.* We first give the exact flat identity used in the comparison. Put $N = h^{-1}$. For fine translations τ_μ, define

$$A_h = h^4 \sum_{x \in B_h(0)} \tau_x, \qquad S_{\mu,h} = h \sum_{t=0}^{N-1} \tau_\mu^t.$$

The symbol A_h here is a block average, rather than an action. The set $B_h(0)$ is the actual centered N^4-site block; in one coordinate its indices are $-(N-1)/2, \dots, (N-1)/2$ for the odd $N = L^k$ used here. The flat field row is $Q^0_\mu = A_h S_{\mu,h}$, sampled at coarse bond origins. The coarse difference obeys

$$\tau_\mu^N - 1 = S_{\mu,h} D^+_{\mu,h}.$$

All these flat translations commute. Consequently

$$(\mathrm{d}_c Q^0 v)_{\mu\nu} = A_h S_{\mu,h} S_{\nu,h} (\mathrm{d}_h v)_{\mu\nu} =: Q^2_{\mu\nu} (\mathrm{d}_h v)_{\mu\nu}. \tag{5.ccl}$$

The actual fixed-L hierarchy has this same linear row: multiplying the block averages combines the base-L digits of the averaging sites and line positions, giving the displayed N-site formula.

Every weight of $Q^2_{\mu\nu}$ is nonnegative, its row sum is one, and its counting column sum is h^4. The latter identity follows by summing over all translated coarse blocks; each fine site has total block-average weight h^4, and each $S_{\mu,h}$ preserves that total weight. Jensen's inequality therefore gives

$$\|Q^2 f\|_{2,c} \le \|f\|_{2,h}. \tag{5.ccli}$$

Thus the flat flux row has its physical norm without a factor counting fine plaquettes. The identity is local. It may be used in a flat parallel frame on a cover without choosing a logarithm of a global holonomy.

5.11.2. *A curvature-small covariant flux comparison.*

Lemma 5.38 (Actual coarse curl controlled by fine curl)**.** For the actual rows at the real reference eq. 5.ccxlix,

$$\|\mathrm{d}_V Q v\|_{2,c} \le C\|\mathrm{d}_U v\|_{2,h} + C\kappa\|v\|_{2,h}. \tag{5.cclii}$$

The constants are uniform in k and volume. ■

Proof. For each coarse plaquette choose a fixed surrounding physical cube containing all four complete row carriers. The current-free local gauge construction gives a fine potential of size $C\kappa$ on this cube, after decreasing the curvature ceiling by its fixed radius factor. Its literal coarse mean has bond angles at most $C_L\kappa$: the actual path lengths and normalized mean majorants are bounded in these physical units. Both fine and coarse comparisons are made in this same real frame.

The actual coefficient comparison eq. 3.dcccxiii then gives $Q = Q^0 + \mathcal{R}_Q$ on these rows, with $\|\mathcal{R}_Q v\|_{2,c} \le C_L\kappa\|v\|_{2,h}$ on their fixed enlarged carriers. There is no derivative of this row error at the fine scale: the following difference acts on the coarse unit lattice. Its L^2 norm is bounded by a fixed constant. Also $\mathrm{d}_V - \mathrm{d}_c = O_L(\kappa)$ as a coarse matrix, while $(\mathrm{d}_U - \mathrm{d}_h)v = O_L(\kappa)v$ on the fine cube in this frame. Insert these three comparisons in eq. 5.ccl and use eq. 5.ccli. They give the asserted bound for that plaquette and its fixed neighbours.

The gauge transformations are unitary, so these local norm bounds are covariant. A fine cell occurs in only a fixed number of the surrounding coarse cubes. Summing their squared estimates proves eq. 5.cclii. No single global flat frame has been selected. □

5.11.3. *The effective Hessian, with its constraint curvature.* Let

$$H_L = \mathscr{D}_U - \Delta_U^{(2)}[\omega], \qquad G_1^{-1} = H_L + D_U R D_U^\sharp + Q^\sharp a_f Q.$$

This is the actual physical second precision by eq. 3.cmxxi. Its row lift is

$$\mathcal{H} = G_1 Q^\sharp (Q G_1 Q^\sharp)^{-1}.$$

It is horizontal, $Q\mathcal{H} = 1$, and $\|\mathcal{H}a\|_{\mathcal{E}} \le C\|a\|_{2,c}$. The reference coarse spacing is one, so all row weights a_f are bounded above and below.

Proposition 5.39 (Physical nonflat effective curl bound)**.** The actual critical action germ satisfies

$$\begin{aligned} D^2S(V)[a,a] &\ge c\|\mathrm{d}_V a\|_{2,c}^2 - C(\kappa+\gamma)\|a\|_{2,c}^2, \\ |D^2S(V)[a,b]| &\le C\|a\|_{2,c}\|b\|_{2,c}. \end{aligned} \tag{5.ccliii}$$

Its exact Hessian is

$$D^2S(V) = \mathcal{H}^\sharp H_L \mathcal{H} = (QG_1Q^\sharp)^{-1} - a_f. \tag{5.ccliv}$$

These are local statements at the given physical critical reference. ■

Proof. Differentiate the actual critical graph in its fixed reference Landau slice. Its first derivative is $\mathcal{H}$, by the physical row-saddle identity. Twice differentiating its constraint gives

$$QA''[a,b] + q''(0)[\mathcal{H}a, \mathcal{H}b] = 0.$$

The first derivative of the fine action is $Q^\sharp\omega$. The second chain rule for the action therefore gives $D^2S = \mathcal{H}^\sharp H_L \mathcal{H}$. Equivalently the differentiated stationarity equation is

$$H_L\mathcal{H} = Q^\sharp D^2 S.$$

The horizontality of $\mathcal{H}$ annihilates its gauge penalty. After adding the row mass, multiplication by G_1, then by Q, proves the second identity in eq. 5.ccliv. Thus the artificial mass is subtracted in the stated order.

The actual Wilson form estimate and the constraint-curvature estimate give

$$\langle v, H_L v\rangle \geq (1 - C\kappa)\|\mathrm{d}_U v\|_2^2 - C(\kappa+\gamma)\|v\|_{\mathcal{E}}^2.$$

Insert $v = \mathcal{H}a$. The lift bound controls the last term by $C(\kappa+\gamma)\|a\|_2^2$. Since $Qv = a$, Lem. 5.38 implies

$$\|\mathrm{d}_U v\|_2^2 \geq c\|\mathrm{d}_V a\|_2^2 - C\kappa^2\|v\|_2^2.$$

Absorb its last term by the same lift bound. This proves the lower inequality. The fine Lagrangian form is bounded in energy and the lift is bounded, which proves the upper inequality and its polarized form. All its bounds use the actual fine Hessian and multiplier; an ambient unconstrained Hessian has not been substituted. □

5.11.4. *The actual outer plain-fibre precision.* Now use the actual one-step outer pivot chart based at V:

$$V(u) = e^{i\Phi_V(u)}V, \qquad \mathsf{C}_V = D\Phi_V(0), \qquad \Phi_V(u)|_{\mathrm{free}} = u.$$

Its dimensionless outer block size is the fixed L. The first-step chart estimates give

$$\|\mathsf{C}_V\|_{2\to 2} \leq C_L, \qquad \|\mathsf{C}_V u\|_2 \geq \|u\|_2, \qquad \|\langle \mu, D^2\Phi_V(0)\rangle\|_{2\to 2} \leq C_L\|\mu\|_\infty. \tag{5.cclv}$$

These are finite one-step bounds, independent of the inner depth. Let $K_G(V)$ be the actual relative trace-contour Hessian of eq. 4.ccxxxii. On a block-axial real reference it is the absolute contour Hessian.

At this physical reference the coarse gradient is ω. The full centred composed-action Hessian on free outer coordinates is therefore

$$K_A(V) = \mathsf{C}_V^\sharp D^2 S(V)\mathsf{C}_V + \langle \omega, D^2\Phi_V(0)\rangle. \tag{5.cclvi}$$

The second term cannot be omitted. It is the nonlinear plain-constraint contribution to the outer fibre Hessian. Subtracting the linear centering of the action has no effect on this equation.

Lemma 5.40 (The geometric outer curl-gauge gap)**.** On the real block-axial, small-curvature outer reference,

$$\|\mathrm{d}_V\mathsf{C}_V u\|_2^2 + \langle u, K_G(V)u\rangle \geq c_L\|u\|_2^2. \tag{5.cclvii}$$

■

Proof. Apply the proved actual first-step gap eq. 3.cxxx with zero independent current. Its action part is $\mathsf{C}_V^\sharp \mathscr{D}_V^{\mathrm{Wilson}}\mathsf{C}_V$. The exact plaquette upper estimate bounds it by

$$C_L\|\mathrm{d}_V\mathsf{C}_V u\|_2^2 + C_L\|F(V)\|_\infty\|\mathsf{C}_V u\|_2^2.$$

The outer curvature is $O_L(\kappa)$ by the local mean comparison in Lem. 5.38. Use eq. 5.cclv and decrease κ to absorb this last mass term into half the first-step gap. The resulting inequality is eq. 5.cclvii. This uses the first-step geometry and gauge, rather than treating the nonlocal effective action as a finite-range Wilson action. □

Proposition 5.41 (Nonflat late-depth outer Gaussian gap)**.** For fixed sufficiently small κ, γ, the actual outer precision satisfies

$$c_L I \leq \tau K_A(V) + K_G(V) \leq C_L I \tag{5.cclviii}$$

for real τ in a fixed interval about one. The constants are independent of the inner depth and volume. ■

Proof. Insert $\mathsf{C}_V u$ in eq. 5.ccliii. Equations eq. 5.cclv and eq. 5.cclvi give

$$\langle u, K_A(V)u\rangle \geq c\|\mathrm{d}_V\mathsf{C}_V u\|_2^2 - C_L(\kappa+\gamma)\|u\|_2^2.$$

Add the gauge term and use Lem. 5.40. Choose the two ceilings small enough to absorb the error. The upper bound follows from the effective Hessian and the finite outer chart and gauge

bounds. Finally changing τ near one costs at most $C_L|\tau-1|\|u\|_2^2$, so a fixed interval preserves both inequalities. □

5.11.5. *The explicit independent-current completion.* We specify the operator to which the complex assertion applies. For a field-current pair $P=(\mathbf{U},\mathbf{J})$ in a small tube about the preceding real physical pair, form the canonical G,H,G_1 in eq. 3.cmxv, in that order, and put

$$\begin{aligned}\omega_P &= H(P)^\sharp\mathbf{J}, \qquad \Gamma_P=(Q_{\mathbf{U}}G_1(P)Q_{\mathbf{U}}^\sharp)^{-1}-a_f,\\ \mathcal{K}_A(P) &= \mathsf{C}_{\mathbf{V}}^\sharp\Gamma_P\mathsf{C}_{\mathbf{V}}+\langle\omega_P,D^2\Phi_{\mathbf{V}}(0)\rangle,\\ \mathcal{K}_\tau(P) &= \tau\mathcal{K}_A(P)+K_G(\mathbf{V}), \qquad \mathbf{V}=M^k\mathbf{U}.\end{aligned} \tag{5.cclix}$$

The lift inside ω_P is the first lift. The row covariance inside Γ_P uses the second inverse. At the physical pair, eq. 5.ccliv and eq. 5.cclvi identify this operator exactly with the physical precision just estimated.

The actual current inverse, normalized row inverse and readout bounds show

$$\|\mathcal{K}_\tau(P)-\mathcal{K}_1(U,j_U)\|_{2\to2}\le C_L\{\,\varepsilon+\gamma+\gamma_{\mathbf{J}}+|\tau-1|\,\}. \tag{5.cclx}$$

Here ε is the weighted C^1 tube radius about the real regular fine reference and $\gamma_{\mathbf{J}}$ its independent-current amplitude. To check this estimate, perturb the actual inverse and its normalized row trace in energy norms, then invert the row matrix using its real coarse gap. The row weights are bounded in the present unit coarse spacing. The first-lift readout has its already proved supremum bound. Finally the actual plain-mean, pivot and relative gauge coefficients have the uniform one-step derivative bounds eq. 5.cclv. Their background changes are $O_L(\varepsilon)$ by the admitted hierarchical row and node-frame majorants. These facts give each term in eq. 5.cclx; there is no fine operator-norm comparison at scale h^{-2}.

After reducing the fixed radii, the right side is less than half the real gap. Thus $\mathcal{K}_\tau(P)$ is holomorphic and invertible on a common complex tube, with uniform inverse norm. For real symmetric pairs in that tube it has the same positive lower bound. No Hermitian positivity of the complex matrix is asserted.

This proves a matched explicit outer Gaussian precision on physical regular critical germs and the stated off-current extension. Away from the block-axial locus the relative gauge in eq. 4.ccxxxii specifies the extension. An independently prescribed absolute-gauge completion, signed profile, enlarged cube domain or history-conditioned matrix still requires its own exact comparison.

5.12. **Local Gaussian domains for the canonical nonflat coarse form.** We now admit independent cube parameters for the actual canonical coarse Gaussian near a real physical critical pair. The real spectral gap and the local coefficient expansion are separate inputs. Here they are supplied by Props. 3.112 and 5.41. The construction below also records the background domain on which its local coefficients are holomorphic.

Use a homogeneous inner hierarchy of arbitrary depth, with inner coarse spacing one. The outer step has the fixed blocking integer L. Fix a real physical critical pair $P_*=(U_*,j(U_*))$ satisfying the small curvature and current requirements of Prop. 5.41. Use its actual coarse datum $V_*=M^kU_*$, its one-step plain pivot chart, and the stated relative contour gauge. Choose a block axial representative when identifying the physical absolute gauge factor. All real transposes are extended bilinearly to the complex domains.

For $P=(U,J)$ near P_*, let Γ_P,ω_P and $K_\tau(P)$ be the explicit canonical extension in eq. 5.cclix. In particular ω_P uses the first lift and Γ_P uses the second inverse. We retain the $\langle\omega_P,\Phi_V''(0)\rangle$ term in the outer action Hessian. The following construction uses this specified matrix. An independent-current extension of its local Gaussians does not identify a separately prescribed history or signed-profile precision.

5.12.1. *The two uniform premises.* Assign the free outer fine-bond coordinates to their starting unit cells. A cell has at most a fixed number d_L of real coordinates; this number does not involve the inner fine mesh. The plain pivot map and its first two derivatives read a fixed L-dependent neighborhood. After an aligned reblocking, the named families therefore give an exact expansion

$$K_\tau(P) = \sum_C K_C(P,\tau), \qquad \sup_y \sum_{z,C} e^{\kappa_0\sigma_0(C)} \|1_y K_C 1_z\| + \sup_z \sum_{y,C} e^{\kappa_0\sigma_0(C)} \|1_y K_C 1_z\| \le B_0. \quad (5.\text{cclxi})$$

Here C is a connected carrier of fixed cubes of side M_0, with its full determining data, endpoints and short joins. The shifted length σ_0 is the carrier length of the positive-walk construction. The constant B_0 and M_0 are fixed before depth and volume. The exponent κ_0 can be chosen at any required fixed finite value by making the choices in Prop. 3.112 first. The permitted current ceiling and complex tube are retained from those choices.

At real physical data and τ near one, the geometric gap gives

$$c_L I \le K_\tau(P_*) \le C_L I. \quad (5.\text{cclxii})$$

After a fixed decrease of the background and current tube, the same real bounds, with changed constants, hold for every real admitted P. This follows from the actual family perturbation bound; it does not require the nearby independent current to be a Wilson gradient. Complex perturbations have the same operator-norm bound. The variable τ ranges in a fixed disc about one.

For completeness the locality in eq. 5.cclxi includes the row inverse in Γ_P. It is supplied by eq. 3.mxvi, with its actual mass subtraction. The outer chart factors and $\Phi_V''(0)$ enlarge the carrier by only a fixed star. The rooted family for ω_P retains its fine-current input bond by Prop. 3.111. Thus the current term has a genuine local carrier, as does the row-Schur term. A completed kernel decay bound alone would not prove eq. 5.cclxi.

5.12.2. *An admissible local background tube.* The background tube is a weighted C^1 tube in the actual fine relative field A, with an independent weighted current ball for $J - J_*$. For the homogeneous geometry the assigned physical cell scale is one. Given a finite carrier, retain a fixed complete data collar. A local C^1 field on that collar can be extended to a global relative field by a smooth cutoff which equals one on the read set. The cutoff is formed at the unit-cell scale, rather than the inner fine mesh. It satisfies

$$|\chi| + |D\chi| \le C_L.$$

Consequently

$$\|\chi A\|_{C^1} \le C_L \|A\|_{C^1(\text{collar})}. \quad (5.\text{cclxiii})$$

To construct such a cutoff, take the distance in the unit-cell graph from the read set, truncate it in a collar of fixed width, and interpolate its values by the fixed smooth partition on unit cells. Bounded overlap gives the displayed derivative bound. Make it zero before the outer edge of the supplied collar. Extension by zero then adds no fine-mesh jump. Multiplication of the independent current by a bounded cutoff preserves its current norm and takes no derivative of that current.

Choose the local radius smaller than the global tube radius divided by the constant in eq. 5.cclxiii. Every such local datum has an admitted extension relative to the fixed real reference. Exact determining-data locality in Prop. 3.112 makes the coefficient independent of which extension is used. This proves a local holomorphic domain for each coefficient. These are C^1 field domains; they are not independent scalar fine-bond discs with a mesh-free radius. The cube parameters introduced below are independent of these field variables. The geometry is the fixed homogeneous geometry in this statement. No extension theorem for an arbitrary partly specified proper history is used.

5.12.3. *Full-carrier truncation and a combined short power.* Fix a requested cube-parameter radius $S > 2$. Choose $b > 2(C_L + 1)$, and set

$$H = I - K_\tau/b.$$

Symmetrize each carrier coefficient by its transpose. Its endpoints and determining data are unchanged, its row/column family norm does not increase, and its sum is still the symmetric matrix H. For a positive integer R, put

$$H_< = \sum_{\sigma_0(C)\le R} H_C, \qquad H_> = H - H_<. \tag{5.cclxiv}$$

The tail has Schur norm at most $Ce^{-\kappa_0 R}$. For large R, real data satisfy

$$0 \le H_< \le qI, \qquad q < 1, \tag{5.cclxv}$$

by eq. 5.cclxii. The lower bound uses $H \ge I/2$ and a tail smaller than $1/4$. Shrink the common complex tube once more if necessary. Then $\|H_<\|_{2\to 2} \le q' < 1$ throughout it, for a fixed q'.

Every carrier in $H_<$ has diameter at most $CM_0(R+1)$. For $j \ge 1$, combine the matrix entries of $H_<^j$ before taking absolute values. Its matrix range is at most

$$B_j = CM_0 j(R+1).$$

The number of unit-cell coordinates in a ball of radius B_j is at most $C_L(1+B_j)^4$. A Hilbert row has norm at most $(q')^j$; Cauchy–Schwarz on that row, and then on columns, therefore gives

$$\|H_<^j\|_{\mathrm{Sch}} \le C_L(1+B_j)^2(q')^j. \tag{5.cclxvi}$$

The data read by this combined entry are retained in the two radius-B_j endpoint balls. Each short word has its whole carrier in those balls: its successive carriers are connected and have total diameter at most the sum of their declared ranges. The balls can be joined by a fixed short path. This is the reason for truncating by the full carrier in eq. 5.cclxiv. Truncation by endpoint distance would not justify this data claim.

The exact long-word remainder is

$$E_j = H^j - H_<^j = \sum_{i=0}^{j-1} H_<^i H_> H^{j-1-i}. \tag{5.cclxvii}$$

Keep its actual joined-carrier family. At a fixed reserved carrier rate its norm is bounded by

$$\|\mathbf{E}_j\| \le CjB_H^j e^{-cR}. \tag{5.cclxviii}$$

The constants are independent of the inner depth. Choose $R = Dm$, with $cD > 2\log(1+B_H) + 2$. Next choose an aligned cube side M_{G} larger than a fixed multiple of B_m. It may be taken to be a power of L. The combined short entries now meet a bounded number of these cubes, with a bound independent of m.

For the long terms, reblocking does not lose their rate. An old connected carrier can be visited by a curve of length at most $CM_0\sigma_0(C)$. Covering that curve and its CM_0 collar by M_{G}-cubes gives

$$\#C_{\mathrm{G}} \le C_L\{1 + (M_0/M_{\mathrm{G}})\sigma_0(C)\}. \tag{5.cclxix}$$

Choose M_{G} also so that the coefficient of $\sigma_0(C)$ in $(\log S)\#C_{\mathrm{G}}$ fits in the reserved old carrier rate. Thus weighting a full carrier by independent parameters of modulus at most S preserves eq. 5.cclxviii. No fine-background coordinate count enters eq. 5.cclxvi: the coordinates counted there are the outer free Gaussian coordinates at spacing one. The fine background is read as determining data.

5.12.4. *The actual local covariance.* Let $\mathbf{T}$ be the family obtained by combining and filing $H^m_<$ as above and adding the long-word family E_m. Its sum is H^m. Multiply each term by the product of its declared cube parameters, and denote the resulting matrix by T_s. On the held root guard replace each parameter by one. For $j < m$, similarly put

$$A_{j,s} = H^j_< + (E_j)_s.$$

The near prefix is held without parameters. Its rows from a root wall read only its fixed radius-B_m guard. The long prefix keeps its complete carrier parameters. The preceding bounds give

$$\sup_{|s_\Delta|<S} \|T_s\|_{\mathrm{Sch}} \le C_L S^{C_L}(1+B_m)^2(q')^m + CmB_H^m e^{-cDm} =: q_m \longrightarrow 0. \tag{5.cclxx}$$

Its convergence is exponential up to a polynomial in m.

For a finite root coordinate set W, let χ_W denote coordinate restriction, not a fluctuation cutoff. With $c_n = 4^{-n}\binom{2n}{n}$, define

$$\begin{aligned} R_W(s) &= b^{-1/2}\chi_W \sum_{j<m} A_{j,s} \sum_{v\ge 0} c_{mv+j} T_s^v, \\ D_W(s) &= R_W(s) R_W(s)^{\mathsf{T}}. \end{aligned} \tag{5.cclxxi}$$

The series converges normally in the weighted row/column norm after m is fixed large enough. Prefix norms grow only polynomially in R, by eq. 5.cclxvi and eq. 5.cclxviii. The binomial coefficients satisfy $0 < c_n \le 1$. At complete parameters the ordinary matrix identity is

$$R_W(1) = \chi_W K_\tau(P)^{-1/2}, \qquad D_W(1) = \chi_W K_\tau(P)^{-1}\chi_W^{\mathsf{T}}. \tag{5.cclxxii}$$

Indeed $H^{mv+j} = H^j(H^m)^v$, so grouping the convergent binomial series by its residue class modulo m gives the first identity. Its square gives the second. This identity is asserted for the complete matrices. Their filed summands need not commute.

For real comparison data put

$$R_{0,*} = b^{-1/2}\sum_{j<m} c_j H^j_{<,*}, \qquad D_{0,W} = \chi_W R_{0,*}^2 \chi_W^{\mathsf{T}}.$$

By eq. 5.cclxv,

$$b^{-1} I \le D_{0,W} \le C_L I \tag{5.cclxxiii}$$

for every W. The lower bound follows by zero-extending a vector in W: $R_{0,*} \ge b^{-1/2} I$. There is no Dirichlet inverse of an indefinite saddle here.

The long prefixes and the $v \ge 1$ terms in eq. 5.cclxxi are bounded by a polynomial in m, R times $q_m + mB_H^m e^{-cDm}$. Their norms can therefore be made smaller than any prescribed fixed inverse power of M_{G}, since $M_{\mathrm{G}} = O_L(M_0 m^2)$. Finally reduce the common complex field, current and τ tubes so that the finite held prefixes have the same perturbation budget. Their coefficient Lipschitz bounds follow from Cauchy on the local tube in eq. 5.cclxiii. All choices are uniform in depth and volume. For example they can ensure

$$\sup_{|s_\Delta|<S} \|D_{0,W}^{-1/2}(D_W(s) - D_{0,W})D_{0,W}^{-1/2}\| < \frac{1}{4} \tag{5.cclxxiv}$$

simultaneously for every root coordinate set W. The finer $o(M_{\mathrm{G}}^{-4})$ budget is available for per-cube determinant estimates.

Proposition 5.42. For every fixed $S > 2$, the canonical nonflat outer precision specified above has the local Gaussian extension eq. 5.cclxxi. It is holomorphic on independent cube discs $|s_\Delta| < S$ and on the common local C^1 background, independent-current and τ tubes. Its complete covariance is the actual marginal eq. 5.cclxxii. Every local covariance has the uniform complex sector eq. 5.cclxxiv. Its coefficients read their full declared data carriers. Setting parameters outside a wall to zero gives

literal wall dependence and fixed-root heredity, with the held guard retained as part of that wall. These assertions are uniform in the homogeneous inner depth and compatible volume. ■

Proof. The preceding construction proves the identities, bounds and normal convergence. A term which survives zero parameters outside a wall has its whole parameter carrier there, in addition to the fixed held guard. Its local coefficient reads only those data. Two wall systems which agree on these complete read sets therefore give the same coefficient. This proves heredity. Take components after adding their complete held guards and read sets, merging components whose guarded sets meet. Separated components then use disjoint coordinate sets and read sets; no surviving joined carrier connects them. Their Gaussian covariance is block diagonal, and their normalized Gaussian integrals factor.

On small tori perform the finite construction on one common sufficiently large cover. Retain all lifted data carriers before truncation and all short power endpoint balls before projection. Average families over deck shifts before descent. Periodic auxiliary parameters are identified on their images, and held guards are their full deck-periodic inverse images. Their full lifted carrier weights remain charged. The row/column Schur bounds descend without a sheet factor, as in Cor. 3.104. Descend the unrestricted root matrix before restricting its coordinates to W. Indeed let I be isometric pullback from the base to the periodic sector of the cover. Periodicity of parameters, guards and averaged families gives $R_{\mathrm{cov}} I = I R_{\mathrm{base}}$, and the periodic sector is reducing for these matrices and their transposes. Thus

$$I^{\mathsf{T}} R_{\mathrm{cov}} R_{\mathrm{cov}}^{\mathsf{T}} I = R_{\mathrm{base}} R_{\mathrm{base}}^{\mathsf{T}}.$$

Only then restrict the base coordinates to W. At complete parameters the classical operators and their positive matrix functions restrict to this sector, so this covariance is the actual finite matrix marginal. A covariance restricted to one chosen lift of W would not establish that assertion. This is an operator identity, not a comparison of quantum partition functions on different volumes. □

5.12.5. *Normalized complex Gaussian integrals.* The sector just proved also specifies the determinant branch and the normalization used in local Gaussian estimates. For $d = \dim W$, define

$$d\mu_{D_W}(u) = (2\pi)^{-d/2} \det(D_W)^{-1/2} e^{-u^{\mathsf{T}} D_W^{-1} u/2}\, du, \qquad u \in \mathbb{R}^d. \tag{5.cclxxv}$$

Continue the square root from the positive real comparison matrix $D_{0,W}$. Writing $D_W = D_{0,W}^{1/2}(I + E) D_{0,W}^{1/2}$, with $\|E\| < 1/4$, gives

$$|\det(I+E)|^{-1/2} \le (4/3)^{d/2}, \qquad \mathrm{Re}\, u^{\mathsf{T}} D_W^{-1} u \ge c_L |u|^2 \quad (u \in \mathbb{R}^d).$$

The inverse estimate follows from the norm-convergent series for $(I+E)^{-1}$ and eq. 5.cclxxiii. Consequently

$$\int_{\mathbb{R}^d} |d\mu_{D_W}| \le C_L^d, \qquad \int_{\mathbb{R}^d} d\mu_{D_W} = 1. \tag{5.cclxxvi}$$

The second equality is first the real Gaussian identity. The same dominating Gaussian on every smaller sector permits holomorphic continuation to the declared domain. Polynomial moments and fixed parameter derivatives follow by differentiating that dominated integral, or by Cauchy on a smaller sector. The empty selected expectation is exactly one.

The factor C_L^d is local: there are at most $C_L M_{\mathrm{G}}^4$ free coordinates per localization cube of a wall. Thus it costs a fixed exponential per wall cube, with no factor involving the total torus or the inner fine coordinate count. This is the normalization needed when a local Gaussian is used in a connected polymer integral. It does not assert zero-freeness of every sharply truncated whole-volume Gaussian integral. The normalized cutoff expansion and its interacting vertices must still be formed with their actual frozen cutoffs.

The result proves the Gaussian parameter-domain statement for the matrix and reference domain stated here. § 5.13 proves the proper-hierarchy version for eq. 5.cclxxviii, retaining its second-lift

outer current readout. The two off-current formulas agree on physical critical pairs; they are not identified elsewhere. Nonlinear core membership is established by the actual tower and substitution maps in Cors. 3.130 and 3.131.

5.13. **The fluctuation precision on a proper inner hierarchy.** The mass removed from a row Schur matrix is essential for the fluctuation covariance. We prove its lower bound on the actual outer constraint, including the second derivative of that constraint. The inner hierarchy may have proper regions and mixed scales. The current remains an independent variable until the final physical identification.

Work in level-k units. The inner sequence ends at Ω_k; its top row length is one. Retain an additional union Ω_{k+1} of complete L-blocks, with its prescribed separation from Ω_k^c. Put $\Theta' = \Omega_{k+1} \cap \mathbb{T}^{(k+1)}$ for the block centres and $\Theta = B(\Theta')$ for their level-k sites. Let X be the level-k bonds touching Θ, and $\check{X}$ their nonpivot bonds. All pivot double blocks and contour paths are retained. The separation floor below puts this entire stock inside the interior top rows of the inner sequence. Write ι for extension from X by zero to its independent row space. Thus $\iota^\sharp \iota = 1$ in counting coordinates; there is no mixed-scale measure factor on these length-one rows. The field and row pairings elsewhere retain their physical weights. The marked geometry may retain inward bonds, but Q and its row space use only the independent interior and outward rows.

Use a real regular reference and the common weighted C^1 complex tube of Props. 3.112 and 3.171. The independent current satisfies its weighted supremum bound. The enlarged regularity clause includes every complete cube needed in the two adjacent layers, including cubes lying wholly in the upper member. Choose all proof tiles first, then a common larger separation floor. The ceilings are independent of the fine mesh, depth, volume, conditioning set and all larger admitted geometries.

5.13.1. *The precise form and its two multiplier readouts.* Write $V = \mathcal{M}^k \mathbf{U}$ on the complete outer stock and let q_V be its raw one-step constraint logarithm. The actual pivot graph has

$$q_V(\Phi_V(u)) = 0, \qquad \Phi_V(u)|_{\check{X}} = u, \qquad C_V = D\Phi_V(0).$$

Let h_V be the pivot right inverse of $q_V'(0)$ and write $C_V^{(2)} = \frac{1}{2} q_V''(0)$. This superscript distinguishes the quadratic row map from the pivot lift C_V. The graph derivative satisfies

$$\Phi_V''(0)[u, v] = -2 h_V C_V^{(2)}(C_V u, C_V v). \tag{5.cclxxvii}$$

Indeed the free coordinates have zero second derivative, and twice differentiating the constraint determines all pivot coordinates by its invertible pivot block. Every map in this identity reads its complete one-step double block and has a bounded row and column norm depending only on L.

Let $b_V w(y, x)$ be the derivative of the relative contour logarithm

$$\frac{1}{i} \log\{(e^{iw} V)(y, x) V(y, x)^{-1}\}.$$

Set $G_V^{(2)} = b_V^\sharp b_V$, with one unit weight for every noncentral site in a retained block. This is the relative contour quadratic form. It is the Hessian of the absolute trace-contour functional when the reference averaged contours equal one.

The ordered inner operators are exactly eq. 3.cmxv. In particular put

$$\begin{aligned}\Sigma_1 &= (QG_1Q^\sharp)^{-1},\\ \omega_* &= H^\sharp\mathbf{J},\\ \omega_{1*} &= H_1^\sharp\mathbf{J},\\ E_V^{(2)}[\omega](w,z) &= 2\langle\omega, \iota h_V C_V^{(2)}(w,z)\rangle,\\ \Delta_{\mathrm{out}} &= \iota^\sharp\Sigma_1\iota - a_{\mathrm{top}} - E_V^{(2)}[\omega_{1*}],\\ A_Y &= e_Y^\sharp C_V^\sharp(\Delta_{\mathrm{out}} + G_V^{(2)})C_V e_Y.\end{aligned} \tag{5.cclxxviii}$$

Here e_Y extends the free coordinates on a conditioning set $Y = \check{X}(B(\Theta''))$, $\Theta'' \subset \Theta'$, by zero. Its retained blocks and collars are those of the conditioning geometry. The constant top row mass is $a_{\mathrm{top}} = a_0 I$; for the unit mass convention it is I. The term inside G_1 uses ω_*; the outer constraint term uses ω_{1*}. These are distinct away from physical currents.

5.13.2. *A lower bound before the outer gauge is added.*

Lemma 5.43 (The top-supported Schur form)**.** At every admitted real pair, for a top row field w supported on X,

$$\langle w, (\iota^\sharp\Sigma_1\iota - a_{\mathrm{top}})w\rangle \geq c\|\mathrm{d}_V w\|^2_{2,\mathcal{P}_X} - C(\alpha_0+\gamma_0)\|w\|_2^2. \tag{5.cclxxix}$$

Here w is extended by zero off X, and $\mathcal{P}_X$ is the complete finite stock of level-k plaquettes used by the outer block curl estimates. The form on the left has operator norm at most a fixed constant. ■

Proof. Put $v = H_1\iota w$. The actual proper row lift gives $Qv = \iota w$ and $\|v\|_{\mathcal{E}} \leq C\|w\|_2$. The equality $G_1^{-1}v = Q^\sharp\Sigma_1\iota w$ gives

$$\langle w, (\iota^\sharp\Sigma_1\iota - a_{\mathrm{top}})w\rangle = \langle v, (\mathscr{D}_U - \Delta'_{\pi,U}[J] - S^\sharp\Delta_U^{(2)}[H^\sharp J]S + DRD^\sharp)v\rangle. \tag{5.cclxxx}$$

This is the variational identity for the complete Schur matrix, followed by its exact row-mass subtraction. It uses neither criticality nor horizontality of v.

At the real reference R is an orthogonal projection, so the last term is nonnegative. The Wilson plaquette form and the current form estimates of § 3.13 and eq. 3.cmx bound the right side of eq. 5.cclxxx below by

$$c\|\mathrm{d}_U v\|_2^2 - C(\alpha_0+\gamma_0)\|v\|_{\mathcal{E}}^2.$$

The multiplier $H^\sharp J$ has the required row-weighted supremum bound. The second constraint jet and S have their bounded energy forms, so its term has the stated $C\gamma_0$ bound. No derivative of the independent current occurs.

Every plaquette in $\mathcal{P}_X$ and every carrier of its four top rows lies wholly in Ω_k. There the assigned scale is one. The local proof of Lem. 5.38 therefore gives

$$\|\mathrm{d}_V Qv\|_{2,\mathcal{P}_X} \leq C\|\mathrm{d}_U v\|_2 + C\alpha_0\|v\|_{\mathcal{E}}.$$

To see why the proper exterior changes nothing, choose a fixed physical cube around each of these complete plaquettes. In its real small gauge the actual top row differs from the flat flux row by $O(\alpha_0)$ in both physical row and column norms. The flat identity eq. 5.ccl and its Jensen bound have no depth factor. The coarse derivative has unit spacing. The cubes have bounded overlap; all norms outside them on the right may simply be kept. Thus the estimate does not replace the proper inner inverse by a homogeneous inverse. Since $Qv = \iota w$, it proves eq. 5.cclxxix. The upper bound follows from the proper row inverse and the constant mass on the supported top rows. □

Lemma 5.44 (The outer geometric inequality)**.** For every retained block family and its full pivot stock,

$$\|u\|_2^2 \leq C_L\{\|\mathrm{d}_V C_V e_Y u\|^2_{2,\mathcal{P}_X} + \|b_V C_V e_Y u\|_2^2\}. \tag{5.cclxxxi}$$

On the free subspace whose reconstructed field vanishes on each retained box tree, the same inequality holds with the second term omitted. ■

Proof. First take a flat frame. In a block, compare a path to a site with each coordinate-order path to that site. Successive plaquette swaps express their difference as a sum of at most C_L plaquette curls. Hence an internal bond is its mean contour-potential difference plus a sum of these curls. Squaring and summing bounds all internal bonds by the two terms on the right. In the tree version use the unique tree path instead; its potential is zero.

Across a block face, a plaquette with one transverse step compares neighboring crossing bonds. Its remaining two bonds are internal and already bounded. The transverse face grid is connected and has at most L^3 sites. Thus all crossing values differ from a common face value by controlled curls and internal bonds. The plain mean of that face is its common crossing value plus controlled internal path terms. It vanishes because $q_V'(0)C_V e_Y u = 0$, including each boundary pivot row. This controls the common value. Outside retained blocks the extended field has zero internal bonds, so the same argument applies to a boundary face. A fixed bond or plaquette enters at most C_L such block comparisons. The free restriction of $C_V e_Y u$ is $e_Y u$, proving the claim at a flat reference.

For a real small-curvature reference choose the regular real gauge on each block and its neighboring double blocks. Their sizes depend only on L. The plain row, pivot lift, relative contour derivative and coarse curl differ from their flat counterparts by $C_L\alpha_0$ in the finite row and column norms. The gauge changes are unitary. Absorb this perturbation in half the flat inequality and sum the same bounded-overlap comparisons. Vanishing on a box tree is preserved by these linear unitary coordinate changes. □

Proposition 5.45 (Proper fluctuation covariance)**.** For fixed sufficiently small ceilings, the exact matrix eq. 5.cclxxviii satisfies

$$c_L I \le A_Y \le C_L I \tag{5.cclxxxii}$$

at every admitted real pair. The same bounds hold on the strict tree-zero subspace when the gauge term is omitted. The inverses extend holomorphically to a common weighted C^1 complex background tube and independent-current ball, with uniform inverse norms. All conclusions are uniform in the proper inner hierarchy and the conditioning set. ■

Proof. The outer second-jet bound and the proper readout estimate give $\|E_V^{(2)}[H_1^\sharp J]\| \le C_L\gamma_0$. Insert $w = C_V e_Y u$ in eq. 5.cclxxix, add the relative gauge, and use Lem. 5.44. The pivot lift is bounded and its free restriction is the identity. Decreasing $\alpha_0 + \gamma_0$ absorbs the negative mass term. The same proof on the tree-zero subspace omits the gauge and uses the second part of that lemma. All upper bounds follow from the bounded factors in eq. 5.cclxxviii.

The proper energy and normalized row inverse bounds, together with their local coefficient families, imply

$$\|A_Y(\mathbf{U},\mathbf{J}) - A_Y(U,J_0)\|_{2\to 2} \le C_L(\|A'\|_{C^1_{\text{weighted}}} + \|\mathbf{J} - J_0\|_{\text{current}}).$$

The same holds on the tree-zero free coordinates. For the row Schur factor use its normalized inverse difference identity; for the two readouts retain their different lifts. The outer pivot and contour coefficients have fixed finite ranges. Restriction and zero extension have norm one, so the bound is independent of Y. It is a relative energy comparison, not a fine-lattice operator comparison at scale η^{-2}. A perturbation below half the real gap proves the assertion. □

5.13.3. *Local inverse families and logarithms.* The locality assertion requires more than the completed operator gap. We record how the existing carrier construction applies to this particular matrix. The mass-removed family eq. 3.mxvi, the rooted family of $H_1^\sharp J$, and the finite outer factors give an exact connected-carrier expansion of A_Y. For this second-lift readout repeat the proof of Prop. 3.111 with the named family of H_1 in place of H: its physical transpose pairs a unit top-row seed with the fine current, and the family column bound sums the cellwise energy pairings. It gives

$C\gamma_0$ with no whole-volume current norm. The bare restriction identity follows from $Q_0H_1 = P_0$, so that its separate bare term is retained exactly. The precision family's row and column sums, charged by a fixed exponential carrier rate, are bounded. Each term retains the complete inner regions, outer blocks, pivot rows and the trace of Y on its read set. These are precisely the data needed to multiply two terms.

The inverse construction of Cor. 3.104 can now be applied on the outer free coordinates, whose spacing is one and whose multiplicity per cell is bounded by C_L. Here are its domain and counting checks in this setting. Choose $b > 2C_L$ and write $H_Y = I - A_Y/b$. On a smaller common tube it has Hilbert norm at most $q < 1$. Truncate its family by full carrier length at R, giving $H_< + H_>$. The omitted family has norm Ce^{-cR}. Combine $H_<^m$ before taking absolute values. Its matrix range is $O(mR)$ in physical units, and hence

$$\|H_<^m\|_{\mathrm{Sch}} \le C_L(1+mR)^2 q_1^m, \qquad q_1 < 1. \tag{5.cclxxxiii}$$

The complete data of every contributing short word lie in the corresponding endpoint balls. Enlarge the separation floor so that these balls, including their fixed carriers, remain inside Ω_k. This is possible after m, R have been fixed, independently of depth. In these balls the inner assigned scale is one; in the extended outer sequence the only additional scale is L. Consequently the parameter count in a reblocked endpoint ball is bounded independently of the number of finer layers. The arbitrary boundary of Y changes its recorded zero-extension mask, not that count.

The same collar gives the required local background domains. Relative to the fixed global real reference, extend a local complex potential from a short-word read ball by multiplying it by a smooth cutoff equal to one on all reads and zero before the edge of its supplied collar. Its first difference is bounded in unit scale. The entire cutoff collar lies in Ω_k, so all its weights have scale one; multiplication preserves the weighted C^1 norm within a fixed factor. Extend by zero outside the collar. A bounded cutoff preserves the independent-current norm without taking a current derivative. Decrease the local complex radii by that factor. This supplies an admitted global extension for estimating each combined short coefficient. Its value is independent of the extension by exact determining-data locality. Long coefficients retain the local domains of their original complete NCW carriers. This does not require an extension of an arbitrary partially specified proper history.

Keep the long-word identity

$$H_Y^m - H_<^m = \sum_{i=0}^{m-1} H_<^i H_> H_Y^{m-1-i}$$

as a family with its full joined mixed-scale carriers. Its norm is at most $CmB_H^m e^{-cR}$. Take $R = Dm$ with D fixed large, then m large. Reblock after these choices. The short-power term meets only a bounded number of new cubes; the long carriers pay for their cube parameters from a reserved part of their old carrier rate. Thus, for every fixed requested parameter radius $S > 2$, the filed mth power has family norm less than $1/2$ on $|s_\Delta| < S$. The finitely many prefixes are bounded. The exact identity

$$A_Y^{-1} = b^{-1}\Big(\sum_{j=0}^{m-1} H_Y^j\Big)(I - H_Y^m)^{-1}$$

then gives a normally convergent local inverse family. This is the inverse of the compressed precision, not a marginal of an inverse taken before conditioning.

For the logarithm use the same grouped words in

$$\log A_Y = (\log b)I - \sum_{j=1}^{m} H_Y^j \sum_{v\ge 0} \frac{(H_Y^m)^v}{mv + j}. \tag{5.cclxxxiv}$$

At complete parameters this is the convergent real spectral logarithm and its holomorphic continuation. At other parameters the formula specifies its filed local extension. Its diagonal trace at a bond is a sum of closed joined carriers containing that bond. The same family norm bounds it, so the bound per outer cell is uniform. Differences between two regions or conditioning sets cancel term by term until a carrier meets their differing read sets. Parameter walls and fixed-root heredity follow by setting to zero every term whose complete carrier leaves the wall. No coefficient is evaluated on an unrecorded extension of the background.

For normalized Gaussian integrals use the binomial grouped series eq. 5.cclxxi, with A_Y in place of the homogeneous matrix. The two premises of that construction have now been proved: eq. 5.cclxxxii and the complete carrier family just described. Its combined short words read the same top-scale endpoint balls; its long words retain the same mixed-scale carriers. Its held real prefix is at least $b^{-1/2}I$, and its tail can be made arbitrarily small before decreasing the common complex tube. Consequently it gives the uniform local complex sector eq. 5.cclxxiv and the normalized Gaussian identity eq. 5.cclxxvi for every coordinate selection inside Y. At complete parameters its covariance is the selected marginal of A_Y^{-1}. The conditioning by Y has already occurred. The determinant branch is continued from the same positive real precision. These assertions do not identify two independently chosen off-parameter extensions of a logarithm. For small periods perform the construction on one common compatible cover and retain all lifted read balls before projection. Average the filed families over deck shifts, then descend the complete operator before any coordinate selection. The row and column sums descend without a sheet factor, as in Cor. 3.104; the reducing-sector calculation in the proof of Prop. 5.42 identifies the descended covariance with the actual base matrix inverse.

5.13.4. *Identification at a physical critical pair.* Suppose now that U is a regular constrained-critical field of the inner hierarchy and $J = j_U = Q^\sharp\omega$. Then $H^\sharp J = H_1^\sharp J = \omega$, since both lifts are right inverses of Q. The physical Ward identity makes H_1 the horizontal derivative of the actual critical graph, and the differentiated constraint gives its Lagrangian Hessian. Thus the second derivative of the critical action with respect to the supported top datum is $\iota^\sharp\Sigma_1\iota - a_{\mathrm{top}}$, as in eq. 5.ccliv, now on the proper hierarchy. Composing with the actual outer pivot graph adds $\langle\omega, \iota\Phi_V''(0)\rangle$. By eq. 5.cclxxvii this is exactly the negative $E_V^{(2)}[H_1^\sharp J]$ term in eq. 5.cclxxviii. Adding the specified relative contour Hessian and restricting free coordinates gives A_Y exactly. In an averaged-contour axial representative it is also the absolute-contour physical Gaussian precision. The equality continues on the corresponding physical holomorphic chart. No identification with an independently prescribed signed or counterterm-modified precision is used.

5.14. **An actual diagonal deformation of the homogeneous backgrounds.** A change of a plaquette weight changes the principal part of the background equation. Its derivative contains second differences of the potential. We therefore construct the deformed background in a finite-p second-order space before differentiating the hierarchy. The parameter in this section is a constant diagonal weight, not a spatially varying source.

Fix the odd blocking integer L, coarse spacing one, fine spacing $h = L^{-j}$ and a compatible periodic volume. Real flat references with arbitrary holonomy are permitted. Use their parallel frames and physical pairings as in § 3.43. For $a = (a_1, \dots, a_4)$ near 1 set

$$\mathscr{A}_h^a(U) = \sum_{\mu<\nu} a_\mu a_\nu \sum_x \left(1 - \tfrac{1}{2}\operatorname{tr} U_{\mu\nu}(x)\right). \tag{5.cclxxxv}$$

No factor depending on h is inserted into this four-dimensional Wilson action. Its normal-coordinate physical gradient is denoted $J_h^a(A)$ when $U = e^{ihA}W_0$. The actual group mean, its straightening q_h, and its node factor v_h are unchanged.

5.14.1. *A second-order inverse with physical cell norms.* Let C_y be unit cells, with a fixed enlargement C_y^+ for difference stencils. For $p > 4$ put

$$\begin{aligned} \|f\|_{\mathcal{F}_p} &= \sup_y \|f\|_{L^p(C_y^+)}, \\ \|A\|_{\mathcal{W}_p} &= \sup_y \sum_{r=0}^{2} \|D^r A\|_{L^p(C_y^+)}. \end{aligned} \tag{5.cclxxxvi}$$

All mixed forward differences and the physical measure h^4 are included. Any of the fixed larger cells gives an equivalent norm. Uniform discrete extension and Morrey estimates imply

$$\|A\|_{X_\alpha} \le C_{p,\alpha} \|A\|_{\mathcal{W}_p}, \qquad 0 < \alpha < 1 - 4/p. \tag{5.cclxxxvii}$$

One direct verification is to use the piecewise multilinear extension of DA on each shifted grid. Its $W^{1,p}$ norm is bounded by the grid $W^{1,p}$ norm, and its nodal values are exact. The continuum Morrey estimate on an enlarged unit cube bounds the nodal increments. Applying the same argument to A, and summing the finitely many staggered components, proves eq. 5.cclxxxvii. It has no mesh or volume factor. Local frames on a fixed periodic cover deal with cells that cross the fundamental boundary; unitary deck factors preserve the estimates.

Lemma 5.46 (The actual joint inverse on local L^p forces)**.** For the actual flat rows and $H_0 = \mathrm{d}^\sharp \mathrm{d} + DRD^\sharp$, the system

$$H_0 A - Q^\sharp \omega = f, \qquad QA = b \tag{5.cclxxxviii}$$

has a unique solution satisfying

$$\|A\|_{\mathcal{W}_p} + \|\omega\|_\infty \le C_p(\|f\|_{\mathcal{F}_p} + \|b\|_\infty). \tag{5.cclxxxix}$$

The same bound holds with a sufficiently small exponential weight on the cell norms. Constants are independent of depth, volume and real flat holonomy. ∎

Proof. Retain $K_0 = H_0 + Q^\sharp Q$ and $S = QK_0^{-1}Q^\sharp$. The energy cell kernels of K_0^{-1} and the exponential coarse inverse of S were proved in Prop. 3.182. A force in $\mathcal{F}_p$, $p > 2$, has bounded local L^2 norm. Resolvent energy bounds between unit cells and their exponential sums therefore give

$$\|K_0^{-1} f\|_{2,\mathrm{cell},\infty} + \|QK_0^{-1} f\|_\infty \le C_p \|f\|_{\mathcal{F}_p}.$$

For the second term, each physical row is supported in a fixed unit star and has uniformly bounded L^2 density. There is no point evaluation of an energy function. The exact formulas

$$\sigma = S^{-1}(b - QK_0^{-1} f), \quad A = K_0^{-1}(f + Q^\sharp \sigma), \quad \omega = \sigma - b$$

bound the multiplier and the cell L^2 norm of A.

The component scalar equation is exactly

$$LA = f + DPD^\sharp A - Q^\sharp QA + Q^\sharp \sigma, \qquad P = 1 - R. \tag{5.ccxc}$$

The actual factorization $DPD^\sharp = (DF) M_s^{-1} (DF)^\sharp$ in eq. 3.mccxxxviii maps cell L^2 to L^∞. This uses the scalar smoothing of its columns already proved there. The actual row density gives $\|Q^\sharp c\|_\infty \le C\|c\|_\infty$; the division by h^4 in the physical transpose cancels the row coefficient $O(h^4)$. Thus all terms in eq. 5.ccxc other than f are bounded pointwise by the asserted right side of eq. 5.cclxxxix. Here the local finite-p estimate Cor. 3.80 has outer $W^{1,p}$ terms, so an explicit nested bootstrap is needed. The energy kernels first bound the outer H^1 norm. The scalar equation and its local $p = 2$ estimate give $W^{2,2}$; the strict four-dimensional embeddings give $DA \in L^3$ and A in every fixed finite L^q. Its next $p = 3$ estimate gives $W^{2,3}$, hence $DA \in L^8$ and $A \in L^\infty$. If $p \le 8$ the final p estimate now applies. If $p > 8$, first apply the $p = 8$ estimate to obtain $DA \in L^\infty$, and then apply the desired finite p estimate. Choose a fixed enlargement large enough for all these successive cutoffs. All other sources in the scalar equation were already bounded; $f \in L^p$ belongs

to each lower exponent used on these fixed cells. This proves the field bound without an endpoint singular-integral estimate.

For the weighted assertion use the existing exponential energy kernels first and the scalar estimate separately on each cell. Weights on neighboring enlarged cells differ by a fixed factor. No derivative is taken of a truncated distance weight, and no pointwise estimate is inferred directly from a cell L^2 estimate. Uniqueness is the same K_0, S energy argument as before. □

Let $K_a = \mathrm{d}^\sharp W_a \mathrm{d}$, where $(W_a F)_{\mu\nu} = a_\mu a_\nu F_{\mu\nu}$. Constant weights give the elementary bound

$$\|(K_a - K_1)A\|_{\mathcal{F}_p} \le C|a-1|\|A\|_{\mathcal{W}_p}. \tag{5.ccxci}$$

Indeed this is a sum of finitely many second differences with coefficients $a_\mu a_\nu - 1$. This is the place where a mere X_α solution space would not suffice.

5.14.2. *The weighted equation is solved, rather than postulated.* The complete normal Wilson gradient has the decomposition

$$J_h^a(A) = K_a A + N_h^a(A). \tag{5.ccxcii}$$

On a fixed complex X_α ball and a fixed weight polydisc,

$$\|N_h^a(A)\|_\infty \le C\|A\|_{X_\alpha}^2, \quad \|N_h^a(A) - N_h^a(\widetilde{A})\|_\infty \le Cr\|A - \widetilde{A}\|_{X_\alpha}. \tag{5.ccxciii}$$

These are consequences of the actual plaquette proof of Lem. 3.184, applied separately to each of the six orientations before summing. To make the parameter dependence explicit, the four-factor logarithm is $F = \mathrm{d}A + E_h(A)$ with $DE_h = O(A\,DA)$; the sine remainder has rough one-difference bound $O(h^3\|F\|_\infty^3)$. Each is multiplied by the constant $a_\mu a_\nu$. The normal-to-left differential is $1 + O(hA)$, and its product with $K_a A$ is bounded by $Ch\|A\|_\infty h^{-1}\|DA\|_\infty$. Thus no unbounded second difference occurs in the nonlinear remainder. These finite expressions are jointly holomorphic in A, a on a larger fixed ball; Cauchy estimates there give the Lipschitz bound in eq. 5.ccxciii.

Set $C_h = q_h - Q$, and let $\mathcal{L}_0^{-1}$ be the inverse of Lem. 5.46. The actual penalized equation is equivalent to the fixed point

$$\begin{pmatrix} A \\ \omega \end{pmatrix} = \mathcal{L}_0^{-1} \begin{pmatrix} -(K_a - K_1)A - N_h^a(A) + (q_h'(A) - Q)^\sharp \omega \\ B - C_h(A) \end{pmatrix}. \tag{5.ccxciv}$$

The constraint in this equation is the entire actual recursion. In particular its physical transpose uses the fixed-input-leg $C_L h^4$ moment of eq. 3.mccc; no directional Hessian estimate is substituted for a column-density estimate. Its nonlinear terms have the bounds eq. 3.mcclx.

Proposition 5.47 (Holomorphic anisotropic critical backgrounds)**.** Fix $p > 4$ and $0 < \alpha < 1 - 4/p$. There are $\varepsilon, r, \rho > 0$, depending on these choices and L but not on j or the volume, such that for $|a-1| < \varepsilon$, $\|B\|_\infty < \rho$, the actual mean fibre has a holomorphic critical orbit $U_j^a(B)$. A unique mean-slice representative and its full multiplier satisfy

$$\|A_j^a(B)\|_{\mathcal{W}_p} + \|\omega_j^a(B)\|_\infty \le C_p\|B\|_\infty. \tag{5.ccxcv}$$

The prescribed literal representative has actual mean $e^{iB}V_0$. For real a, B the field is real and is the local constrained minimum in a fixed strong chart, modulo gauges equal to one at the coarse nodes. The orbit and total action descend across the overlapping real-flat charts of Prop. 3.192. ■

Proof. In the joint norm $\|A\|_{\mathcal{W}_p} + \|\omega\|_\infty$, the Lipschitz constant of eq. 5.ccxciv on radius r is at most $C_p|a-1| + C_{p,L}r$, by eq. 5.cclxxxvii and eq. 5.ccxci and eq. 5.ccxciii. Choose ε first so the first term is at most $1/8$, then r so the second term is at most $1/8$, and finally $C_p\rho < r/4$. The fixed point is invariant and contractive. The iteration from zero converges locally uniformly on the fixed complex product ball. It constructs the jointly holomorphic pair and proves eq. 5.ccxcv; it does not assume the desired background or its inverse.

The fixed point first solves the equation with its gauge penalty retained. The actual identities eq. 3.mcclxx and eq. 3.mcclxxi still hold because the group mean has not changed. For $\tau_A\lambda = 0$,

gauge invariance of the weighted action gives $\langle J_h^a(A), \Gamma_A \lambda \rangle = 0$, while the constraint force also vanishes in that test. The site construction used in the penalty-removal proof of Prop. 3.183 makes $\lambda \mapsto RD^\sharp \Gamma_A \lambda$ onto $\operatorname{ran} R \cap Z_\alpha$. Its correction uses the actual τ_A, the unchanged site inverse $G_s R$, and the smooth E_q. Our field lies in its required X_α ball by eq. 5.cclxxxvii. Therefore the remaining penalty annihilates every vector in that range and is zero. For complex fields this is a range and bilinear nondegeneracy argument, not an inference from a possibly zero complex square. All tests are finite-array gauge directions. They need not satisfy a uniform $\mathcal{W}_p$ norm for this exact identity to apply.

The literal node correction uses sampled smooth profiles with uniform bounds of every fixed order, as in eq. 3.mcclxxxii. Its node values are $O(B)$ and its logarithm has bounded local $W^{3,p}$ norm. The discrete product and exponential rules hence preserve the field $W^{2,p}$ bound. It gives the claimed actual literal mean by the exact plain/straightened factorization, not by equating their derivatives.

For real weights in this smaller ball, $W_a \geq cI$. On the linear slice and $\ker Q$, the weighted quadratic form plus the unchanged gauge penalty is a relative $O(|a-1|)$ perturbation of the proved positive flat form. The actual nonlinear Hessian and multiplier terms add a relative $O(r)$ form error. The constrained chord argument in the isotropic proof therefore retains a positive lower bound. This proves the local minimum and local orbit uniqueness.

For clarity, uniqueness is also valid against an admitted X_α competing critical field. Put it into the actual mean slice by the existing site construction. Its finite-array equation, eq. 5.ccxc and the constant principal perturbation give $\|A\|_{\mathcal{W}_p} \leq C_p(\|B\|_\infty + r^2) + C_p \varepsilon \|A\|_{\mathcal{W}_p}$. The competing multiplier is bounded by the same smooth-column weak readout used in eq. 3.mccxci; the weighted Wilson form changes its constant only by a fixed factor. Absorb the last term, shrink r, and use the contraction's larger uniqueness ball. Thus no extra $W^{2,p}$ assumption on competing orbits is hidden in this argument. The geometric flat-reference transitions preserve the equation and the original strong bounds. The same upgrade and uniqueness identify their total orbits on overlaps, proving the asserted descent. □

5.14.3. *Localization, affine probes and actual free coercivity.* The preceding inverse also gives a localized analytic response, including a derivative of the weight. Here the weight is one global parameter: no decay in a fictitious location of a is claimed. The flat inverse with K_a in place of K_1 is its Neumann series in the bounded operator $(K_a - K_1) : \mathcal{W}_p \to \mathcal{F}_p$. The weighted cell bound in Lem. 5.46 makes that series convergent at a fixed positive spatial rate. Smooth multiplication by the unit-cell partition is bounded on $\mathcal{W}_p$ by the discrete product rule through order two. The actual Wilson and constraint residuals are supported in fixed physical stars and have the same uniform Banach Cauchy bounds as in eq. 4.cclxix. Expanding this equation with the a-dependent inverse gives the same ordered rooted trees as there. Their propagator sums are uniform on a slightly larger weight polydisc. The scalar majorant for arity at least two converges after decreasing ρ once. Consequently every fixed-order background jet, and its first a derivative on a smaller polydisc, has exponential cell moments uniform in j. This proves the required response localization from the actual equation, rather than assigning a small global inverse to an arbitrary short carrier.

At the trivial flat reference let $A_\mu^F(x) = \frac{1}{2} \sum_\nu F_{\nu\mu} x_\nu$, with constant antisymmetric F. Then

$$K_a A^F = 0, \qquad D^\sharp A^F = 0, \qquad Q_h A^F = B^F. \tag{5.ccxcvi}$$

The first identity differentiates a constant weighted curl; the second is antisymmetry, and the third is the exact centroid count of the actual straight row. Exponential inverse kernels act on polynomial-growth data, so uniqueness of the extended joint inverse identifies its affine response with A^F and multiplier zero. The literal response adds only the actual node-frame gradient. This remains true after one a derivative: the transverse affine response is independent of a. Complete invariant densities with zero first jet therefore have coefficient-preserving direct and successive pullbacks,

by the argument of eq. 5.clxxvi and eq. 5.clxxvii. Individual fixed-reference Taylor pieces are not asserted invariant.

For the Taylor vertices and Fourier coefficient assertions below, take the trivial flat reference, as in the isotropic classical comparison. The existence and descent theorem above continues to allow arbitrary real flat holonomy. Put $S_j^a(B) = \mathscr{A}_{h_j}^a(U_j^a(B))$ and $T_{j,m}^a = D_B^m S_j^a(0)$. Positivity of the actual flux averages in eq. 5.ccxxx gives, for real a,

$$c\,\mathrm{d}^\sharp\mathrm{d} \le T_{j,2}^a \le CI, \tag{5.ccxcvii}$$

uniformly in depth. Indeed $W_a \ge cI$ bounds the fine curl energy below, the literal and straight means have the same curl, and the smooth exact trial lift bounds it above. The weighted actual background minimizes that fine energy at its mean. This establishes the free gap needed for the Gaussian comparison below without assuming an effective precision.

5.14.4. *Mesh comparison with a genuine parameter derivative.*

Proposition 5.48 (Anisotropic Taylor convergence and its weight jet)**.** For each $0 < \sigma < 1$ there are a sufficiently small real weight cube $\mathcal{A}_\sigma$ about 1 and $s_\sigma > 0$ such that, for $m = 2, 3, 4$,

$$\sup_{a\in\mathcal{A}_\sigma}\left\{\|T_{j+1,m}^a - T_{j,m}^a\|_{m,s_\sigma} + \sum_{\lambda=1}^4 \|\partial_{a_\lambda}(T_{j+1,m}^a - T_{j,m}^a)\|_{m,s_\sigma}\right\} \le C_\sigma L^{-\sigma j}. \tag{5.ccxcviii}$$

The norm is the rooted exponential kernel norm eq. 5.ccxx. The actual bulk companions and their first weight jets thus converge in that norm. Their finite torus versions are the corresponding periodic multilinear kernels. ∎

Proof. Choose $\beta < 1$ close enough to one and p so large that $\beta < 1 - 4/p$. The preceding construction and literal correction give a uniform X_β bound. For real weights the interpolation and actual mean estimates Props. 5.22 and 5.27 are unchanged. The energy estimate is simply the sum of its six orientation estimates multiplied by $a_\mu a_\nu$. The exact row-seed repair of Lem. 5.28 is unchanged as a field construction; its first-variation bound is multiplied by bounded weights. The weighted local minimum proved above is applicable in both directions of the two-mesh trial comparison. Hence, uniformly for real a in a fixed cube and real B in a fixed smaller ball,

$$|S_{j+1}^a(B) - S_j^a(B)|/\mathcal{V} \le C_\beta h_j^\beta. \tag{5.ccxcix}$$

The complex actions on the larger product ball are uniformly bounded per volume: each plaquette contributes Ch_j^4, and there are $O(h_j^{-4}\mathcal{V})$ plaquettes.

Fix m real source profiles of supremum at most one, a real weight centre a_* in a smaller cube, and one coordinate λ. Apply Lem. 5.30 to the $m+1$ variables of

$$f(t,z) = \mathcal{V}^{-1}(S_{j+1}^{a_*+te_\lambda} - S_j^{a_*+te_\lambda})\left(\sum_{i=1}^m z_i b_i\right).$$

All its real values on the fixed cube are small by eq. 5.ccxcix, and the enclosing complex polydisc is uniformly bounded. The resulting mixed derivative is bounded by $Ch_j^\beta(1+j)^{2(m+1)}$. The version without t gives the same statement for the undifferentiated vertex. This is a joint real-to-jet argument; Cauchy's inequality has not been applied to a real-only bound on a.

Cosine and sine profiles give the same bound for the vertex symbols at real external momenta. The localized background trees above, the physical plaquette density h_j^4, and the $O(h_j^{-4})$ plaquettes per unit cell give a uniform larger holomorphic momentum strip for these symbols. Its first weight jet has the same bound by Cauchy on the larger weight polydisc. For a fixed m each external distance is dominated by a fixed multiple of the root distances of the background jets; hence the exponential moments used here require no all-arity claim.

Apply the iterated strip interpolation argument of Prop. 5.32 to each symbol and its weight derivative. On a sufficiently smaller strip it gives the power $\theta = (1 - s/s_0)^{4(m-1)}$ of the real-momentum bound. Fourier contour shifts on a slightly larger strip than the output one bound its absolute exponentially weighted kernel sum. Choose β and then $s > 0$ so that $\beta\theta > \sigma$; the fixed powers of $1 + j$ are absorbed in that strict margin. This proves eq. 5.ccxcviii for all three orders at their common smaller rate. The parameter cube and the original holomorphic radii may depend on these choices, but not on depth.

Finally the differentiated fixed-point trees commute with periodic summation in their distinct external slots. After choosing a lift of an internal vertex, each child input image is independently summed. There is no extra closed-loop image constraint in these classical rooted trees. Thus the periodic multilinear kernels are the exact periodizations used above; no assertion that periodization commutes with ordinary pointwise products is needed. □

The conclusion supplies an actual differentiated classical hierarchy. It does not construct a proper history from arbitrary curvature-only coarse data, admit independent enlarged cube parameters, or produce a spatially varying anisotropy. Those are different domain questions.

5.15. **The actual anisotropic Gaussian increment.** We compare the constrained Gaussian of the weighted classical hierarchy with the weighted massive lattice determinant. Both the comparison and the convergence of successive increments retain a weight derivative. These are separate steps: a uniformly bounded cumulative regulator error alone does not imply convergence of its successive differences.

Keep the homogeneous domain of Prop. 5.47, using the trivial flat reference for the Taylor coefficients and their bulk symbols. Put $\mathsf{A} = \mathrm{diag}(a_\mu)$, acting on the vector index. For a complete invariant pointed functional, let $b_{\mu\nu}$ be its quadratic coefficient in the single plane $\{\mu, \nu\}$, in the physical convention of Prop. 5.14. At fixed diagonal weights there are six such coefficients. Axis permutations also permute the weights; scalar isotropy is not assumed at $a \neq 1$.

5.15.1. *The weighted physical gauge and its uniform gap.* At the actual background $U = U_j^a(B)$, re-center group coordinates at zero and let $q = q_U, Q = Q_U, D = D_U$ be the actual re-centered rows and gradient. Thus $qq^\sharp = 1$ and $QD = \mathrm{d}_c q$. These site rows are not the effective fixed-reference map τ_A away from zero. Define

$$\begin{aligned} \Delta_a &= D^\sharp \mathsf{A} D, & K_a &= (\mathscr{A}_h^a)''(U) + \mathsf{A}DD^\sharp\mathsf{A}, \\ \widetilde{K}_a &= \mathsf{A}^{-1/2} K_a \mathsf{A}^{-1/2}, & V_s &= q^\sharp q, \\ V_v &= \mathsf{A}^{-1/2} Q^\sharp Q \mathsf{A}^{-1/2} - \mathsf{A}^{1/2} D q^\sharp q D^\sharp \mathsf{A}^{1/2}. \end{aligned} \tag{5.ccc}$$

The scalar averaging precision is $\Delta_a + V_s$. In original vector coordinates it is $(\mathscr{A}_h^a)'' + \mathsf{A}D(1 - q^\sharp q)D^\sharp\mathsf{A} + Q^\sharp Q$; its congruent version is $\widetilde{K}_a + V_v$. The gauge is $(1 - q^\sharp q)D^\sharp\mathsf{A}$, with scalar Faddeev–Popov operator Δ_a on the corresponding constrained site variables. These choices are tied to one another.

The real positive branches of $\mathsf{A}^{1/2}$ extend holomorphically to a fixed complex polydisc about 1. Their coordinate Jacobian is field independent and disappears on vacuum subtraction. In the original vector coordinates the massive regulator is $s\mathsf{A}$, not sI. After congruence it is sI, as in eq. 5.cliv.

Lemma 5.49 (Uniform weighted averaging and interpolation inverses)**.** For real a and real actual backgrounds on a fixed sufficiently small domain, both averaging precisions are uniformly comparable to the free physical H^1 form. The same holds for

$$M = K_* + 1, \qquad S_t = M + t(V - 1), \quad 0 \le t \le 1, \quad (K_*, V) = (\Delta_a, V_s) \text{ or } (\widetilde{K}_a, V_v). \tag{5.ccci}$$

On a smaller complex weight/background domain these normalized operators have uniform relative-form inverses. Their weighted Bloch inverses are holomorphic in a fixed external momentum strip. No positivity assertion is made at complex parameters. ■

Proof. At $a = 1$ and a flat reference these are the background-gauge and site gaps of Prop. 5.20. Their upper forms have the same H^1 bound. Since the weights are constant,

$$|\langle v, (K_a - K_1)v\rangle| \le C|a-1|\|v\|_{H^1}^2$$

at a flat reference; the corresponding statement for Δ_a is immediate. The Q and $qD^\sharp$ terms have bounded relative forms, so their weighted changes satisfy the same estimate. The actual background has uniformly small X_α norm by eq. 5.ccxcv and eq. 5.cclxxxvii. Exact plaquette and transport comparisons give an additional relative $C\rho$ error, with the actual row densities retained. Taking $|a-1| + \rho$ sufficiently small preserves both gaps. The massive endpoint has the same gap; every real interpolation is their convex combination.

For complex parameters normalize by the fixed free $(L_h + 1)^{-1/2}$. The error from the real flat operator is small in operator norm, so a Neumann series proves the stated inverse bound. A small exponential physical cell conjugation changes each derivative form and each finite-carrier row form by $O(s)$. Its normalized inverse is again a Neumann series, uniformly in depth. This is the fixed-strip assertion. It uses relative-form estimates and the actual re-centered rows, not a complex orthogonal decomposition. □

5.15.2. *The regulator remainder is bounded with its weight jet.* Let $G = M^{-1}$ and $W = V - 1$. The exact integrated resolvent Taylor identity of eq. 5.clxxxix reads

$$\begin{aligned}\log\det(K_* + V) - \log\det(K_* + 1) + \operatorname{Tr} G + \tfrac{1}{2}\operatorname{Tr} G^2 = {}& \operatorname{Tr} GV + \operatorname{Tr} G^2 V - \tfrac{1}{2}\operatorname{Tr} GVGV \\ &+ \int_0^1 t^2 \operatorname{Tr}(GWGWS_t^{-1}W)\,dt.\end{aligned} \tag{5.cccii}$$

It holds first in finite dimensions, with coherent log branches; the polarized bulk traces below then give its volume limit. Use the *fixed isotropic* free comparison $G_0 = (L_h + 1)^{-1}$, with the identity in colour and vector indices, and put

$$B = G_0^{1/2} M G_0^{1/2}, \quad B_t = G_0^{1/2} S_t G_0^{1/2}, \quad C = G_0^{1/2} V G_0^{1/2}, \quad X = C - G_0. \tag{5.ccciii}$$

The integral trace is then $\operatorname{Tr}(B^{-1}XB^{-1}XB_t^{-1}X)$. In particular anisotropy has not been hidden in a parameter-dependent free reference whose differentiated trace might have a large rank.

For the vector case set $E = Q\mathsf{A}^{-1/2}G_0^{1/2}$ and $F = qD^\sharp \mathsf{A}^{1/2} G_0^{1/2}$. Then exactly

$$C = E^\sharp E - F^\sharp F. \tag{5.ccciv}$$

The scalar factorization is $C = (qG_0^{1/2})^\sharp (qG_0^{1/2})$. At a real Bloch momentum there are 12 vector rows and 3 site rows per physical coarse cell. The normalized vector C has rank at most 15, and the scalar one at most 3. The physical transposes and the constant congruence are part of these formulas.

All factors in eq. 5.ccciii and eq. 5.ccciv, and their first two background jets, are uniformly bounded on a fixed complex weight polydisc and momentum strip. Here are the estimates behind that assertion. The exact Wilson Hessian is a sum of finitely many derivative forms with bounded plaquette coefficients. Their two background derivatives are controlled by the X_α bounds and localized jets established above. Multiplication by $a_\mu a_\nu$ does not change their fine difference orders. The actual q, Q transports have uniformly bounded physical path length; their complete column densities and two differentiated moments are those of eq. 3.mccc. Also D' is zeroth order. Normalizing every derivative form on each side by $G_0^{1/2}$ therefore bounds all these jets without a fine-volume factor. Holomorphy on a larger weight polydisc gives the same statements after one a derivative. The diagonal inverse bounds come from Lem. 5.49.

To bound the polarized trace, use the four-grade algebra recording the two external momenta $p, -p$, as in the proof of eq. 5.cxciv. Its diagonal fine momenta are $\kappa, \kappa+p, \kappa-p, \kappa$. The normalized matrix inverses are finite triangular inverses with at most two strict jet steps. The jet of eq. 5.ccciv still factors through four copies of the coarse rows, hence has rank at most 60 in the vector case and 12 in the scalar case. Analytic transposes are taken before the jet construction; they do not reverse the four grades. Each term with a C factor thus has bounded trace norm by rank times the bounded operator norms.

The only remaining terms in the last line of eq. 5.cccii have three G_0 factors. For a fixed small complex shift z,

$$\int_{[-\pi,\pi]^4} \|G_0(\kappa+z)\|_{\mathcal{S}_3}^3 \frac{d\kappa}{(2\pi)^4} \le C \int_{\mathbb{R}^4} (1+c|q|^2)^{-3}\, dq < \infty. \tag{5.cccv}$$

This is the exact alias partition of the fine Brillouin cube. Schatten Hölder, followed by Hölder in κ for differently shifted factors, bounds their mixed traces. The bounded normalized anisotropic factors B^{-1}, B_t^{-1} do not affect this estimate. For real external p, cyclic trace identities are applied after integrating κ, where their shifts are legitimate torus reindexings. Holomorphic continuation then proves the identities and bounds for complex p. No complex contour reindexing is assumed. The bounds are uniform on a larger weight polydisc, so Cauchy's inequality legitimately bounds one weight derivative of the whole remainder.

The actual saddle factors must also be retained. For an onto constraint C_0 and T_* equal to the unconstrained site or background-gauge precision, block elimination gives

$$|\det \mathbb{S}(T_*, C_0)| = \det(T_* + C_0^\sharp C_0)\, \det\{C_0(T_* + C_0^\sharp C_0)^{-1} C_0^\sharp\} \tag{5.cccvi}$$

for real parameters. A constant congruence gives the vector version of eq. 5.ccc. The actual smooth row lifts and their H^1 energy bound give uniform upper and lower bounds on these coarse Schur matrices. They have 12 or 3 rows per cell, and the preceding weighted inverse estimates bound their mixed log derivatives on the same strip. Their branches are fixed by positivity on the real domain and then continued. Thus their plane coefficients and first weight jets are bounded as well. These are coarse finite ranks per fibre; no assertion of fixed rank for the full finite-volume trace is used.

5.15.3. *Current corrections and coefficient-preserving pullbacks.* The finite physical Gaussian gauge-change identity eq. 5.civ is algebraic for any invariant action. Apply it to $\mathscr{A}_h^a$ with the weighted divergence just used. Its actual multiplier correction is the Hessian term $-\langle \mu, q'' \rangle$ on the straightened fibre. It is not assumed to be third order in momentum as a matrix. As in that finite identity, coarse stabilizer factors are canceled before taking the flat limit or a holomorphic continuation. The remaining fine and coarse Schur expressions are the gapped ones estimated above. Thus no logarithm of an uncanceled singular coarse Faddeev–Popov factor is continued through the flat field.

For completeness its coefficient vanishes for every weight. Write the joint determinant ratio as $L_a(V,\nu)$, with $L_a(V,0) = 0$. Global colour covariance gives the full first ν derivative zero at $(1,0)$. The mixed V,ν Hessian $K_a(p)$ obeys its gauge Ward identity $d(p)^\sharp K_a(p) = 0$; analytic expansion at $p = 0$ gives $K_a(0) = 0$. The actual multiplier is the derivative of the classical coarse action. Its linear response $P_a(p)$ is $O(p^2)$: gauge covariance gives its zero constant term, and independent coordinate reflections in midpoint coordinates remove its odd linear term. Constant diagonal weights preserve these reflections. The quadratic jet of $L_a(V, \nu_a(V))$ is consequently $O(p^3)$, since its terms are a product of $K_a = O(p)$ and $P_a = O(p^2)$, or two P_a factors. This proves $b_{\mu\nu}[L_a \circ \nu_a] = 0$ for every plane. The exact identity on the weight polydisc also has zero first weight derivative. It is the functional argument of Prop. 5.8, with its hypotheses now verified for the weighted action.

The direct affine-response identity eq. 5.ccxcvi proves coefficient preservation for the weighted critical pullback. The successive version uses actual nesting, not identification with a direct bare

Wilson lift. A full-depth weighted critical field is critical on every smaller actual mean fibre. Its partial literal mean lies in the common small chart by the same mean-domain estimates. Local orbit uniqueness identifies it with the successive critical construction. Differentiating this identity on an affine probe gives the intermediate affine field, with its raw link-length factor, plus an actual gradient. The complete functional's vanished first jet removes the second derivative of the critical map; its two-leg Ward identity removes that gradient. This is precisely the literal/straightened distinction in eq. 5.clxxvi and is unchanged by a.

Define the vacuum-subtracted weighted massive physical logarithm

$$\mathcal{L}_h^a(s,U)=\log\det(\Delta_{a,U}+s)-\tfrac12\log\det(\widetilde{K}_{a,U}+s),\qquad(\mathcal{L}_h^a)^\sharp=\mathcal{L}_h^a(1)-\partial_s\mathcal{L}_h^a(1)+\tfrac12\partial_s^2\mathcal{L}_h^a(1). \tag{5.cccvii}$$

Let Ψ_j^a be the actual cumulative physical Gaussian logarithm of this weighted hierarchy in the canonical contour gauge. Gauge-change invariance makes it equal to the weighted background-gauge expression after the physical coarea factors are included. The preceding trace and Schur estimates give

$$b_{\mu\nu}[\Psi_j^a]=\widetilde{\beta}_a^{\mu\nu,\sharp}(h_j^2)+E_j^{\mu\nu}(a),\qquad\sup_{j,a}(|E_j^{\mu\nu}(a)|+|\partial_aE_j^{\mu\nu}(a)|)\le C. \tag{5.cccviii}$$

The error is holomorphic on a fixed smaller weight polydisc. The mass substitution is $z=h_j^2s$ even in the weighted case: both scalar and congruent vector physical operators are h_j^{-2} times the bare ones. The plaquette area h_j^2 squared cancels the site density h_j^{-4} in its plane coefficient. The left side of eq. 5.cccii combines to the averaging logarithm minus $\mathcal{L}_h^a(1)-\partial_s\mathcal{L}_h^a(1)+\frac12\partial_s^2\mathcal{L}_h^a(1)$; the signs here follow from $(\log\det)'=\operatorname{Tr}G$ and $(\log\det)''=-\operatorname{Tr}G^2$.

5.15.4. *The differentiated Gaussian polarization is continuous.* The actual one-step contour gauge remains $\sum_x(1-\frac12\operatorname{tr}T_x)$. Its cubic and quartic vertices, the actual plain mean vertices, Haar terms and coarea convention in eq. 5.ccxxxix are unchanged. Only the input Taylor triple $\mathfrak{J}_j^a=(T_{j,2}^a,T_{j,3}^a,T_{j,4}^a)$ has changed. The real gap eq. 5.ccxcvii and the fixed contour gap retain uniform full saddle inverses; replacing the lower constant one by $c>0$ only changes their constants. The rooted trace proof of Prop. 5.36 therefore applies on this weighted class and its smaller complex neighborhood.

Here is the extra derivative estimate needed, beyond continuity of the undifferentiated formula. Let Π_j^a be the actual Gaussian polarization. For a weight direction put a dot over its derivative. If $\mathbb{G}$ is its full field/multiplier saddle inverse and Z its actual response column, then

$$\dot{\mathbb{G}}=-\mathbb{G}\begin{pmatrix}\dot{T}_2&0\\0&0\end{pmatrix}\mathbb{G},\qquad\dot{Z}=\dot{\mathbb{G}}\,I_{\text{datum}}. \tag{5.cccix}$$

The augmented $\dot{V}_3,\dot{V}_4$ are exactly the differentiated action vertices. The constraint and literal trace-gauge vertices are fixed. Differentiate the two rooted contractions in eq. 5.ccxliii and eq. 5.ccxliv, using eq. 5.cccix, and differentiate the Haar matrix product. Each resulting expression has one dotted factor, bounded in the same smaller weighted Schur norm. Subtracting the formulas for two depths, one factor at a time, gives

$$\begin{aligned}\|\Pi_{j+1}^a-\Pi_j^a\|_{t,2}+\|\dot{\Pi}_{j+1}^a-\dot{\Pi}_j^a\|_{t,2}\le C(&\|\mathfrak{J}_{j+1}^a-\mathfrak{J}_j^a\|_s\\&+\|\dot{\mathfrak{J}}_{j+1}^a-\dot{\mathfrak{J}}_j^a\|_s).\end{aligned} \tag{5.cccx}$$

Uniform bounds for the undifferenced dotted triples follow from their holomorphic weight ball. Rooting the first external leg before summing the loop contractions removes any volume factor, exactly as in the original polarization proof. The complete field and multiplier first derivative of the log determinant still vanishes by colour, so no omitted $V_3[z'']$ term is introduced by the weight derivative.

Proposition 5.50 (The actual diagonal one-loop law)**.** Let $b^a_{j,\mu\nu}$ be the plane coefficient of the actual successive homogeneous Gaussian increment, in the same normalization as eq. 5.cc. For every $0 < \sigma < 1$, on a fixed sufficiently small real weight cube,

$$\begin{aligned} b^a_{j,\mu\nu} &= \frac{11}{3\pi^2} d(a) a_\mu a_\nu \log L + O_\sigma(L^{-\sigma j}), \\ \partial_{a_\lambda} b^a_{j,\mu\nu} &= \frac{11}{3\pi^2} \partial_{a_\lambda}\{d(a) a_\mu a_\nu\} \log L + O_\sigma(L^{-\sigma j}). \end{aligned} \tag{5.cccxi}$$

In particular, for $a(t) = 1 + te$ with $\sum_\lambda e_\lambda = 0$, the actual anisotropic increment obeys

$$\left.\frac{d}{dt}\right|_0 b^{1+te}_{j,\mu\nu} = \frac{11}{3\pi^2}(e_\mu + e_\nu) \log L + O_\sigma(|e| L^{-\sigma j}). \tag{5.cccxii}$$

The leading derivative in the isotropic weight direction is zero. ∎

Proof. Apply eq. 5.cccx to Prop. 5.48. The plane readout is a fixed second-momentum derivative, or equivalently a second absolute moment, and is continuous in the resulting exponential kernel norm. Hence $b^a_{j,\mu\nu}$ and each first weight jet have successive differences $O_\sigma(L^{-\sigma j})$. Their geometric tails converge at that rate to limits, uniformly on the smaller real weight cube.

Exact physical Gaussian composition and the weighted successive affine coefficient preservation proved above give

$$\sum_{\ell=1}^{j} b^a_{\ell,\mu\nu} = b_{\mu\nu}[\Psi^a_j].$$

It can be differentiated at finite j on the common weight domain. The weighted massive law eq. 5.clxix and eq. 5.cccviii show that these two cumulative quantities are respectively $2c\, d(a) a_\mu a_\nu j \log L + O(1)$ and its weight derivative with an $O(1)$ error. Dividing by j and taking Cesaro limits identifies the already proved successive limits and their jets. Since $2c = 11/(3\pi^2)$, this proves eq. 5.cccxi. Finally $\partial_t[d(1+te)(1+te_\mu)(1+te_\nu)]_{t=0} = e_\mu + e_\nu - \frac{1}{2}\sum e_\lambda$, which gives eq. 5.cccxii and the isotropic statement. □

The result concerns the actual homogeneous Gaussian increments and their constant diagonal anisotropy. It uses neither an unproved interacting cutoff symmetry nor a termwise invariant local activity decomposition. It supplies no independent fine-core or history-tower admission and no arbitrary proper-domain extension.

5.16. **A tuned trajectory for the homogeneous regular steps.** The step estimates have to be solved with conditions at opposite ends of the scale interval. The ultraviolet profile is zero, whereas the coupling is prescribed at the infrared end. We solve this problem without requiring the sum of the profile formation bounds to be small. That sum need not converge. The summable quantity is the coupling derivative of the formation map.

Throughout this subsection the integral operations are the homogeneous regular steps on the literal buffered domains. The frozen cutoffs, relative contour gauge, physical pointings and Gaussian normalization are the ones in Prop. 4.46. The large-field complementary operations are not included in the trajectory constructed here.

5.16.1. *The spaces and exact transport.* Fix the blocking integer and localization cubes after the rate choices in Prop. 4.36. Use the same field radius r and carrier rate at every scale, with the larger formation ball and its literal buffer retained. Let $\mathscr{B}_j$ be the space of complete pointed analytic families $h = (h_z)$ at scale j which have zero value, zero first jet and zero companion curvature coefficient. They are gauge invariant and covariant under translations and the hypercubic group. The norm is the infimum of the rooted analytic carrier norms over their compatible local representations. Include the fixed finite-period compatibility norm. All families have their infinite companions and their finite torus versions on the declared compatible volumes.

This infimum is used to identify representations of the same complete pointed functions. The space is completed in that norm. An absolutely summable sequence of representations gives a representation of its sum; hence this completion consists of normally convergent pointed analytic functions, with the same identities. In particular no invariance of each individual local representative is required. Write $H = \sum_z h_z$ for its total finite-volume function.

Let $T_{i,k}$ be the physical transport of eq. 4.ccclxxxiii, with no new Gaussian integration. For $i = k$, set $T_{i,i} = 1$. The common-radius construction gives fixed $C_T \geq 1$ and $0 < \lambda < 1$ such that

$$\|T_{i,k}\|_{\mathscr{B}_i \to \mathscr{B}_k} \leq C_T \lambda^{k-i}, \qquad i \leq k. \tag{5.cccxiii}$$

One may take $\lambda = L^{-\beta}$ with the fixed exponent in the transport theorem. The same bound holds for the compatibility component of the norm, with its fixed cube-unit period exponent.

The exact semigroup identity is

$$T_{j,k} T_{i,j} = T_{i,k}. \tag{5.cccxiv}$$

There are two points in this assertion. First, all-depth classical nesting identifies the two literal intermediate fields up to an old site gauge. The complete h_z is invariant, so its two compositions agree. Second, the pointing weights themselves have an exact refinement identity. For $\xi = L^{j-k}$ and a point t in the intermediate coordinate system,

$$\sum_z \theta_y(\xi z)\theta_z(t) = \theta_y(\xi t). \tag{5.cccxv}$$

In one dimension the right side is piecewise linear with all knots at integers, since ξ^{-1} is an integer. It equals its linear interpolant from those nodal values. Taking the product in four coordinates proves eq. 5.cccxv. The periodic sums give the same identity on compatible tori. The absolute local bounds justify interchanging these sums. Thus eq. 5.cccxiv is an identity of complete pointed functions, even if two chosen filings differ.

Fix a terminal scale N and choose $\lambda < q < 1$. Define an equivalent norm at scale j by

$$\|h\|_{j,*} = \sup_{0 \leq n \leq N-j} q^{-n} \|T_{j,j+n} h\|_{\mathscr{B}_{j+n}}. \tag{5.cccxvi}$$

Then

$$\|h\|_{\mathscr{B}_j} \leq \|h\|_{j,*} \leq C_T \|h\|_{\mathscr{B}_j}, \qquad \|T_{j,j+1} h\|_{j+1,*} \leq q \|h\|_{j,*}. \tag{5.cccxvii}$$

The last inequality follows directly by shifting n to $n+1$ in eq. 5.cccxvi and using eq. 5.cccxiv. Its constants do not depend on the horizon N. This removes the harmless prefactor C_T from a one-step induction.

5.16.2. *The exact step and its two formation derivatives.* Let $\mathcal{N}_j$ be the vacuum-subtracted physical Gaussian pointing for the step from j to $j+1$. Put

$$b_j = b[\mathcal{N}_j^{\infty}], \qquad n_j = \mathcal{N}_j - b_j e_{j+1},$$

where e_{j+1} is the actual classical pointing in eq. 4.ccclviii. The Gaussian comparison and the canonical input bounds give

$$\|n_j\|_{j+1,*} \leq B_n, \qquad |b_j - b_\infty| \leq B_b \lambda_b^j, \qquad b_\infty = \frac{11}{3\pi^2} \log L > 0, \quad 0 < \lambda_b < 1. \tag{5.cccxviii}$$

In particular the individual b_j are bounded. Positivity of every initial b_j is unnecessary.

The scalar power in the physical Gaussian mismatch is kept in the vacuum normalization. Consequently the nonconstant $\mathcal{N}_j$ and b_j do not acquire a coupling derivative from that power. The remaining dependence is in the formation map $\mathcal{F}_j(x, h)$. For a fixed frame value θ_j, its cutoff and fluctuation scaling are frozen. Write

$$\epsilon(t) = t^{-1} (\log t)^m, \qquad m = 2p > 1,$$

after increasing the coupling floor. The Gaussian cutoff tail is absorbed in this bound; $p > 1/2$ makes $\exp[-c(\log t)^{2p}]$ smaller than every fixed negative power of t.

For every fixed profile bound H_*, the buffered formation theorem gives, on slightly larger profile and coupling domains,

$$\begin{aligned} \|\mathcal{F}_j(x,h)\| &\le C_{H_*}\epsilon(\theta_j),\\ \|D_h\mathcal{F}_j(x,h)\| &\le C_{H_*}\epsilon(\theta_j),\\ \|\partial_x\mathcal{F}_j(x,h)\| &\le C_{H_*}\epsilon(\theta_j)/\theta_j. \end{aligned} \tag{5.cccxix}$$

Here $|x/\theta_j - 1|$ is smaller than a fixed constant and $\|h\|_{j,*} < H_* + 1$. All norms on the right concern the complete compatible family. The constants include the fixed equivalence in eq. 5.cccxvii. They are uniform in j, N and volume.

Let $\mathcal{P}_{j+1}$ subtract the companion curvature coefficient times e_{j+1}, and put

$$r_j(x,h) = b[\mathcal{F}_j(x,h)^\infty], \qquad f_j(x,h) = \mathcal{P}_{j+1}\mathcal{F}_j(x,h).$$

The coefficient readout and this projection are bounded on the fixed-radius spaces, by the complete two-leg Ward moment. Thus eq. 5.cccxix also holds for r_j, f_j, with changed constants.

Up to its positive scalar vacuum factor, the actual regular step is

$$e^{-xS_j+H} \;\longmapsto\; e^{-xS_{j+1}+H\circ p_j^{\mathrm{lit}}+\mathcal{N}_j+\mathcal{F}_j(x,h)}. \tag{5.cccxx}$$

Extracting the two curvature coefficients gives the exact recursion

$$\begin{aligned} x_{j+1} &= x_j - b_j - r_j(x_j,h_j),\\ h_{j+1} &= T_{j,j+1}h_j + n_j + f_j(x_j,h_j). \end{aligned} \tag{5.cccxxi}$$

The coupling is independent of the torus because its readout uses the infinite companion. The finite-period corrections remain in h_{j+1}. No finite quantum determinant has been replaced by the determinant on a periodic cover.

5.16.3. *Forward stability for a prescribed coupling sequence.* Choose

$$H_* \ge 1 + \frac{2B_n}{1-q}. \tag{5.cccxxii}$$

Fix a sufficiently large real number X, and define the nominal frame

$$a_j = X + \sum_{\ell=j}^{N-1} b_\ell, \qquad a_N = X. \tag{5.cccxxiii}$$

The summable errors in eq. 5.cccxviii imply

$$|a_j - \{X + b_\infty(N-j)\}| \le B_a, \qquad c(X+N-j) \le a_j \le C(X+N-j) \tag{5.cccxxiv}$$

once $X \ge 2B_a + 2$. Freeze $\theta_j = a_j$ throughout the construction. For a fixed small $\delta > 0$ consider coupling sequences in

$$\mathcal{D}_N = \{x : \ |x_j - a_j| \le \delta a_j, \quad 0 \le j \le N\}.$$

Use its slightly enlarged open polydisc for holomorphic estimates. The finite forward recursion in eq. 5.cccxxi, with $h_0 = 0$, defines $h_j(x)$. For X large enough,

$$\|h_j(x)\|_{j,*} \le H_* \quad (0 \le j \le N). \tag{5.cccxxv}$$

Indeed the next norm is at most $qH_* + B_n + C_{H_*}\epsilon(a_j)$. By eq. 5.cccxxii, the first two terms leave at least $(1-q)H_*/2$ of room, and the last term fits there when the coupling floor is fixed. This is an induction in the complete compatible family, so the gauge, symmetry and periodic identities are retained.

The dependence on the coupling sequence has a stronger bound than the profile size itself. Put

$$k_j = \epsilon(a_j)/a_j, \qquad D = \|x - \widetilde{x}\|_\infty.$$

For the two forward solutions, eq. 5.cccxix gives

$$d_{j+1} \le \{q + C_{H_*}\epsilon(a_j)\}d_j + C_{H_*}k_jD, \qquad d_j = \|h_j(x) - h_j(\widetilde{x})\|_{j,*}.$$

Choose X so the bracket is at most some $q_1 < 1$. For earlier $i < j$, the envelope in eq. 5.cccxxiv and monotonic decrease of $(\log t)^m/t^2$ for large t give $k_i \le Ck_j$. The bounded error B_a in that envelope changes only the fixed constant. Hence

$$d_j \le CD\sum_{i<j} q_1^{j-1-i}k_i \le Ck_jD. \tag{5.cccxxvi}$$

No sum of $\epsilon(a_j)$ over all scales appears in this stability estimate.

5.16.4. *The backward coupling contraction.* The terminal condition is $x_N = X$. Summing the first recursion in eq. 5.cccxxi backward suggests the map

$$(\Phi x)_j = a_j + \sum_{\ell=j}^{N-1} r_\ell(x_\ell, h_\ell(x)), \qquad (\Phi x)_N = X. \tag{5.cccxxvii}$$

We prove it is an invariant contraction on $\mathcal{D}_N$.

The following two elementary estimates are uniform in N, j:

$$\begin{aligned} \sum_{\ell=j}^{N-1} \epsilon(a_\ell) &\le C\{1 + (\log a_j)^{m+1}\}, \\ \sum_{\ell=0}^{N-1} k_\ell &\le C\frac{(\log X)^m}{X}. \end{aligned} \tag{5.cccxxviii}$$

To prove them, use eq. 5.cccxxiv to compare with the integer sequence $X + cn$, allowing fixed constant changes in its argument. The first integral is bounded by $\int_X^{Ca_j}(\log t)^m\,dt/t$. For the second, integration by parts bounds $\int_{cX}^{\infty}(\log t)^m\,dt/t^2$ by $C(\log X)^m/X$. For a noninteger $m > 1$, the same integration by parts uses $m(\log t)^{m-1}/t^2$; choosing X large absorbs it in half of the original integral. The finite first terms are covered by the same bounds.

The first line and eq. 5.cccxix give

$$|(\Phi x)_j - a_j| \le C_{H_*}\{1 + (\log a_j)^{m+1}\}.$$

Since $(1 + \log^{m+1} t)/t$ tends to zero, this is at most $\delta a_j/2$ for all $a_j \ge cX$, once X is fixed large enough. Thus the backward map is strictly inside its relative box.

For two sequences, the coupling and profile slopes give

$$\begin{aligned} |r_\ell(x_\ell, h_\ell(x)) - r_\ell(\widetilde{x}_\ell, h_\ell(\widetilde{x}))| &\le Ck_\ell D + C\epsilon(a_\ell)d_\ell \\ &\le Ck_\ell D. \end{aligned}$$

The second line of eq. 5.cccxxviii therefore proves

$$\|\Phi x - \Phi\widetilde{x}\|_\infty \le K(X)\|x - \widetilde{x}\|_\infty, \qquad K(X) \le C\frac{(\log X)^m}{X} < \frac{1}{2}. \tag{5.cccxxix}$$

For each finite N, the relative box is a complete closed subset of the finite supremum-norm space. Its diameter may grow with N; neither its contraction constant nor the floor does.

Proposition 5.51. For every sufficiently large infrared inverse coupling X and every finite horizon N, the actual homogeneous regular recursion eq. 5.cccxxi has a unique trajectory in the displayed weak-coupling box with

$$h_0 = 0, \qquad x_N = X.$$

It is real for real data, has $\|h_j\|_{j,*} \le H_*$, and satisfies

$$\begin{aligned} c(X+N-j) \le x_j \le C(X+N-j), \\ x_0 = X + b_\infty N + O\{1+(\log(X+N))^{m+1}\}. \end{aligned} \tag{5.cccxxx}$$

All constants and the coupling floor are independent of N and compatible volume. The finite-volume profiles are the actual profiles of the stated integral operations, with their compatible companions. ■

Proof. The invariant contraction has one fixed point. Its forward profiles satisfy eq. 5.cccxxv. Conversely every trajectory with the two stated end conditions has those forward profiles and satisfies eq. 5.cccxxvii. This proves uniqueness in the specified box. The real maps preserve real sequences, so iteration from the real nominal frame gives real trajectories. The relative box and eq. 5.cccxxiv give the first line of eq. 5.cccxxx. The sum of $b_j - b_\infty$ is bounded by eq. 5.cccxviii; the first line of eq. 5.cccxxviii bounds the sum of the interaction corrections. This gives its second line. Finally the exact identity eq. 5.cccxx at each step identifies the recursively formed density and its positive real normalizer. This identification uses the actual formation map, not only the abstract inequalities of a hypothetical flow. □

5.16.5. *Analytic tuning in a frozen presentation.* Keep the frame and all its cutoffs fixed at a real reference endpoint X_0. Replace the terminal condition by $x_N = X_0 + \zeta$, where $|\zeta| < cX_0$ for a fixed small $c > 0$. The backward map becomes

$$(\Phi^\zeta x)_j = a_j(X_0) + \zeta + \sum_{\ell=j}^{N-1} r_\ell(x_\ell, h_\ell(x)).$$

For small enough c, the same relative box and slightly larger coupling discs are invariant. Its contraction constant is unchanged. Iteration converges normally in ζ, and the forward profile maps are holomorphic. Thus the tuned trajectory is holomorphic on that disc.

Let a prime denote its endpoint derivative. The proof of eq. 5.cccxxvi gives

$$\|h_j'\|_{j,*} \le Ck_j \sup_\ell |x_\ell'|.$$

Differentiate the backward equation and use the same summable slopes. Then

$$\sup_j |x_j'| \le 1 + K(X_0) \sup_j |x_j'|, \qquad \sup_j |x_j' - 1| \le \frac{K(X_0)}{1 - K(X_0)}.$$

After increasing the floor,

$$\frac{3}{4} \le x_j' \le \frac{5}{4} \quad \text{on a smaller real interval,} \qquad \|h_j'\|_{j,*} \le Ck_j. \tag{5.cccxxxi}$$

The bare tuning is consequently strictly increasing in that real interval. These derivatives concern one frozen presentation. They do not differentiate its sharp cutoff or recompute it from the moving endpoint.

The complex bound for $x_j' - 1$ on a fixed smaller disc also yields, for every integer $s \ge 2$,

$$|x_j^{(s)}| \le C_s \frac{(\log X_0)^m}{X_0^s}, \tag{5.cccxxxii}$$

uniformly in the horizon. Apply Cauchy's estimate to $x_j' - 1$, with disc radius a fixed multiple of X_0. Its supremum is $O((\log X_0)^m / X_0)$, and each additional derivative costs one factor X_0^{-1}. This proves eq. 5.cccxxxii.

The construction controls the regular operations on the stated common domains. It is a coupling and profile trajectory, not a bound for the mass or source moments of all complementary histories. Those quantities require the positive history estimates used in the full construction.

5.17. **Universality for bounded ultraviolet profiles at a fixed horizon.** We keep one finite horizon, one family of regular maps and one frozen cutoff presentation. The ultraviolet irrelevant profile may now be any member of a bounded ball. Retuning the bare coupling to the same infrared value makes the final profiles exponentially close. This is a comparison within that same finite problem; it does not compare different horizons or construct an infinite-horizon flow.

5.17.1. *The fixed presentation and a bounded initial ball.* Use the complete compatible quotient spaces and physical regular maps of Prop. 5.51. Fix

$$\lambda < q < q_1 < q_2 < 1. \tag{5.cccxxxiii}$$

The adapted norm eq. 5.cccxvi makes the exact transport have norm at most q. Its equivalence constant C_T is independent of the horizon. The ultraviolet space $\mathscr{B}_0$ consists of the same gauge-invariant, hypercubic-covariant, normalized complete pointings, with zero first jet and zero companion curvature coefficient. All finite-period versions and their companions are included. An input with a nonzero marginal coefficient is not part of the irrelevant ball considered here.

Fix $R_{\mathrm{uv}} < \infty$. We shall allow $\|h_0\|_{\mathscr{B}_0} < R_{\mathrm{uv}} + 2$ and prove the estimates on the smaller ball $\|h_0\| \le R_{\mathrm{uv}}$. Take the common profile ceiling H_* large enough that

$$H_* \ge 2C_T(R_{\mathrm{uv}} + 2) + 1 + \frac{2B_n}{1-q}. \tag{5.cccxxxiv}$$

The enlarged formation domains are chosen with this ceiling. All constants below may depend on this fixed ball and on the fixed rates, but not on depth, horizon or compatible volume.

Choose a real reference endpoint X_0 above the coupling floor, and fix the entire presentation at

$$a_j = X_0 + \sum_{\ell=j}^{N-1} b_\ell, \qquad \theta_j = a_j, \quad a_N = X_0. \tag{5.cccxxxv}$$

These are scalar inverse-coupling frames, not diagonal weight parameters. In particular every cutoff, fluctuation scaling, gauge normalization and map stays fixed when h_0 or the endpoint is varied. Set

$$e_j = \frac{(\log a_j)^m}{a_j}, \qquad k_j = e_j/a_j, \qquad e_* = \frac{(\log X_0)^m}{X_0}. \tag{5.cccxxxvi}$$

Increase the floor when necessary. The HRT envelopes give $a_j \asymp X_0 + N - j$ and

$$\sum_{j<N} k_j \le C\frac{(\log X_0)^m}{X_0}, \qquad \sum_{j<N} e_j k_j \le Ce_*^2, \qquad \sup_j e_j k_j \le Ce_*^2/X_0. \tag{5.cccxxxvii}$$

For the second estimate compare with $\int_{cX_0}^{\infty} (\log t)^{2m} t^{-3}\, dt$. One integration by parts and a larger floor bound this integral by $C(\log X_0)^{2m}/X_0^2$. The last estimate is the corresponding supremum bound. We will also use

$$k_i \le Ck_j \ (i<j), \qquad e_\ell \le Ce_j\{1 + (\ell - j)/X_0\} \ (j \le \ell \le N). \tag{5.cccxxxviii}$$

Indeed the bounded Gaussian increments give $a_j \le a_\ell + C(\ell - j)$, while $a_\ell \ge cX_0$. For large arguments the logarithmic ratio is bounded when $a_\ell \le a_j + O(1)$; the bounded error in the nominal envelope covers the exceptional initial signs. Thus $e_\ell/e_j \le Ca_j/a_\ell$, which proves the second inequality. The same envelope proves the first one by monotonic decrease of $(\log t)^m/t^2$.

On the enlarged fixed domains the exact regular recursion is

$$x_{j+1} = x_j - b_j - r_j(x_j, h_j), \qquad h_{j+1} = T_j h_j + n_j + f_j(x_j, h_j). \tag{5.cccxxxix}$$

The input ceiling above and Prop. 4.46 give, uniformly there,

$$|r_j| + \|f_j\| \le Ce_j, \quad |\partial_x r_j| + \|\partial_x f_j\| \le Ck_j, \quad \|D_h r_j\| + \|D_h f_j\| \le Ce_j. \tag{5.cccxl}$$

Norms are the appropriate adapted norms. Fixed equivalence constants have been included in C. The scalar coefficients use the infinite companion, so the coupling sequence is independent of the torus. Finite-period differences remain in the profiles.

Proposition 5.52 (Analytic tuning with a nonzero initial profile)**.** For every fixed R_{uv} there is a sufficiently large floor X_0, independent of N, such that eq. 5.cccxxxix has a unique trajectory in the HRT relative coupling box with

$$h_0 = H, \qquad x_N = X_0 + \zeta, \quad \|H\| < R_{\mathrm{uv}} + 2, \quad |\zeta| < cX_0. \tag{5.cccxli}$$

It is jointly holomorphic in H, ζ, real for real data, and has $\|h_j\|_{j,*} \le H_*$. At a real endpoint in this presentation its coupling envelope and bare law are those of HRT, with constants uniform on the input ball. ■

Proof. For a prescribed coupling sequence in the fixed relative box, solve the profile equation forward starting from H. Its first norm is at most $C_T(R_{\mathrm{uv}} + 2)$. The induction

$$\|h_{j+1}\|_{j+1,*} \le qH_* + B_n + Ce_j \le H_*$$

is valid by eq. 5.cccxxxiv and a larger floor. The map is holomorphic on the enlarged coupling and input domains. For two sequences with the same initial H, its difference obeys

$$d_{j+1} \le q_1 d_j + Ck_j \|x - \widetilde{x}\|_\infty, \qquad d_0 = 0,$$

after making $Ce_j \le q_1 - q$. Therefore $d_j \le Ck_j \|x - \widetilde{x}\|_\infty$, exactly as in eq. 5.cccxxvi.

The backward map is

$$(\Phi^{H,\zeta} x)_j = a_j + \zeta + \sum_{\ell=j}^{N-1} r_\ell(x_\ell, h_\ell(x, H)), \qquad (\Phi^{H,\zeta} x)_N = X_0 + \zeta.$$

The same sum of k_j as in HRT makes its supremum-norm contraction constant less than $1/2$, uniformly in H. Its correction from a_j is at most $|\zeta| + C\{1 + (\log a_j)^{m+1}\}$. Choose c small and then the floor large so this is strictly inside the relative box at every j. The fixed-point iteration is invariant and locally normally convergent in H, ζ. It constructs the claimed holomorphic tuning map. No implicit inverse without a uniform bound is being assumed. Every other trajectory with these end data has the same forward profile and hence is the same fixed point. Reality follows by iteration. The bounded initial profile changes only the common formation constants in the proof of eq. 5.cccxxx. □

5.17.2. *The exact mixed-end linear inverse.* Linearize along any trajectory in the smaller complex domains. Write $u_j = \delta x_j$ and $v_j = \delta h_j$, and allow additive step sources $\sigma_j \in \mathbb{C}$, $\tau_j \in \mathscr{B}_{j+1}$. The exact linear system is

$$\begin{aligned} u_{j+1} &= A_j u_j - R_j v_j + \sigma_j, \\ v_{j+1} &= D_j v_j + F_j u_j + \tau_j, \qquad u_N = \xi, \quad v_0 = \eta, \end{aligned} \tag{5.cccxlii}$$

where

$$A_j = 1 - \partial_x r_j, \quad R_j = D_h r_j, \quad D_j = T_j + D_h f_j, \quad F_j = \partial_x f_j.$$

Thus $|A_j - 1|, \|F_j\| \le Ck_j$, $\|R_j\| \le Ce_j$, and $\|D_j\| \le q_1$. All products below use the actual operators; the symbols D_j here are scale-profile maps, not lattice derivatives.

For $j \le \ell$ put

$$P_{j\ell} = \prod_{t=j}^{\ell} A_t^{-1}, \qquad U_{ji} = D_{j-1} \cdots D_{i+1} \quad (i < j), \qquad U_{i+1,i} = 1. \tag{5.cccxliii}$$

The empty backward product is one. By eq. 5.cccxxxvii, the A_j do not vanish and $|P_{j\ell}| \le C$. Also $\|U_{ji}\| \le q_1^{j-1-i}$. Solving one equation backward and the other forward gives exactly

$$\begin{aligned} u_j &= u_j^0 + (\mathcal{B}v)_j, \qquad u_j^0 = P_{j,N-1}\xi - \sum_{\ell=j}^{N-1} P_{j\ell}\sigma_\ell, \\ v_j &= v_j^0 + (\mathcal{K}u)_j, \qquad v_j^0 = D_{j-1}\cdots D_0\eta + \sum_{i<j} U_{ji}\tau_i, \\ (\mathcal{B}v)_j &= \sum_{\ell\ge j} P_{j\ell}R_\ell v_\ell, \quad (\mathcal{K}u)_j = \sum_{i<j} U_{ji}F_i u_i. \end{aligned} \tag{5.cccxliv}$$

In the sums with $\ell \ge j$ the upper limit is $N-1$; at $j = N$ those sums vanish. The first homogeneous forward product at $j = 0$ is one.

For later use define positive scalar kernels

$$B^+_{j\ell} = Ce_\ell \mathbf{1}_{j\le\ell<N}, \qquad K^+_{ji} = Ck_i q_1^{j-1-i}\mathbf{1}_{i<j}. \tag{5.cccxlv}$$

They majorize the two exact operator kernels. In unweighted coupling supremum norm their product satisfies

$$\|B^+K^+\|_{\infty\to\infty} \le C\sup_j \sum_{\ell\ge j} e_\ell \sum_{i<\ell} q_1^{\ell-1-i}k_i \le C\sum_\ell e_\ell k_\ell \le Ce_*^2 =: \vartheta < \tfrac12. \tag{5.cccxlvi}$$

The middle step uses $k_i \le Ck_\ell$. This is the mixed-end loop. It contains both formation derivatives. A sum of e_j alone, which could grow with the horizon, has not been used as a smallness parameter.

Consequently the exact positive Green envelopes are

$$\begin{aligned} |u| &\le \sum_{n\ge0}(B^+K^+)^n(|u^0| + B^+|v^0|), \\ |v| &\le |v^0| + K^+\sum_{n\ge0}(B^+K^+)^n(|u^0| + B^+|v^0|). \end{aligned} \tag{5.cccxlvii}$$

The notation $|v_j|$ means its adapted norm. Every term is nonnegative and each intermediate scale is explicitly summed. The series converges absolutely in the coupling supremum norm; the profile output then follows from the forward kernel. This also proves uniqueness of eq. 5.cccxlii without a sign or self-adjointness assumption on its complex coefficients.

These formulas give useful estimates for arbitrary finite step sources. In fact

$$\begin{aligned} \|u\|_\infty &\le C\Big\{|\xi| + \sum_{i<N}|\sigma_i| + e_0\|\eta\| + \sum_{i<N} e_{i+1}\|\tau_i\|\Big\}, \\ \|v_j\| &\le q_1^j\|\eta\| + Ck_j\|u\|_\infty + \sum_{i<j} q_1^{j-1-i}\|\tau_i\|. \end{aligned} \tag{5.cccxlviii}$$

For the first line, a profile impulse at step i contributes at most $C\sum_{\ell\ge i+1} e_\ell q_1^{\ell-1-i} \le Ce_{i+1}$ to $B^+|v^0|$. The initial profile contributes Ce_0, by eq. 5.cccxxxviii. The scalar direct sources have exactly their backward sums in eq. 5.cccxliv. Apply $(1-\vartheta)^{-1}$ to finish. The second line is the forward equation and $k_i \le Ck_j$.

For example a scalar impulse at i has direct envelope $C\mathbf{1}_{j\le i}$; a profile impulse at i has direct envelope $q_1^{j-1-i}\mathbf{1}_{j\ge i+1}$. Their complete responses are those vectors propagated by eq. 5.cccxlvii. This explicitly retains the backward leakage caused by retuning the terminal coupling. No symmetric exponential bound for an arbitrary scale impulse is claimed.

5.17.3. *Exponential dependence on the initial irrelevant profile.* For the initial-profile response set $\xi = 0$, $\sigma = \tau = 0$ in eq. 5.cccxlii. Introduce

$$\|u\|_E = \max_j \frac{|u_j|}{e_j q_2^j}, \qquad \|v\|_Q = \max_j q_2^{-j}\|v_j\|. \tag{5.cccxlix}$$

The terminal $u_N = 0$ causes no difficulty in this norm. The backward kernel has the bound

$$\|\mathcal{B}v\|_E \le C\|v\|_Q \sup_j \sum_{n\ge 0} q_2^n \frac{e_{j+n}}{e_j} \le C_B\|v\|_Q, \tag{5.cccl}$$

where sums stop at the finite horizon. The last inequality follows from $e_{j+n}/e_j \le C(1+n/X_0)$, not from a false monotonicity in j. For the forward kernel,

$$\|\mathcal{K}u\|_Q \le C\|u\|_E \sup_j \sum_{i<j} q_2^{-1}(q_1/q_2)^{j-1-i} k_i e_i \le C_K e_*^2 \|u\|_E. \tag{5.cccli}$$

Here eq. 5.cccxxxvii even gives an additional factor X_0^{-1}, which is not needed. The loop norm $C_B C_K e_*^2$ is less than $1/2$ after the same fixed floor increase. Since $\|v^0\|_Q \le \|\eta\|$, solving the two inequalities proves

$$|u_j| \le C e_j q_2^j \|\eta\|, \qquad \|v_j\|_{j,*} \le C q_2^j \|\eta\|. \tag{5.ccclii}$$

The proof applies uniformly to complex trajectories on the smaller product domains. It is an inverse estimate with opposite end conditions, rather than an estimate obtained by evolving the scalar coupling forward.

Proposition 5.53 (Finite-horizon exponential universality)**.** Let $H, \widetilde{H}$ lie in the smaller bounded initial-profile ball, and use the same endpoint, horizon and frozen presentation. Then

$$\begin{aligned} |x_j(H) - x_j(\widetilde{H})| &\le C e_j q_2^j \|H - \widetilde{H}\|_{\mathscr{B}_0}, \\ \|h_j(H) - h_j(\widetilde{H})\|_{j,*} &\le C q_2^j \|H - \widetilde{H}\|_{\mathscr{B}_0}. \end{aligned} \tag{5.ccliii}$$

In particular the analytic bare tuning map has $\|D_H x_0\| \le C e_0$, and $\|D_H h_N\| \le C q_2^N$. These constants are independent of the horizon and compatible volume. ■

Proof. The jointly holomorphic trajectory can be differentiated in an arbitrary Banach direction η of the initial profile. Its derivative solves exactly eq. 5.cccxlii with the initial-response data just used. The initial adapted norm costs at most $C_T\|\eta\|_{\mathscr{B}_0}$. Apply eq. 5.ccclii and integrate this derivative along the straight segment between H and $\widetilde{H}$. That segment stays in the retained Banach ball. This proves the nonlinear difference bounds, not only stability of a formal linear recurrence. □

5.17.4. *All initial-profile jets in one frozen endpoint disc.* The derivative estimates above hold on a fixed larger H ball and a fixed larger disc $|\zeta| < cX_0$. Banach-valued Cauchy and polarization on strict inner margins therefore give, for integers $r \ge 1$, $s \ge 0$,

$$\begin{aligned} \|D_\zeta^s D_H^r x_j\| &\le C_{r,s} e_j q_2^j X_0^{-s}, \\ \|D_\zeta^s D_H^r h_j\|_{j,*} &\le C_{r,s} q_2^j X_0^{-s}. \end{aligned} \tag{5.ccliv}$$

The constants include the fixed input-ball margin and the usual finite-order factorials. One way to obtain them is to apply Cauchy to the already bounded first H derivative, taking $r-1$ further profile derivatives and s endpoint derivatives. Thus every profile jet retains the exponential factor. There is no count of its microscopic input coordinates.

For completeness, pure endpoint derivatives have the HRT bounds uniformly on this initial ball. The direct scalar product differs from one by at most $C\sum k_j$; the profile feedback contributes at

most Ce_*^2 by eq. 5.cccxlvi. For endpoint variation $\xi = 1$, $\eta = \sigma = \tau = 0$, eq. 5.cccxlviii consequently gives

$$\sup_j |\partial_\zeta x_j - 1| \le C\frac{(\log X_0)^m}{X_0}, \qquad \|\partial_\zeta h_j\|_{j,*} \le Ck_j. \tag{5.ccclv}$$

On a smaller real interval the first scalar derivative lies between 3/4 and 5/4. For $s \ge 2$, Cauchy applied to $\partial_\zeta x_j - 1$ yields

$$|\partial_\zeta^s x_j| \le C_s(\log X_0)^m X_0^{-s}, \qquad \|\partial_\zeta^s h_j\|_{j,*} \le C_s k_j X_0^{1-s}. \tag{5.ccclvi}$$

These are derivatives of the single presentation eq. 5.cccxxxv. They do not differentiate a sharp cutoff or replace its reference frame by one recomputed from the moving endpoint.

5.17.5. *The actual finite-volume interaction and law.* For real profiles and the same real endpoint $X = x_N$, let $\mathcal{V}$ be a fixed final coarse volume. The complete finite-volume interaction is $\mathcal{H}_N^H(V) = \sum_z h_{N,z}^H(V)$. There are $O(\mathcal{V})$ unit anchors. The local analytic norm controls the supremum of each complete pointing on the working field ball. Thus

$$\sup_V |\mathcal{H}_N^H(V) - \mathcal{H}_N^{\widetilde{H}}(V)| \le C\mathcal{V}q_2^N\|H - \widetilde{H}\|_{\mathscr{B}_0}. \tag{5.ccclvii}$$

The exact regular-step identity of LCF and the tuning construction identify these with the actual finite-volume effective interactions of the stated regular integral operations. Scalar vacuum factors may differ and do not affect a normalized final law.

To state such a comparison precisely, fix a common real final integration domain $\mathcal{D}$ inside the working ball and a fixed positive finite measure ν there, with nonzero total mass. Neither depends on the ultraviolet profile. Product Haar measure restricted to a fixed smaller real bond ball is one choice. Define

$$d\mathbb{P}_H(V) = Z_H^{-1}e^{-XS_N(V)+\mathcal{H}_N^H(V)}\mathbf{1}_{\mathcal{D}}(V)\,d\nu(V). \tag{5.ccclviii}$$

The real continuous densities have finite positive normalizers. If $\delta = C\mathcal{V}q_2^N\|H - \widetilde{H}\|$, then their likelihood ratio is between $e^{-2\delta}$ and $e^{2\delta}$: the unnormalized ratio is between $e^{-\delta}$ and e^{δ}, as is the ratio of the normalizers. Therefore, with the convention $\|\mathbb{P} - \mathbb{Q}\|_{\mathrm{TV}} = \frac{1}{2}\int |d\mathbb{P} - d\mathbb{Q}|$,

$$\|\mathbb{P}_H - \mathbb{P}_{\widetilde{H}}\|_{\mathrm{TV}} \le \min\left\{1, \quad \exp(C\mathcal{V}q_2^N\|H - \widetilde{H}\|_{\mathscr{B}_0}) - 1\right\}. \tag{5.ccclix}$$

The fixed multiplicative constant absorbs the factor two. This is a finite-volume bound on one common final domain. It is not uniform over growing volumes, and it proves neither clustering nor consistency between horizons. No complementary-history measure has been introduced in this comparison.

5.18. **Decay of the diagonal stress response in the regular trajectory.** The diagonal one-loop coefficient is useful only after the irrelevant part of the response has been included. We derive that coupled response from the weighted regular step and prove its decay. The memory term is estimated with the running coupling weight. An unweighted smallness bound on that term would not give the result.

Use the actual regular trajectory $(x_j, h_j)_{0\le j\le N}$ of Prop. 5.51, with terminal coupling $x_N = X$. Its frame, real cutoff and all integral conventions remain fixed during the response. Write b_j for its Gaussian scalar increment and m_j for the tracefree diagonal Gaussian increment in eq. 4.cdxxvii. The index in both symbols is the transfer from j to $j+1$. The actual comparison proves

$$|b_j - b_\infty| + |m_j - b_\infty| \le C\lambda_0^j, \qquad b_\infty = \frac{11}{3\pi^2}\log L > 0, \quad 0 < \lambda_0 < 1. \tag{5.ccclx}$$

5.18.1. *The stress representative and its exact transport.* Let $\mathcal{E} = \{e \in \mathbb{R}^4 : \sum_\mu e_\mu = 0\}$, with its Euclidean norm. For $e \in \mathcal{E}$ define the complete pointing

$$E_{j,e,z}(V) = \sum_{p \| \mu\nu} (e_\mu + e_\nu)\theta_z(m_p)a_p(U_j(V)). \tag{5.ccclxi}$$

The sum uses the original fine plaquettes in scale-j units. The actual critical orbit here is isotropic. These pointings are linear in e, gauge invariant, and covariant under simultaneous axis permutations and permutation of the entries of e. They have uniform local norm and plane readouts

$$b_{\mu\nu}[E_{j,e}] = e_\mu + e_\nu.$$

These assertions follow from the fine density and exact hat quadrature, with the actual affine response.

Their total is the derivative of the weighted classical action:

$$\sum_z E_{j,e,z}(V) = D_a S_j^a(V)[e]\Big|_{a=1}. \tag{5.ccclxii}$$

Indeed differentiation of the critical orbit at fixed literal mean is tangent to its constraint fibre. Pairing that derivative with the physical action gradient gives zero. Only differentiation of the plaquette weights remains. This is a total-action identity. It does not identify the derivative of every separately chosen weighted action pointing.

The particular choice eq. 5.ccclxi has exact isotropic transport:

$$T_{j,j+1}E_{j,e} = E_{j+1,e}. \tag{5.ccclxiii}$$

All-depth nesting identifies the original fine plaquette traces in the two expressions. The scale change and eq. 5.cccxv identify their pointing weights. Both equalities are applied to the complete functions before any local filing. This avoids an unnecessary irrelevant term of size equal to the stress coefficient itself.

5.18.2. *The zero-readout response space.* Use the reflection-invariant profile space of the weighted formation theorem, with all six plane readouts zero. Let $\mathscr{V}_j$ consist of bounded linear maps $v : \mathcal{E} \to \mathfrak{H}_j^{\mathrm{ref}}$ which are covariant under the axis permutation action. Its norm is the operator norm in the same compatible quotient norm as HRT. The identity

$$\mathcal{E} \ni e \longmapsto (e_\mu + e_\nu)_{\mu<\nu}$$

is the stress embedding.

The transport bound used in HRT also holds on the reflection space with six zero readouts. To see this, repeat the actual slow-field estimate in Lem. 4.34. Reflections kill every cross-plane curvature pairing. The six zero readouts therefore make its entire quadratic curvature form zero. The remaining proof uses only that cancellation, complete gauge invariance, analytic carrier bounds and the companion property. Its block interpolation and anchor sum are unchanged. Thus the same-radius estimate and exact complete-function semigroup hold, with fixed changed constants. Use the horizon-adapted norm on this space as in eq. 5.cccxvi. We may therefore fix

$$\|T_j\|_{j,*\to j+1,*} \le q < 1, \qquad T_j = T_{j,j+1}. \tag{5.ccclxiv}$$

The constants do not depend on N.

For clarity, the stress readout of a permutation-covariant linear response is one scalar. The stabilizer of the plane $\{\mu,\nu\}$ makes the coefficient of e_μ, e_ν equal, and makes the two complementary coefficients equal. The condition $\sum e_\mu = 0$ consequently reduces its readout to $c(e_\mu + e_\nu)$. Axis permutations make c the same for all planes. Reflections exclude cross-plane terms. A scalar isotropic readout of this response is zero. This elementary argument also shows that the scalar coupling has no first-order variation in this channel.

5.18.3. *The response equations from the actual step.* At scale j, perturb the exponent by

$$-t_j \sum_z E_{j,e,z} + \sum_z v_j(e)_z.$$

Here t_j is scalar and $v_j \in \mathscr{V}_j$. The leading-action perturbation is obtained by differentiating the constant weight

$$a = 1 + (t_j/x_j)e.$$

Equation eq. 5.ccclxii makes this exactly the stated first-order perturbation of the actual exponent. The output leading action is represented by $E_{j+1,e}$ using the same identity. All subsequent zero-readout terms are assigned to v_{j+1}. Thus no equality of individual weighted action pointings is being imposed.

Let $\mathcal{P}^{\mathrm{ref}}$ subtract the six plane readouts times the corresponding original fine-action plane pointings. It is a bounded linear map on the fixed-radius spaces. Differentiate the exact weighted regular step at $a = 1$ and the actual pair (x_j, h_j). Its moving centre is compared with the fixed isotropic kernel by Prop. 4.54. The actual fixed-kernel jet is the moving jet minus the rooted sphere family $\mathcal{B}_{j,e}$. By Cor. 4.55 this correction has six zero readouts. The pointings below are the selected fixed-total pointings of that comparison; no independent per-anchor filing is identified from equality of totals. Equations eq. 4.cdxxiv and eq. 4.cdxxvii give the exact linear system

$$\begin{aligned} t_{j+1} &= \left(1 - \frac{m_j}{x_j} + d_j\right) t_j + L_j v_j, \\ v_{j+1} &= T_j v_j + \mathcal{E}_j v_j + \frac{t_j}{x_j} A_j. \end{aligned} \tag{5.ccclxv}$$

The operators on the right are derivatives of the specified formation map, not independent assumptions about a scalar recursion. Their definitions are as follows. If the stress readout of $D_a \mathbf{F}_j^a[e]|_1$ is $\mu_j(e_\mu + e_\nu)$, then $d_j = -\mu_j/x_j$. The map L_j is minus the stress readout of $D_h \mathbf{F}_j[v]$. The map $\mathcal{E}_j$ is $\mathcal{P}^{\mathrm{ref}} D_h \mathbf{F}_j$. Finally

$$\begin{aligned} A_j[e] = \; & D_a T_j^a h_j[e]\Big|_1 + q_{j,e} \\ & + \mathcal{P}^{\mathrm{ref}} \, D_a \mathbf{F}_j^a[e]\Big|_1 - \mathcal{B}_{j,e}. \end{aligned} \tag{5.ccclxvi}$$

The first term has six zero readouts by eq. 4.cdxxv. The middle term is the actual Gaussian remainder in eq. 4.cdxxvii. This identifies the full forcing and its normalization. The final term is the actual sharp-cutoff boundary correction. Its compatible norm is superpolynomially small in the frozen coupling reference, so it preserves the stated forcing bound. The signs in the first line come from extracting the positive Gaussian logarithm from a negative action exponent.

Write

$$\epsilon_j = \frac{(\log x_j)^m}{x_j}, \qquad k_j = \epsilon_j / x_j.$$

The fixed-frame envelopes in HRT make these quantities comparable to their versions with a_j. The actual derivative bounds give

$$|d_j| \le C k_j, \qquad \|L_j\| + \|\mathcal{E}_j\| \le C\epsilon_j, \qquad \|A_j\| \le C_{H_*}. \tag{5.ccclxvii}$$

In particular the old profile's weight derivative is only bounded; it has no extra power of the fluctuation coupling. Its factor t_j/x_j in eq. 5.ccclxv is retained. No spatially varying weight is used in these identities.

5.18.4. *Eliminating the irrelevant response.* Start with the pure bare stress perturbation $v_0 = 0$. Choose the infrared floor so $q + C \sup_j \epsilon_j \le q_1 < 1$. The second equation and its actual operator bounds give the causal estimate

$$\|v_j\|_{j,*} \le C \sum_{i<j} q_1^{j-1-i} \frac{|t_i|}{x_i}. \tag{5.ccclxviii}$$

This follows by successively substituting that equation and bounding each product of its profile operators by q_1 per step. The constant is independent of horizon. Substitution into the first equation exhibits the memory bound

$$C\epsilon_j \sum_{i<j} q_1^{j-1-i} \frac{|t_i|}{x_i}.$$

The denominator here belongs to the old index i. It cannot be replaced by a claim of smallness for the unweighted memory sum.

5.18.5. *The coupling weight and the diagonal product.* Set

$$w_j = x_j/x_0, \qquad Y_j = t_j/w_j.$$

The actual scalar recursion is $x_{j+1} = x_j - b_j - r_j$, with $|r_j| \le C\epsilon_j$. Consequently

$$\frac{1 - m_j/x_j + d_j}{w_{j+1}/w_j} = 1 + \frac{b_j - m_j + r_j + x_j d_j}{x_{j+1}}. \tag{5.ccclxix}$$

This exact identity uses no monotonicity of the trajectory. For a large enough floor, the bounded Gaussian increments and small formation correction make x_{j+1} comparable to x_j. By HRT and eq. 5.ccclx,

$$\sum_{j<N} \frac{|b_j - m_j| + \epsilon_j}{x_{j+1}} \le \frac{C}{X} + C\frac{(\log X)^m}{X}. \tag{5.ccclxx}$$

The geometric numerator in the first part has bounded sum, and all $x_j \ge cX$. For the second part use the second scale sum in eq. 5.cccxxviii. Thus, for $i < k$, the actual diagonal product obeys

$$\prod_{i\le j<k} \left|1 - \frac{m_j}{x_j} + d_j\right| \le C\,\frac{x_k}{x_i}. \tag{5.ccclxxi}$$

Take absolute values in eq. 5.ccclxix, use $1 + u \le e^u$ for nonnegative u, and multiply. The factors w telescope. Early increments of either sign are harmless; they were only required to be bounded.

5.18.6. *The weighted memory estimate.* The identity

$$\frac{w_i}{x_i} = \frac{1}{x_0}$$

is the decisive cancellation. Divide the first response equation by w_{j+1}, insert eq. 5.ccclxviii, and use that identity. It gives

$$|Y_{j+1}| \le (1 + \eta_j)|Y_j| + C\frac{\epsilon_j}{x_{j+1}} \sum_{i<j} q_1^{j-1-i}|Y_i|, \qquad \eta_j = C\frac{|b_j - m_j| + \epsilon_j}{x_{j+1}}. \tag{5.ccclxxii}$$

The sum of the coefficients $\eta_j + \epsilon_j/x_{j+1}$ is bounded by eq. 5.ccclxx and becomes small with the infrared floor.

For completeness put $M_j = \max_{i\le j} |Y_i|$. The geometric age sum in eq. 5.ccclxxii is at most $M_j/(1 - q_1)$. Hence

$$M_{j+1} \le M_j \left\{1 + \eta_j + \frac{C\epsilon_j}{(1 - q_1)x_{j+1}}\right\}.$$

Multiplication and eq. 5.ccclxx give $M_j \le C|t_0|$ uniformly in j, N. Returning to eq. 5.ccclxviii then gives

$$\|v_j\|_{j,*} \le C\frac{|t_0|}{x_0}\sum_{i<j} q_1^{j-1-i} \le C\frac{|t_0|}{x_0}.$$

Both bounds use the coupling weight throughout the memory sum.

Proposition 5.54. The first tracefree diagonal response of the actual regular trajectory, with bare coefficient t_0 and no bare irrelevant response, satisfies

$$|t_j| \le C\frac{x_j}{x_0}|t_0|, \qquad \|v_j\|_{j,*} \le C\frac{|t_0|}{x_0}. \tag{5.ccclxxiii}$$

The constants and infrared floor are independent of horizon and compatible volume. For $|t_0| \le C_0\sqrt{x_0}$ and fixed sufficiently large $X = x_N$, its final nonconstant insertion tends to zero with bound

$$|t_N| + \|v_N\|_{N,*} \le C_X x_0^{-1/2}. \tag{5.ccclxxiv}$$

Since $x_0 = X + b_\infty N + O(\log^{m+1}(X+N))$, this is $O_X(N^{-1/2})$. ■

Proof. The preceding causal response construction and weighted estimates prove eq. 5.ccclxxiii. At $j = N$, $x_N = X$. Insert the stated bound on t_0 and the actual bare coupling law from HRT. The classical stress pointing has uniformly bounded norm, so these coefficient and profile bounds also control the resulting nonconstant insertion on the final working field ball. □

This proves the diagonal stress decay for the stated regular integral operations. It uses the actual weighted Gaussian law and the actual formation derivatives. It is a first-response statement; it does not claim a finite anisotropic trajectory or a variable-weight domain. The complementary-history insertions in a full rotation argument require their own source and mass estimates.

5.19. **A scalar insertion and nonvanishing in the regular sector.** Endpoint tuning gives an exact insertion identity when the entire regular presentation is held fixed. We use that identity to prove a positive variance bound which is uniform in the ultraviolet depth on a fixed terminal torus. The measure is the positive product of the specified regular kernels, capped in one common coarse field domain. It is not identified with the full Wilson measure.

The proof has two ingredients. The flat flux contraction makes every effective classical action nonconstant on the same two coarse patches. The endpoint derivative of the terminal profile is small, so the transferred scalar insertion retains this separation. Positivity then gives both patches a depth-independent probability.

5.19.1. *One frozen presentation and its exact density.* Fix a terminal torus in the compatible volume class of § 4.9 and Prop. 4.46. Its integer period $\ell \ge 2$ is divisible by the chosen localization sizes and exceeds ten cubes at each of those sizes. These sizes and the volume floor are fixed before the endpoint coupling is varied. Fix a real endpoint X above the coupling floor. For each ultraviolet depth N, take the HRT presentation at this reference endpoint. Keep every frame θ_j, fluctuation scale, relative contour factor, free colour-ball cutoff, branch and domain fixed. Different depths have different finite lattices, but the estimates are uniform in N. No derivative below compares different presentations.

Vary only the terminal coupling to $X + t$, with $|t| < cX$ in its analytic tuning disc. Write

$$\alpha_N(t) = x_0^{(N)}(X+t), \qquad H_N(t,V) = \sum_z h_{N,z}^{(N)}(X+t,V), \qquad S_N(V) = A(U_N(V)). \tag{5.ccclxxv}$$

The ultraviolet profile is zero. The classical action S_N is independent of t. All intermediate coupling and profile dependences are formed densities; they are not extra parameters of the frozen kernels.

The exact positive composition of these kernels has, relative to normalized terminal product Haar measure, the density

$$\mathcal{K}_N(t,V) = e^{C_N(t)} \exp\{-(X+t)S_N(V) + H_N(t,V)\}. \tag{5.ccclxxvi}$$

The scalar C_N includes every numerical, Gaussian-vacuum and profile-vacuum factor in the exact regular steps. It is real at real t, with its analytic logarithm fixed there. It need not be bounded uniformly in N.

Let $\mathbb{Q}_N$ be the positive chain measure formed from those frozen kernels and their Haar/coarea measures, before the ultraviolet factor $e^{-\alpha_N(t)S_0}$ is inserted. It is independent of t. Equivalently, use the successive deterministic mean constraints and their positive regular weights. This description keeps precisely the retained regular component and its contour factors. On every finite lattice the measure is finite and all moments of the initial Wilson action S_0 are finite.

Choose below one common real raw-coarse domain Ω in the terminal field ball, independent of N, t. Define the capped regular probability

$$d\mathbb{P}^{\mathrm{reg}}_{N,t} = \frac{\mathbf{1}_{\{V\in\Omega\}} e^{-\alpha_N(t)S_0}}{\mathcal{Z}^{\mathrm{reg}}_N(t)}\, d\mathbb{Q}_N. \tag{5.ccclxxvii}$$

Its terminal marginal is

$$d\nu_{N,t}(V) = \frac{\mathbf{1}_\Omega(V)}{Z_N(t)} e^{-(X+t)S_N(V)+H_N(t,V)}\, dV, \qquad \mathcal{Z}^{\mathrm{reg}}_N(t) = e^{C_N(t)} Z_N(t). \tag{5.ccclxxviii}$$

For real t near zero these are positive. Conditional expectations at a specified V mean the canonical coarea fibre ratios. This version is defined throughout the admitted coarse chart, including $V = 1$.

The HRT bounds, on fixed smaller tuning discs, give

$$\frac{3}{4} \le \alpha_N'(0) \le \frac{5}{4}, \qquad \|h_N(0)\| \le H_*, \qquad \|\partial_t h_N(0)\| \le C\frac{\epsilon(X)}{X}, \quad \epsilon(X) = X^{-1}(\log X)^m, \quad m > 1. \tag{5.ccclxxix}$$

For every fixed $s \ge 2$, Cauchy on the same frozen discs also gives

$$|\alpha_N^{(s)}(0)| \le C_s \frac{(\log X)^m}{X^s}, \qquad \|\partial_t^s h_N(0)\| \le C_s \frac{\epsilon(X)}{X^s}. \tag{5.ccclxxx}$$

The profile assertion follows by applying Cauchy to its first derivative on a fixed smaller disc. These are exactly endpoint derivatives in eqs. 5.cccxxxi and 5.cccxxxii; none differentiates a sharp cutoff.

5.19.2. *The scalar conditional identity and centering.* Put

$$T_N = \alpha_N'(0) S_0, \qquad O_N(V) = S_N(V) - \partial_t H_N(0,V). \tag{5.ccclxxxi}$$

Proposition 5.55 (Exact scalar action insertion)**.** For the capped regular measure,

$$\mathbb{E}^{\mathrm{reg}}_{N,0}[T_N \mid V] = O_N(V) - C_N'(0). \tag{5.ccclxxxii}$$

Consequently its centered form is

$$\mathbb{E}^{\mathrm{reg}}_{N,0}[T_N - \mathbb{E}^{\mathrm{reg}}_{N,0} T_N \mid V] = O_N(V) - \nu_{N,0}(O_N). \tag{5.ccclxxxiii}$$

This is a constant scalar action insertion. It makes no assertion about a spatially varying local source. ∎

Proof. At fixed V, differentiate the actual fibre composition defining $\mathcal{K}_N$. Its only endpoint-dependent ultraviolet factor is $e^{-\alpha_N(t)S_0}$, since $h_0 = 0$ and $\mathbb{Q}_N$ is frozen. Finite-dimensional dominated differentiation gives

$$\partial_t \log \mathcal{K}_N(0,V) = -\alpha_N'(0)\mathbb{E}[S_0 \mid V].$$

Differentiating eq. 5.ccclxxvi gives $C_N'(0) - S_N + \partial_t H_N(0)$. These identities prove eq. 5.ccclxxxii. The cap does not change a fibre conditional at an admitted $V \in \Omega$. Integrate that equality against

the terminal marginal and subtract it. This cancels the complete numerical vacuum derivative $C_N'(0)$, proving eq. 5.ccclxxxiii. The argument did not remove a vacuum term from the uncentered identity. □

Corollary 5.56 (Conditional variance and scalar information)**.** The exact decomposition is

$$\mathrm{Var}_{\mathbb{P}^{\mathrm{reg}}_{N,0}}(T_N) = \nu_{N,0}\{\mathrm{Var}(T_N \mid V)\} + \mathrm{Var}_{\nu_{N,0}}(O_N). \tag{5.ccclxxxiv}$$

The normalized endpoint scores are respectively $-T_N + \mathbb{E}T_N$ and $-O_N + \nu_{N,0}O_N$. Thus the two variances are the corresponding scalar Fisher informations, and coarse conditioning cannot increase them. ■□

Proof. Differentiate the normalized densities in eq. 5.ccclxxvii and eq. 5.ccclxxviii. The centered conditional identity identifies their scores. Apply the elementary conditional-variance formula. All variables have finite moments on each finite regular graph. □

5.19.3. *The same two action patches at every depth.* Let $n_b = 4\ell^4$ be the number of stored positive terminal bonds. In the normalization $\frac{1}{2}\operatorname{tr} T^2 = 1$, fix a real Abelian colour direction T, and the coarse field

$$B_2(x) = T\cos(2\pi x_1/\ell), \qquad B_\mu(x) = 0 \quad (\mu \neq 2). \tag{5.ccclxxxv}$$

Its supremum is one and its curl is nonzero. The period-two case in the next formula is a kinematic check; the regular-measure conclusions use only the compatible torus fixed above. Write

$$q_\ell = \|\mathrm{d}_c B\|_2^2 = \begin{cases} 4\ell^4, & \ell = 2, \\ 2\ell^4 \sin^2(\pi/\ell), & \ell \geq 3. \end{cases} \tag{5.ccclxxxvi}$$

The difference acts on stored oriented positive bonds, so the two parallel links on a period-two circle remain distinct lattice variables.

Lemma 5.57 (A uniform positive quadratic direction)**.** There are $R_0 > 0$ and $M_\ell < \infty$, independent of N, such that

$$S_N(1) = DS_N(1) = 0, \qquad D^2S_N(1)[B,B] \geq q_\ell, \qquad \sup_{\|A\|_\infty < R_0} |S_N(e^{iA})| \leq M_\ell. \tag{5.ccclxxxvii}$$

For real admitted fields $S_N \geq 0$. ■

Proof. At the identity the actual fine response to coarse datum B satisfies the literal linear mean constraint. The difference between the plain and straightened rows is a coarse gradient, so their curls agree. The exact flat identity and contraction eq. 5.ccl, eq. 5.ccli give

$$\|\mathrm{d}_c B\|_{2,c} \leq \|\mathrm{d}_h A^{\mathrm{lin}}\|_{2,h}.$$

The fine Wilson Hessian in this direction is exactly $\|\mathrm{d}_h A^{\mathrm{lin}}\|_{2,h}^2$ in the displayed colour normalization. Its first jet is zero, so the second derivative of the background map adds no acceleration term. This proves the middle assertion in eq. 5.ccclxxxvii. No positivity of a mass-added coarse Schur matrix is being used for this conclusion.

The actual local action trees of Prop. 4.17 give a normally convergent analytic action on a fixed complex coarse ball. Each original fine density has its physical h^4 weight; the fine plaquette count therefore cancels in a unit coarse cell. Summing its rooted pointings on the terminal torus bounds the total by $C_A\ell^4$ on a smaller fixed radius R_0. Take this as M_ℓ, enlarging it to include $N = 0$ if necessary. The field is real at real data, and its actual Wilson plaquette terms are nonnegative. Their sum proves the last assertion. □

Choose once

$$0 < r_\Omega \leq \min\{r/4, R_0/4, \pi/4\}, \qquad \Omega = \{V = e^{iA} : \max_b |A_b| < r_\Omega\}. \tag{5.ccclxxxviii}$$

The radius is fixed before N, X vary. Let

$$\begin{aligned} 0 < a &\le \min\{r_\Omega/4, R_0/2, q_\ell R_0^3/(8M_\ell)\},\\ d_\ell &= q_\ell a^2/4, \qquad L_\ell = 2M_\ell/R_0,\\ 0 < \delta_\ell &\le \min\{r_\Omega/4, a/8, d_\ell/(8L_\ell)\}. \end{aligned} \tag{5.ccclxxxix}$$

These constants are positive and do not depend on ultraviolet depth or endpoint coupling. Define product patches in raw coordinates by

$$P_0 = \{e^{iA} : \max_b |A_b| < \delta_\ell\}, \qquad P_1 = \{e^{iA} : \max_b |A_b - aB_b| < \delta_\ell\}. \tag{5.cccxc}$$

Both lie in Ω, and they are disjoint.

Lemma 5.58 (Uniform separation on fixed patches)**.** For every N,

$$\inf_{P_1} S_N - \sup_{P_0} S_N \ge \tfrac{3}{4} d_\ell. \tag{5.cccxci}$$

■

Proof. The scalar function $z \mapsto S_N(e^{izB})$ is bounded by M_ℓ on $|z| < R_0$. Its divided coefficients have bounds $M_\ell R_0^{-m}$. For $a \le R_0/2$, the terms of degree at least three have absolute sum at most $2M_\ell a^3/R_0^3 \le q_\ell a^2/4$. Its quadratic term is at least $q_\ell a^2/2$. Hence $S_N(e^{iaB}) \ge d_\ell$, uniformly in depth.

On the real r_Ω-ball, Cauchy in any unit coarse Banach direction gives $\|DS_N\| \le L_\ell$: a complex disc of radius $R_0/2$ stays inside the action ball. The line between a patch point and its centre is in that real ball. The variation of S_N on either patch is therefore at most $L_\ell \delta_\ell \le d_\ell/8$. Subtracting the two errors proves eq. 5.cccxci. □

For normalized Haar measure on SU(2), the log-coordinate density is

$$j(A) = (2\pi^2)^{-1}(\sin|A|/|A|)^2.$$

On $|A| \le \pi/2$ it is at least $2/\pi^4$. Thus the same two patches have the explicit product-Haar lower bound

$$\mathrm{Haar}(P_i) \ge m_\ell := \left(\frac{8}{3\pi^3}\delta_\ell^3\right)^{n_b} > 0. \tag{5.cccxcii}$$

Their dimension is $3n_b = 12\ell^4$, not an ultraviolet dimension. The common cap has Haar mass

$$m_\Omega = \left\{\frac{r_\Omega - \frac{1}{2}\sin(2r_\Omega)}{\pi}\right\}^{n_b} > 0.$$

5.19.4. *Uniform positive probabilities and variance.* The terminal pointing bounds imply

$$|H_N(0,V)| \le \ell^4 H_* =: H_\ell, \qquad |\partial_t H_N(0,V)| \le C\ell^4 \frac{\epsilon(X)}{X} \quad (V \in \Omega). \tag{5.cccxciii}$$

Choose X_ℓ above the HRT floor so that, for all $X \ge X_\ell$, the second quantity is at most $d_\ell/8$. This is possible because $\epsilon(X)/X \to 0$. Then the transferred observable has separation

$$\inf_{P_1} O_N - \sup_{P_0} O_N \ge d_\ell/2. \tag{5.cccxciv}$$

All choices of patches precede this coupling threshold.

Since $0 \le S_N \le M_\ell$ on the cap, its terminal normalizer obeys

$$m_\Omega e^{-XM_\ell - H_\ell} \le Z_N(0) \le m_\Omega e^{H_\ell}. \tag{5.cccxcv}$$

In particular each patch probability is at least

$$\nu_{N,0}(P_i) \ge p_{X,\ell} := m_\ell e^{-XM_\ell - 2H_\ell} > 0. \tag{5.cccxcvi}$$

These estimates do not use or bound the possibly extensive vacuum factor e^{C_N}.

Proposition 5.59 (Finite-volume regular nonvanishing)**.** For the fixed compatible terminal torus above and $X \geq X_\ell$, uniformly over all ultraviolet depths,

$$\mathrm{Var}_{\nu_{N,0}}(O_N) \geq c_{X,\ell} := p_{X,\ell}^2 d_\ell^2/4 > 0, \qquad \mathrm{Var}_{\mathbb{P}_{N,0}^{\mathrm{reg}}}(T_N) \geq c_{X,\ell}. \tag{5.cccxcvii}$$

Consequently $\mathrm{Var}_{\mathbb{P}_{N,0}^{\mathrm{reg}}}(S_0) \geq (16/25)c_{X,\ell}$. ■

Proof. For independent terminal samples V, V', $\mathrm{Var}(O_N) = \frac{1}{2}\mathbb{E}[(O_N(V) - O_N(V'))^2]$. Restrict to $P_0 \times P_1$ and $P_1 \times P_0$. The two probabilities and eq. 5.cccxciv give the first lower bound. The second follows from eq. 5.ccclxxxiv. Finally $T_N = \alpha_N'(0)S_0$ and $\alpha_N'(0) \leq 5/4$. This proves the last bound. The explicit constant may be small as X or ℓ changes; only uniformity in ultraviolet depth is asserted. □

5.19.5. *Generating functions and endpoint contact terms.* The fixed presentation also gives exact higher scalar identities. For sufficiently small t, the conditional coarea kernels satisfy

$$\begin{aligned}\log \mathbb{E}_{N,0}^{\mathrm{reg}}[e^{-(\alpha_N(t)-\alpha_N(0))S_0} \mid V] = C_N(t) - C_N(0) - tS_N(V) \\ + H_N(t,V) - H_N(0,V).\end{aligned} \tag{5.cccxcviii}$$

Every logarithm is its germ at $t = 0$. The global identity is

$$\mathbb{E}_{N,0}^{\mathrm{reg}} e^{-(\alpha_N(t)-\alpha_N(0))S_0} = e^{C_N(t)-C_N(0)} \frac{Z_N(t)}{Z_N(0)}. \tag{5.cccxcix}$$

Both follow by changing only the ultraviolet exponential in the same finite integral. In particular no moving-frame or cutoff derivative is hidden in these formulas.

For a genuine bare scalar source s, let $t = \psi_N(s)$ solve $\alpha_N(t) = \alpha_N(0) + s$. On a common smaller complex disc this inverse exists: the HRT complex derivative is uniformly close to one. Substitution in eq. 5.cccxcviii is the conditional cumulant-generating function of $-S_0$ for that source.

Let $\kappa_r(S_0 \mid V)$ denote its ordinary conditional cumulants. With $B_{q,r}$ the exponential partial Bell polynomials, differentiation gives

$$\sum_{r=1}^{q} (-1)^r \kappa_r(S_0 \mid V) B_{q,r}(\alpha_N'(0), \ldots, \alpha_N^{(q-r+1)}(0)) = C_N^{(q)}(0) - \mathbf{1}_{\{q=1\}} S_N(V) + \partial_t^q H_N(0,V). \tag{5.cd}$$

The convention is determined by $\partial_t^q [m(t)^r/r!]_{t=0} = B_{q,r}(m'(0), \ldots)$. For example the second and third identities are

$$\begin{aligned}(\alpha_N')^2 \,\mathrm{Var}(S_0 \mid V) - \alpha_N'' \mathbb{E}[S_0 \mid V] &= C_N'' + \partial_t^2 H_N, \\ -(\alpha_N')^3 \kappa_3(S_0 \mid V) + 3\alpha_N'\alpha_N'' \,\mathrm{Var}(S_0 \mid V) - \alpha_N''' \mathbb{E}[S_0 \mid V] &= C_N''' + \partial_t^3 H_N.\end{aligned} \tag{5.cdi}$$

All quantities here are evaluated at $t = 0$. The contact terms involving higher bare tuning derivatives cannot be dropped.

There is a useful vacuum-free version. The profiles and action vanish at the flat field for every endpoint. Subtract eq. 5.cccxcviii at $V = 1$ to obtain

$$\log \frac{\mathbb{E}[e^{-sS_0} \mid V]}{\mathbb{E}[e^{-sS_0} \mid 1]} = -\psi_N(s) S_N(V) + H_N(\psi_N(s), V) - H_N(0,V). \tag{5.cdii}$$

The reference fibre is the canonical coarea version, not an arbitrary value assigned to a conditional expectation on a null event. This exact ratio removes C_N at every order. For instance

$$\mathrm{Var}(T_N \mid V) - \mathrm{Var}(T_N \mid 1) = \partial_t^2 H_N(0,V) + \frac{\alpha_N''(0)}{\alpha_N'(0)} O_N(V). \tag{5.cdiii}$$

The endpoint bounds therefore control this field-dependent difference by $C_\ell(\log X)^m/X^2$, uniformly in depth. They do not bound its vacuum value. More generally Cauchy for the inverse source and eq. 5.ccclxxx give, for each fixed $r \geq 2$,

$$\sup_{V\in\Omega} |\kappa_r(S_0 \mid V) - \kappa_r(S_0 \mid 1)| \leq C_{\ell,r}\frac{(\log X)^m}{X^r}. \tag{5.cdiv}$$

Indeed $\psi_N'(0) = 1/\alpha_N'(0)$, while $|\psi_N^{(r)}(0)| \leq C_r(\log X)^m/X^r$ for $r \geq 2$. The latter follows by inverting the near-identity analytic tuning on a disc of radius cX and applying Cauchy to its derivative minus its value at zero. Composing the profile first-derivative bound gives the smaller profile contribution. Thus the estimate concerns coarse-field variation of the conditional cumulant, rather than a uniform ultraviolet cumulant bound.

Finally, direct differentiation of the total normalizer gives the consistency identities

$$\begin{aligned}
\partial_t \log \mathcal{Z}_N^{\mathrm{reg}}(0) &= -\mathbb{E}T_N,\\
\partial_t^2 \log \mathcal{Z}_N^{\mathrm{reg}}(0) &= \mathrm{Var}(T_N) - \alpha_N''(0)\mathbb{E}S_0,\\
\partial_t^2 \log Z_N(0) &= \mathrm{Var}_{\nu_{N,0}}(O_N) + \nu_{N,0}(\partial_t^2 H_N).
\end{aligned}$$

They retain the same endpoint contacts as eq. 5.cd and agree with the conditional-variance decomposition.

5.19.6. *A nondegenerate fixed-coarse subsequence.* The common terminal domain also permits an ultraviolet subsequence without changing the coarse cutoff or volume. Only finite-dimensional coarse functions and probabilities are extracted.

Reduce the common endpoint disc once, and write its radius as $T = c_1X$. The complex HRT slope bound gives

$$\sup_{|t|<T} |\alpha_N'(t) - 1| \leq K(X) < \tfrac{1}{4}, \qquad \sup_{|t|<T} \|\partial_t h_N(t)\| \leq C\epsilon(X)/X. \tag{5.cdv}$$

After decreasing c_1 or increasing the coupling floor, integration along the endpoint segment gives $\|h_N(t)\| \leq H_* + 1$. Put $\delta\alpha_N(t) = \alpha_N(t) - \alpha_N(0)$. Then $|\delta\alpha_N(t)| \leq (5/4)|t|$. The bare value $\alpha_N(0)$ itself is not bounded in this argument.

Use the finite colour coordinates $A = (A_{b,c}) \in \mathbb{C}^{3n_b}$, and the polydisc

$$\mathcal{D} = \{(t, A) : |t| < T,\ |A_{b,c}| < 2r_\Omega \text{ for all } b, c\}. \tag{5.cdvi}$$

Its field coordinates obey $\max_b |A_b| < 2\sqrt{3}r_\Omega < \min(r, R_0)$. The closure of the real cap Ω is strictly inside this field domain. Thus $S_N(e^{iA})$, $H_N(t, e^{iA})$, $\partial_t H_N(t, e^{iA})$, and $\delta\alpha_N(t)$ have uniform holomorphic bounds on $\mathcal{D}$, after using a slightly smaller endpoint disc for the displayed derivative. Their bounds depend on the fixed ℓ, X, not on N.

Lemma 5.60 (Finite-dimensional compact extraction)**.** There is a common subsequence $N_k \to \infty$ and holomorphic limits $S_\infty, H_\infty, \delta\alpha_\infty$, locally uniform on $\mathcal{D}$, with

$$S_{N_k} \longrightarrow S_\infty, \quad H_{N_k} \longrightarrow H_\infty, \quad \partial_t H_{N_k} \longrightarrow \partial_t H_\infty, \quad \delta\alpha_{N_k} \longrightarrow \delta\alpha_\infty. \tag{5.cdvii}$$

They are real on real arguments, $\delta\alpha_\infty(0) = 0$, and $3/4 \leq \delta\alpha_\infty'(0) \leq 5/4$. ∎

Proof. This is a normal-family argument on the $1 + 3n_b$ complex coordinates just displayed. On every smaller closed polydisc, the uniform supremum bounds and coordinate Cauchy formulas bound all first coordinate derivatives. The scalar functions are therefore uniformly bounded and equicontinuous on that compact finite-dimensional set. Apply Arzelà–Ascoli to the finite tuple of functions, then use a countable nested exhaustion of $\mathcal{D}$ and a diagonal subsequence. The uniform limits are holomorphic by the finite-dimensional Cauchy integral formula. That formula also identifies the limit of $\partial_t H_N$ with $\partial_t H_\infty$.

Reality passes under uniform convergence. The tuning vanishes at zero, and its first derivative converges by the one-variable Cauchy formula. The real slope interval eq. 5.ccclxxix passes to the limit. No normal-family theorem on an infinite-dimensional field space is being invoked. □

Proposition 5.61 (A nondegenerate coarse ultraviolet subsequence)**.** On this subsequence, the terminal regular probabilities converge in total variation to

$$d\nu_\infty(V) = \frac{\mathbf{1}_\Omega(V)}{Z_\infty} e^{-XS_\infty(V)+H_\infty(0,V)}\, dV. \tag{5.cdviii}$$

The observable $O_\infty = S_\infty - \partial_t H_\infty(0)$ is real analytic near the cap and satisfies

$$\inf_{P_1} O_\infty - \sup_{P_0} O_\infty \geq d_\ell/2, \qquad \mathrm{Var}_{\nu_\infty}(O_\infty) \geq c_{X,\ell} > 0. \tag{5.cdix}$$

In fact $O_{N_k} \to O_\infty$ uniformly on $\overline{\Omega}$, and the variances converge to the displayed positive variance. ■

Proof. The field closure of the cap lies in a compact subpolydisc. Hence both the density exponents and O_{N_k} converge uniformly there. The positive normalizer bounds eq. 5.cccxcv pass to Z_∞, so its value is nonzero. The unnormalized real densities converge uniformly; division by the convergent positive normalizers proves total-variation convergence. The cap is the same for every depth, with fixed product Haar measure. Its boundary has Haar measure zero.

The patch inequalities pass under uniform convergence, and both limiting patch masses are at least $p_{X,\ell}$. The same two-sample variance proof yields eq. 5.cdix. Alternatively bounded uniform convergence of O_{N_k}, together with total variation, gives convergence of its first two moments and hence of its variance. Analyticity and reality are those of the extracted functions. □

There is also a common complex endpoint disc on which normalized coarse source functionals converge. Set

$$D_\ell = C\ell^4\epsilon(X)/X, \qquad t_\ell = \min\{T/2, \log(3/2)/(M_\ell + D_\ell)\}.$$

For $|t| < t_\ell$, the density relative to its positive value at zero differs from one by at most $1/2$, since

$$|-tS_N(V) + H_N(t,V) - H_N(0,V)| \leq |t|(M_\ell + D_\ell).$$

Integrating against $\nu_{N,0}$ gives

$$|Z_N(t)/Z_N(0) - 1| < 1/2. \tag{5.cdx}$$

Thus these capped normalizers are zero free on this smaller, possibly ℓ-dependent disc. Uniform convergence on compact subsets gives locally uniform convergence of normalized coarse expectations of bounded fixed probes, and of their endpoint derivatives. The same holds for bounded holomorphic probes depending on t. This argument does not claim zero freeness on the full tuning disc $|t| < T$.

Corollary 5.62 (Limit of the vacuum-free conditional source ratios)**.** On a common smaller bare-source disc, $\psi_{N_k} \to \psi_\infty$ locally uniformly, where $\delta\alpha_\infty(\psi_\infty(s)) = s$. The logarithms in eq. 5.cdii converge locally uniformly in (s,V) to

$$-\psi_\infty(s)S_\infty(V) + H_\infty(\psi_\infty(s),V) - H_\infty(0,V). \tag{5.cdxi}$$

Their derivatives give the corresponding limiting coarse-field variations of conditional cumulants. No convergence of C_N, its derivatives, or the uncentered conditional source functions is asserted. ■□

Proof. Write $\delta\alpha_N(t) = t + r_N(t)$. On the smaller common disc, $r_N(0) = 0$ and $\sup|r_N'| \leq K(X) < 1/4$. For $|s| < T/2$, the map $t \mapsto s - r_N(t)$ is an invariant contraction on $|t| \leq 2T/3$. It gives the common inverse ψ_N. The same applies to the limit. Uniform convergence of r_{N_k} on that closed smaller disc and the contraction bound imply locally uniform convergence of the inverses. Substitute in the exact vacuum-free identity. Its analytic functions and their derivatives converge by Cauchy on compact subdomains, proving the result. □

This is a subsequential limit at one fixed coarse cutoff and finite volume. The terminal coarse observable is nondegenerate in that limit. The vacuum factor is neither needed nor extracted. No consistency between different terminal volumes, horizons or coarse cutoffs has been proved by this compactness argument.

5.19.7. *What a positive history mixture would add.* Suppose a separately established positive decomposition on the same ultraviolet observable space contains this capped regular probability with weight p_N:

$$\mu_N = p_N \mathbb{P}^{\mathrm{reg}}_{N,0} + (1 - p_N)\rho_N.$$

For any common square-integrable observable, the variance formula for its component flag implies $\mathrm{Var}_{\mu_N}(T_N) \geq p_N \mathrm{Var}_{\mathbb{P}^{\mathrm{reg}}_{N,0}}(T_N)$. Hence a genuine history floor $p_N \geq p_* > 0$ would give $\mathrm{Var}_{\mu_N}(T_N) \geq p_* c_{X,\ell}$. The corresponding S_0 bound has the factor $16/25$.

No such history floor is proved here. The regular kernel product, its gauge weights and its terminal cap are part of the measure in this subsection. There is no asserted full Wilson-law identification, volume-uniform lower bound, continuum Schwinger field or local-source transfer identity. The results are the exact scalar normalization, uniform finite-volume regular nonvanishing, and the nondegenerate fixed-coarse subsequence just constructed. They do not construct a limit of the full ultraviolet measures.

5.20. **Sources, local energies, and separated correlation bounds.**

Source domains and the exact running-shift identity. This section fixes the source variables used in the conditional estimates. The identities are finite-dimensional; the multiscale bounds for the effective energies stated later require separate estimates.

Fix K, a torus T_ℓ, an odd $L > 1$, and positive constants M, c_M with $c_M \geq M$. The depth s corresponds to physical spacing L^{-s}; level j of a run of length K corresponds to depth $K - j$. A source triple is

$$w = (c, (f_1, \ldots, f_n), (z_1, \ldots, z_n)),$$
$$w(x) = c + \sum_i z_i f_i(x),$$

where f_i are real Lipschitz functions, c, z_i are complex, and the family may be empty. Put

$$\|f\|_{\sharp,s} = \max\{\|f\|_\infty, c_M L^{-s} \operatorname{Lip} f\},$$
$$\|w\|_{\flat,s} = |c| + \sum_i |z_i| \|f_i\|_{\sharp,s}.$$

The class $\mathcal{W}^{(s)}_r$ means the triples with $\|w\|_{\flat,s} < r$. It is a union of finite-dimensional source balls, one for each fixed real family. Holomorphy on this class means holomorphy in (c, z) on each such ball. The number $\|w\|_{\flat,s}$ belongs to the chosen triple and can change when its function is represented differently. The physical partition function and every source-local energy are required to agree for two triples that have the same values on all bare plaquettes on which that quantity depends. This representation-independence is a separate part of the source format.

Always $\|w\|_\infty \leq \|w\|_{\flat,s}$ and $c_M L^{-s} \operatorname{Lip} w \leq \|w\|_{\flat,s}$. Thus, if $m = K - s$ and $j \leq m$,

$$c_M a_{K-j} \operatorname{Lip} w = L^{-(m-j)} c_M a_{K-m} \operatorname{Lip} w \leq L^{-(m-j)} \|w\|_{\flat,s},$$
$$a_t = L^{-t}.$$

This is the exact scale gain used when a source is frozen on an earlier block. It follows from the norm definition, not from an analyticity theorem.

Here is an explicit algebraic version of the running profiles. Let P_K be the finite set of bare plaquettes, with barycentres $x(p)$. For each level j choose a finite set Y_j of base points, anchors $p_y \in P_K$, and nonnegative functions $h_y^{(j)}$ on P_K such that

$$\sum_{y \in Y_j} h_y^{(j)}(p) = 1,$$

$$h_y^{(j)}(p) \neq 0 \implies |x(p) - x(p_y)| \leq C_h M a_{K-j}.$$

Choose also profiles $0 \leq \varphi_j(p) \leq 1$. The grid, anchors, partition and profiles are fixed independently of the source throughout the analytic family. They are supplied by the geometric construction; the identities below hold for every finite choice satisfying these conditions.

Let b_j be holomorphic on $D(0,\rho)$ and define

$$d_j = \sup_{0<|z|<\rho} \frac{|b_j(z) - b_j(0)|}{|z|},$$

$$\sum_{j \leq k} d_j \leq \frac{1}{3}.$$

For triples whose function has $\|w\|_\infty < \rho$, set

$$x_k(p) = \beta - \sum_{j \leq k} b_j(0)\varphi_j(p),$$

$$c_j(p;w) = \varphi_j(p) \sum_{y \in Y_j} h_y^{(j)}(p) b_j(w(x(p_y))),$$

$$\zeta_k(p;w) = w(x(p)) + \sum_{j \leq k} \varphi_j(p) \sum_{y \in Y_j} h_y^{(j)}(p)[b_j(w(x(p_y))) - b_j(0)].$$

Then the exact bookkeeping identity is

$$x_k(p) - \zeta_k(p;w) = \beta - w(x(p)) - \sum_{j \leq k} c_j(p;w).$$

To prove it, expand both sides and use $\sum_y h_y^{(j)} = 1$ in each constant term $b_j(0)\varphi_j$. Consequently the Wilson weights in a sourced exponent can be added or subtracted without changing their total bare coefficient. This assertion concerns that total coefficient; it does not assert equality of two effective measures unless the exact integral transport has also been proved.

The same definitions give

$$|\zeta_k(p;w) - w(x(p))| \leq \tfrac{1}{3}\|w\|_\infty,$$

$$|\zeta_k(p;w)| \leq \tfrac{4}{3}\|w\|_\infty.$$

Each value is holomorphic on every source ball with supremum norm below ρ, because only finitely many evaluations and compositions occur. It depends on the source only inside distance $C_h M a_{K-k}$ from p, including the value at p itself; here $a_{K-j} \leq a_{K-k}$ for $j \leq k$.

For a constant source $w \equiv z$, in a region where every $\varphi_j(p) = 1$, this reduces to

$$\zeta_k(z) = z + \sum_{j\le k}[b_j(z) - b_j(0)],$$

$$\zeta_0(z) = z,$$

$$\zeta_{k+1}(z) = \zeta_k(z) + b_{k+1}(z) - b_{k+1}(0).$$

Differentiating at zero gives $\zeta_k'(0) = 1 + \sum_{j\le k} b_j'(0)$ and $|\zeta_k'(0) - 1| \le 1/3$. The derivative bound follows from the definition of d_j by taking the limit at zero. For spatially varying sources, freezing the function w itself costs at most $\operatorname{Lip} w$ times the anchor distance. To freeze $b_j \circ w$ one must work on a smaller source disc. Indeed $h_j(z) = [b_j(z) - b_j(0)]/z$ extends holomorphically to zero and is bounded by d_j. For $|z| \le \rho' < \rho$, Cauchy's estimate gives

$$|b_j'(z)| = |h_j(z) + zh_j'(z)| \le d_j \frac{\rho}{\rho - \rho'}.$$

Thus on the half-disc the additional factor is at most $2d_j$. Apply the mean value integral on the segment between the two source values to bound their composed difference. The displayed depth identity then supplies the factor $L^{-(m-j)}$, with the fixed anchor constant $C_h M/c_M$. The radial bound d_j alone is not a Lipschitz bound on the whole open disc.

All smallness, radius and representation-independence conditions used here must be retained when invoking the sourced RG format. They do not follow from the entire dependence of the bare lattice partition function alone.

5.20.1. *Transporting the observables: sources, analyticity, and bounds independent of the cutoff and of the volume.* The measure $\mu_{K,\ell,\beta}$ is described at the unit scale in §§ 3.1, 4.17 and 5.2, and the present step gives the corresponding description of its correlations. Because $\mathcal{O}(f) = A(f, U)$, a source $w = c + \sum_i z_i f_i$ acts as a complex shift of the bare inverse coupling that depends on position:

$$\rho_0^w = e^{-A(\beta - w, U)},$$

$$Z(w) = \int \rho_0^w \, dU,$$

$$S^T_{n;K,\ell,\beta}(f_1, \dots, f_n) = \partial_{z_1} \cdots \partial_{z_n} \log Z(w)\big|_{w=0}.$$

The renormalisation steps are applied to ρ_0^w. Whatever the source leaves behind is gathered into local numbers, the source energies $e_j(X; w)$ of § 5.20. We set $\mathcal{E}(w) := \sum_{1\le j\le K} \sum_{X\in\mathcal{D}_j} e_j(X; w)$, $\widetilde{Z}(w) := e^{-E-\mathcal{E}(w)} Z(w)$ and $C_g := C(1 + \log g^{-2})$.

Proposition 5.63 (The construction with sources)**.** Let $0 < g \le \gamma_J$. For each first-passage datum (K, β), each $\ell \in \mathfrak{L}(g)$ and each source satisfying $\|w\|_\flat < 2\varrho$, the pair $(E, (e_j(X; \cdot)))$ forms a system of localised source energies. That is, each $e_j(X; w)$ is holomorphic in (c, z) (analyticity). If the f_i are real, it takes real values whenever (c, z) is real. It depends on w only through its values on $X^{\sim 1}$, and it is zero at $w = 0$ (locality). Moreover, uniformly,

$$|e_j(X; w)| \le Ce^{-\kappa_e d_j(X)},$$

$$|\widetilde{Z}(w)| \le e^{C_g \ell^4},$$

$$\widetilde{Z}(0) \ge e^{-C_g \ell^4}$$

(these are, in order: the exponential bound, whose rate $\kappa_e := c\kappa$, $c < 1$, exceeds the entropy rate of the localisation domains through a cube; upper stability; the floor). The same conclusions

hold along a reference run, with every choice frozen at θ_k, as long as $x_k^\natural$ remains in a tube around θ_k with a margin of $C\varrho$. For each K this requirement is a condition on β only. When $g \le \gamma_U$, it is met on the interval I_K of § 5.2.3, an interval that contains the tuned $\beta_K^\natural$. The conclusions also hold for the run stopped at any level k, where the sums are stopped at $j \le k$, the vacuum constant $E_{(k)}$ of the first k steps replaces E, and $C(1+\log x_k)$ per site of $\mathbb{T}^{(k)}$ replaces $C_g\ell^4$ §5.20.1.2. ■

The localized energies in the source transfer. At the trivial pair P_0, let Δ_w denote the difference from the unsourced term. The energy of a domain at level j is

$$e_j(X;w) = \sum_{z\in X\cap\mathbb{T}^{(j)}} \Delta_w E^{(j)}(X,P_0,z) + \Delta_w R^{(j)}(X,P_0), \qquad e_0 = 0.$$

The normalizer and the ratio contribution computed with the fixed real weight cancel in this difference. The source dependence of the coupling shift is already in the sourced regular term. On the fixed source ball of radius r, apply the source-line estimate with reference source zero. On the trivial pair the regular difference is bounded by $Cr^{-1}\|w\|_{\flat,K-j}e^{-(\kappa+1)d_j(X)}$ per pointing. The remainder difference has bound $Cr^{-1}\|w\|_{\flat,K-j}\theta_j^{-\kappa_0/2}e^{-\kappa d_j(X)}$. The at most $CM^4(1+d_j(X))$ pointings use the extra unit of decay, giving

$$|e_j(X;w)| \le CM^4 r^{-1}\|w\|_{\flat,K-j}e^{-\kappa d_j(X)}.$$

The retained source-energy rate can be chosen between the rooted entropy rate and κ. At a witness stop the separated-source bound uses only $j \le k_0$. Coarser origins can read both supports and remain in the source derivatives if the run is continued. If $\mathcal{S}_\emptyset$ denotes the all-small-field label, the vacuum bookkeeping gives

$$E + \sum_{j,X} e_j(X;w) = -\mathcal{E}_K(\mathcal{S}_\emptyset;w).$$

Thus the same E and the sum of these local energies are the constants removed in $\widetilde{Z}$. For a label $\mathcal{S}$, write $\mathsf{T}_j(\mathcal{S};w)$ for its share of these differences. The constant after normalization is

$$-E - \sum_{j,X} e_j(X;w) - \mathcal{E}_K(\mathcal{S};w) = -[E+\mathcal{E}_K(\mathcal{S};0)] - \sum_j [\mathsf{T}_j(\mathcal{S}_\emptyset;w) - \mathsf{T}_j(\mathcal{S};w)].$$

A missing pointing or remainder is rooted at a cube of Z_j^+ by its own domain or its base point. Sum the trivial-pair difference with its rooted decay, including the at most $CM^4(d_j+1)$ pointings per domain. The source share therefore costs $C\#_j(Z_j^+)$. The Gaussian, Haar, and gauge constants at the fixed real weight give the unsourced logarithmic price on the same missing-site count. These are the scalar prices in eq. 4.dxxxi. The weighted product majorant of the literal label terms is required when summing the remaining factors.

Use $s = K - j$ and put

$$V_{a,\ell} = E, \qquad U_{a,\ell}(W) = 0, \qquad e_{a,\ell,s,X}(W) = e_{K-s}(X;w).$$

Here w is the value of the physical source W at the prescribed plaquette points. At $s = K$ the last entry is zero. The source appears through these values and the values of the same function at the running source points, so the entries are functions of W. The radius in the all-state transfer is ϱ with the corresponding source norm, or any smaller fixed radius under the norm comparison of § 5.20. The two stability estimates of Prop. 5.63 then give eq. 5.cdxxxv with this assignment.

The actual domains at that scale are connected unions of cubes of side Ma_s. Their one-layer enlargement contains every source read, with one fixed additional reach for the barycentre of a bare plaquette incident to that enlargement. Use the compatible tori $\ell = 2L^m$ at sufficiently large allowed sides. The cube count in each direction is $2L^{m-m_0+s}$, so the indexing exists at all actual scales. The length $d_j(X)$ of the rooted estimate uses a cube-edge tree within X. The length $m(X)$ used in § 5.23 allows the tree to leave X, and hence $m(X) \le d_j(X)$. The bound for e_j therefore holds with $m(X)$. Choose the retained rate above the rooted closed-walk count for these cube

unions as in eq. 5.cdxlvi. Each union has its original single domain index. This gives the indexing and source range needed for the geometric estimates of D1. The uniform upper bound and floor use the sourced history estimates on the original source ball.

Proposition 5.64 (Correlation bounds: Thm. A (c)(1)–(2))**.** Take g, K, β, ℓ as above and $n \geq 2$. Let the f_i be real Lipschitz functions whose supports lie at mutual distances $\geq \mathsf{d} > 0$. For the second and the third bound, let each support also be contained in a ball of radius R. Then there exists a side $\ell_G \in \mathfrak{L}(g)$, depending only on g, for which

$$|S_n^T| \leq C_n(\mathsf{d}) e^{n c_V \ell^4} \prod_i \|f_i\|_\sharp;$$

$$|S_n^T| \leq C_n^\infty(\mathsf{d}; R) \prod_i \|f_i\|_\sharp \ (\ell \geq Cn(R+1));$$

$$|S_n^T| \leq A(\mathsf{d}; R) B(R)^n (n!)^{\varkappa_\star} \prod_i \|f_i\|_\sharp \ (\ell \geq \ell_G),$$

uniformly, where every constant may also depend on g, $C_n^\infty(\mathsf{d}; R)$ does not increase with d, and one may take $A(\mathsf{d}; R) = \exp(\max\{1, \mathsf{d}^{-5}\})$, after choosing $\varkappa_\star = k + 1$ with the fixed graded exponent k of Prop. 5.76. The sharper form proved there is $[2B(R)]^n (n!)^k \max\{1, \mathsf{d}^{-5n}\} \prod_i \|f_i\|_\sharp$. A polynomial separation prefactor independent of n would require an additional estimate; it is not asserted here. The second and third bounds also hold for $S_n^T[\nu]$ in each periodic Gibbs state ν at β on $\mathbb{L}_K$, with no condition on the volume. ■

Prop. 5.70 is the third main result. Under the law of the histories, the probability that a cell is live, or that it is created, is $\leq Ce^{-cp_0(g_k)}$, uniformly in the volume. The short-distance laws rest on this result. §6.1.1.2 treats the two-point law, clauses (c)(3), (c)(4). It uses these bounds on a single cell and, from their age-resolved form (Prop. 5.71), the age series at a rate $b \geq 8$. The four-point argument for Thm. A(c)(5) requires the series at a rate $b > 16$.

The same tools also give two further results that are used later. The first is the one-point transfer (eq. 5.cdxliv), $|\nu(\mathcal{O}(f)) - \nu'(\mathcal{O}(f))| \leq C_1(R)\|f\|_\sharp$, which compares periodic Gibbs states taken at the same first-passage datum (K, β). With it, one can centre a pure phase at the means of that periodic Gibbs state whose decomposition contains the phase, the coordinates of § 7.7 become compact, and the one-point numbers $\mathfrak{c}_\xi$ of Thm. B(3)(ii) are bounded. It also enters the growth constants of (b)(v), so that a single set of constants covers these components as well. The second consists of the insertion bound and the plate bound (Props. 6.23 and 6.24), which are the a priori estimates on which Prop. 6.26 rests.

Thm. A(a)(ii) uses only the bounds of Prop. 5.64. Thm. A(a)(iii) (for the re-centring), § 6.16, § 6.16 and § 7.7–§ 7.9 also use the one-point transfer in eq. 5.cdxliv. The tuned couplings need not be first-passage data. Prop. A.15 and appendix A.8 apply Prop. 5.63 along reference runs, and this gives the tuned limits the torus bound only. The format underlying Prop. 5.63 is the starting point of §6.1.1.1–§6.1.1.2. The difficulty lies in two places. The first is Prop. 5.63: the source term is marginal, since a step leaves it no smaller, just as it leaves the action no smaller; it takes complex values, so positivity is no longer available; and it must be carried through the large-field operations. The second is Prop. 5.70, in which the ratio of the stability bounds loses $e^{C_g \ell^4}$. Everything else (Cauchy's estimates, reflection positivity, the chessboard estimate) is classical, except for the bookkeeping in n.

5.20.1.1. The curvature source with fixed reference data. **Objects.** The norm $\|f\|_\sharp = \max\{\|f\|_\infty, CM \operatorname{Lip} f\}$ controls how much f can vary within any M-cube of the unit lattice. The sourced densities ρ_k^w arise from ρ_0^w through the operations of §§ 3.1 and 4.17, and every choice in them is the one made in the run at $w = 0$. These choices are the tests χ, the thresholds

ε_k, δ_k, the radii, the sizes $\check{R}_k$, the backgrounds $U_k(\mathbf{V})$ (which minimise the action with no source), the scaling $\mathcal{A}_k = g_k \mathcal{A}_k^{\mathrm{s}}$, the covariances $C^{(k)}$, the gauge-fixing weight and the reference laws of $\mathbf{R}$.

Proposition 5.65 (Kernels; same histories; exactness)**.** To each history h of level k there corresponds a positive kernel $\mathsf{K}_h(U, dV_k)$, built from the choices of the run and from nothing else. For Φ bounded and gauge invariant, the operations carry $\Phi\rho_0$ to

$$\sum_h \tau_h[\Phi],$$

$$\tau_h[\Phi] = \int \Phi(U)\, \rho_0(U)\, \mathsf{K}_h(U, \cdot)\, dU,$$

$$\sum_h \tau_h[\Phi](\mathcal{V}_k) = \int \Phi\rho_0\, dU.$$

For the choice $\Phi = e^{A(w,U)}$ one obtains $\rho_k^w\, dV_k = \sum_h \tau_h^w$, where the sum runs over the histories of ρ_k. Each τ_h^w is a complex measure which, as a function of (c, z), is entire, and $\tau_h^0 = \tau_h \geq 0$. Moreover $\int \rho_k^w\, dV_k = Z(w)$ for $k \leq K$. ∎

Each step consists of finitely many moves. The first is the insertion of $1 = \int dV\, \delta(\mathcal{M}(U)V^{-1})$. The second is a family of decompositions of unity $1 = \sum \prod \chi \prod \chi^c$. The third is a gauge-fixing factor, of total integral 1 over the gauge group; its insertion is harmless since $\Phi\rho_0$, like each a_p, is gauge invariant. The fourth is a set of changes of variables. The last occurs inside $\mathbf{R}$: a term is replaced by the product of a fixed probability law and its integral over a component. Every move is linear in the density and leaves the total integral unchanged, and no move requires positivity. The tests depend on the fields only, so the regions, labels and histories are the same as at $w = 0$.

Proposition 5.66 (Exact insertion of block observables)**.** Given a history h of level k, denote by $Y(h)$ the union of all components that $\mathbf{R}$ has acted upon at levels not exceeding k. A bond c of $\mathbb{T}^{(k)}$ is said to be far from $Y(h)$ when neither the two blocks $B^k(c_\pm)$ nor the bare bonds that join them meet $Y(h)^\sim$. There exists a probability measure P_k on triples (U, h, V), each made of a bare field, a history and a block field, with four properties. First, its marginal on U is $\mu_{K,\ell,\beta}$. Second, under its marginal on (h, V) each bounded gauge-invariant $\Phi(h, V)$ has integral $Z(0)^{-1} \sum_h \int \Phi(h, V)\, \tau_h(dV)$. Third, it is invariant under $(U, h, V) \mapsto (U^u, h, V^{u|})$, where u is a gauge transformation of the bare lattice and $u|$ is its restriction to the sites of $\mathbb{T}^{(k)}$. Fourth, under it $V = \mathcal{M}^k U$ holds on every bond far from $Y(h)$. Consequently, setting $F^{(h)}(V) := \mathbb{E}_{\mathsf{P}_k}[F(\mathcal{M}^k U) \mid h, V]$, which is the conditional expectation with respect to P_k, taken in a version that is invariant in V, one has for each bounded gauge-invariant F on $\mathcal{V}_k$

$$\langle F(\mathcal{M}^k U)\rangle_{K,\ell,\beta} = \frac{\sum_h \int F^{(h)}\, d\tau_h}{\sum_h \int d\tau_h},$$

$$|F^{(h)}| \leq \sup |F|,$$

$$F^{(h)} = F \text{ if } F \text{ reads only bonds far from } Y(h);$$

in particular, $F^{(h)} = F$ for any history in which $\mathbf{R}$ has acted on none of the components. In precisely this sense ρ_k represents the block averages of the bare field. ∎

The mechanism has three parts. First, $\mathbf{T}$ integrates $F \circ \mathcal{M}$ exactly against the density one level lower. Second, on each component on which it acts, $\mathbf{R}$ puts a reference law in place of the law of the block field; this alters the joint distribution of $\mathcal{M}^k U$ and V_k only in a neighbourhood of that component, and it leaves every mass as it was. Third, the steps are glued in succession, each

being regarded as a transport of the gauge-averaged terms. All the assertions are identities between measures and involve neither a constant nor a smallness condition. The role of the proposition is to fix what ρ_k means; nothing is derived from it. In the two-point law §6.1.1.2, a single scale is not isolated by this coupling, because, inside the region it heals, the law of the block field is replaced by $\mathbf{R}$. It is isolated by the exactness with the sources read at depth s, that is, by $\sum_h \tau_h^w(\mathcal{V}_{K-s}) = Z(w)$ (Prop. 5.65, together with §5.20.1.2).

Why the frozen choices still suffice. Bałaban's theorems concern a single real coupling at each step (from these numbers the profiles build the function $g_k^2(x)$ of 119 (1988), (2.24), which coincides with g_k^2 on the last domain), a background that minimises the action appearing in the exponent, and a single coupling-constant counterterm in each step. For this reason the source is not built into that framework but is carried alongside it. In terms of the running shift $\zeta_k(\cdot; w)$ of §5.20.1.2,

$$-A(x_k(\cdot) - \zeta_k(\cdot; w), U) = -A(x_k(\cdot), U) + \sum_{y \in \mathbb{T}^{(k)}} A(h_y^{(k)} \zeta_k(\cdot; w), U),$$

where $h_y^{(k)}$ denote Bałaban's tent functions (Comm. Math. Phys. 119 (1988), (3.40), (3.65)). On the set where $|\partial \mathbf{U} - \mathbf{1}| < \alpha_{0,k} \eta_k^2$ one has

$$|A(h_y^{(k)} \zeta_k(\cdot; w), \mathbf{U})| \le C \alpha_{0,k}^2 \sup |\zeta_k| \le C \varrho \, g_k^2 (\log x_k)^{2q} \ll 1 :$$

it is merely an additional local term, small and analytic, once g is chosen small after ϱ. When the fields are real, $|e^{-A(x_k(\cdot) - \zeta_k, U)}| \le e^{-(1 - C\varrho g^2) A(x_k(\cdot), U)}$; hence a failed test still costs $e^{-c p_0 (g_k)^2}$.

Proposition 5.67 (Reality and positivity at real sources)**.** All the choices are real, and so are the f_i; consequently each move takes real data to real data. Hence, at real (c, z), each of the following quantities is real: the boundary terms, the increments, the activities $E^{(j),w}, R^{(j),w}$ (at real fields), the vacuum constants, the running shifts, and also the $e_j(X; w)$. The exponents are therefore real at real block fields. Suppose moreover that the source is a real constant with $|\zeta| < 2\varrho$. Then, in the operations $\mathbf{T}_k(Z)$ and $\mathbf{T}'_i(X)$ of §5.20.1.2, every exponential factor is strictly positive at real pairs, and

$$x_k(\cdot) - \zeta_k(\cdot; \zeta) > 0,$$
$$\tau_h^\zeta \ge 0 :$$

thus the stability bounds of the run rely on a positivity that is lost at complex w and is still available at real shifts. Furthermore, ρ_0^ζ coincides with the bare density at $\beta - \zeta$, written with the choices belonging to β: these are two presentations of a single measure § 5.2.3. The choices of a reference run do not depend on β. Take a real β whose run has room 2ϱ in the tube, and a real ζ with $|\zeta| < \varrho$; along such a run one then obtains $x_j^\natural(\beta - \zeta) = x_j^\natural(\beta) - \zeta_j(\zeta)$ and $b_j^\natural(\beta - \zeta) = b_j(\zeta)$. These facts enter the runs with real shifts in § 5.2.3 and in appendix A.8, as well as the monotone map that sends the bare coupling to the renormalised coupling § 5.2 and appendix A.8. The conjugated copies of §§ 5.20 and 5.22 and Props. 5.75 and 5.76 make no use of these facts; holomorphy is all they require (with the common-normalizer condition in eq. 5.cdxli). ∎

Changing the real constant in the same frame. Let the reference run at β have room $2r$ through the prefix and take a real $|v| < r$. At the bare level the sourced input is the unsourced one at $\beta - v$. All choices belong to the fixed frame. Suppose the two descriptions agree through level k. The ordinary formation at level k can then be applied to both. The a priori bound by $r/3$ on each

increment beyond its common one-loop term gives

$$|\theta_{k+1} - x^{\natural}_{k+1}(\beta - v)| \le \mathsf{t}_{k+1} - 2r + |\zeta_k(v)| + 2r/3 < \mathsf{t}_{k+1}.$$

Use $|\zeta_k(v)| \le 4|v|/3$ here. This establishes the next admission before comparing the output coefficients. The source-independent kernels act on the same bare input in the two descriptions. Apply the same-frame comparison of presentations from § 5.2.3. It compares the centered totals on the admitted hereditary windows for the common companion. The pointed quadratic readout of those totals uses the same physical convention. This gives $b^{\natural}_{k+1}(\beta - v) = b_{k+1}(v)$ and, by the update of the action weight, $x^{\natural}_{k+1}(\beta - v) = x^{\natural}_{k+1}(\beta) - \zeta_{k+1}(v)$.

The same comparison identifies the unsourced vacuum constant at $\beta - v$. In the all-small-field term, the two densities are continuous on a common open neighbourhood of the identity in the block field. They agree as measures there. The normalized action and activity totals vanish at the trivial background. Evaluate the two densities at the identity, where all the tests pass, to obtain

$$E_{(k)}[\beta - v] = E_{(k)}[\beta] + \sum_{j \le k} \sum_{X} e_j(X; v).$$

This uses equality of the small-field term on the neighbourhood, with the same Haar normalization. Equality of the total partition functions would not determine the individual vacuum constants. A comparison in a different frame needs its own overlap and coupling estimate.

For the normalization at an intermediate witness k_0, sum the constant-source increment bounds only through that witness. The regular term costs $C\theta_j^{-3/2}(\log \theta_j)^{\mathfrak{p}_0}$ at level j. The marked term costs $Cr^{-1}\theta_j^{-\nu}$ by Cauchy's estimate on the composed source disc. Along the reference flow, $\theta_j \ge \theta_{k_0} + c(k_0 - j) - C_0$ on this prefix. The sums give, with $\nu = (\kappa_0 - 4)/2 > 1$,

$$|\zeta'_{k_0}(0) - 1| \le C\left[\theta_{k_0}^{-1/2}(\log \theta_{k_0})^{\mathfrak{p}_0} + r^{-1}\theta_{k_0}^{1-\nu}\right].$$

This bound uses the actual prefix, at the same normalization as the physical source derivatives.

The scope of the mechanism. Because $\mathcal{O}(f) = A(f, U)$ is a weighted action, its source is a coupling shift. A different bounded gauge-invariant local observable Φ need not be a weighted plaquette action. The exact insertion identity can transport $e^{z\Phi}$, but does not put it in the variable-Wilson format or supply its counterterms, source stability or uniform correlation estimates. Those require a separately closed source construction.

Exact insertion of block observables: a coupling of bare field, history and block field. **(i) The setting and the objects.**

Purpose of the block. The effective density of level k decomposes into a finite sum of positive measures indexed by the histories h of level k: $\rho_k\, dV_k = \sum_h \tau_h$. A single application of $\mathbf{T}$ integrates $F \circ \mathcal{M}$ exactly against the full density one level lower, so after k applications one has $\int F\, d(\mathbf{T}^k \rho_0) = \int F(\mathcal{M}^k U)\, \rho_0(U)\, dU$. In the case where $\mathbf{R}$ acts nowhere, $\rho_k\, dV_k$ is the image of $\rho_0\, dU$ under $\mathcal{M}^k$, and the assertion of this block then amounts to the definition of an image measure. Where $\mathbf{R}$ acts on a component, a reference law takes the place of the law of the block field inside that component. This modifies how $\mathcal{M}^k U$ and V_k are jointly distributed on bonds close to that component, and no mass changes. What this block asserts is that the replacements fit together into a single probability measure, defined on triples (bare field, history, block field), with respect to which, away from the components acted upon, the block field coincides with the block average of the bare field. No small factor and no constant enters Statements 1 to 6.

Spaces. Each $\mathcal{V}_j$ is a finite product of copies of the compact group G, and is therefore a compact metrisable space. Finite sets are given the discrete topology, and all measures are Borel measures.

Terms as the measures produced by moves. In parts §5.20.1.1 and § 5.20 the construction is regarded as a chain of moves, a move being a finite family of positive kernels with one kernel for each outcome. The outcomes of the moves of the steps $1, \dots, j$, listed in order, form a string, and such a string is called a history of level j. We write $\mathsf{K}_h(U, \cdot)$ for the kernel obtained by composing

along the string h; it runs from $\mathcal{V}_0$ to the states reached after step j. The admissible histories of level j, namely the strings for which $\mathsf{K}_h \neq 0$, form the finite set $\mathfrak{H}_j$, and $\mathfrak{H}_0 = \{\varnothing\}$. The term of a history $h \in \mathfrak{H}_j$ is defined as the measure into which its string transforms the bare measure, taken as a measure in the block field. Its mass is $\mathsf{t}(h)$:

$$\tau_h(\mathcal{B}) := \int \rho_0(U)\, \mathsf{K}_h(U, \{V_j \in \mathcal{B}\})\, dU,$$

$$\tau_\varnothing = \rho_0\, dU,$$

$$\mathsf{t}(h) := \tau_h(\mathcal{V}_j).$$

The statements and the proofs below use the terms only through this definition.

The two stages of a history. Given $h' \in \mathfrak{H}_{j+1}$, we write $h'|_j \in \mathfrak{H}_j$ for the sub-list of those entries of h' that come from the steps and from the large-field operations of the levels $\leq j$. The strings at the stage reached once the moves of $\mathbf{T}$ of step $j+1$ have been made form a finite set, $\mathfrak{H}^{\mathbf{T}}_{j+1}$. Its elements are the lists $a = (h; P, Q, \Xi)$. Each is formed by some $h \in \mathfrak{H}_j$ together with the outcomes of those three moves of $\mathbf{T}$ which are built from tests:

- $P = P_{j+1}$, the outcome of the plaquette tests (at step 1, the pair (P_0, P_1));
- $Q = Q_{j+1}$, the outcome of the approximate fluctuation tests;
- $\Xi = \Xi_{j+1}$, the outcome of the fluctuation tests together with the recursion along the boundary, which determines $\Omega_{j+1}, \Lambda_{j+1}, S_{j+1}$.

For such an a we set $a|_j := h$. We let $\tau^{\mathbf{T}}_a$ be the measure produced by the string a, taken in the variable V_{j+1}, so that it is a measure on $\mathcal{V}_{j+1}$. The class of the large-field operation of level $j+1$ is denoted $\mathcal{Q}_{j+1}(a)$; it is a set of components whose argument is a string, and it is distinct from the constraint map $\mathcal{Q}_k(U; A)$ introduced in the Notation. It is determined by the entries of a and consists of every component of Z_{j+1} that satisfies the class conditions (part §4.17.1.3). The union of its members is

$$\mathsf{Z}(a) := \bigcup_{X \in \mathcal{Q}_{j+1}(a)} X \subset T_\ell.$$

The components that leave the class in the course of the operation (the drop-outs) are contained in $\mathsf{Z}(a)$, and so are the second-class components, although both kinds remain live. For $h' \in \mathfrak{H}_{j+1}$, the sub-list $h'^{\mathbf{T}} \in \mathfrak{H}^{\mathbf{T}}_{j+1}$ consists of $h'|_j$ together with the outcomes P, Q, Ξ of step $j+1$. Every other entry of h' is an outcome or a class produced within the large-field operation of level $j+1$.

The region of action. Let $h \in \mathfrak{H}_j$. We denote by $Y(h) \subset T_\ell$ the union of those components of the large-field regions of h which have been acted on by the large-field operation at one of the levels $\leq j$; equivalently, it is the union of the class components of these levels. In particular $Y(\varnothing) = \emptyset$, and

$$Y(h') = Y(h'|_j) \cup \mathsf{Z}(h'^{\mathbf{T}})$$

$$(h' \in \mathfrak{H}_{j+1}).$$

Clear and far bonds. To a bond c of $\mathbb{T}^{(j)}$ we attach the set of bare sites $\mathrm{Bl}_j(c) := B^j(c_-) \cup B^j(c_+)$, where $B^0(y) = \{y\}$. We say that the bond c is clear of a set Y when $\mathrm{Bl}_j(c) \cap Y = \emptyset$. A bond c of $\mathbb{T}^{(k)}$ is called far from $Y(h)$ when neither $\mathrm{Bl}_k(c)$ nor any bare bond joining its two blocks meets $Y(h)^\sim$. This set is the union of the enlarged sets $X^\sim$, one for each of the class components X whose union is $Y(h)$. The enlargement adds to such a component one layer of cubes of $\pi_{j(X)}$, and $j(X)$ is the level at which the operation acted on X.

Gauge averages. The G-valued gauge transformations of $\mathbb{T}^{(j)}$ form the group $\mathcal{G}_j$. It is a finite product of copies of G and carries the Haar probability measure dv. It acts through $V \mapsto V^v$, with $(V^v)^{v_0} = V^{v_0 v}$. Given $u \in \mathcal{G}_i$ with $i \le j$, we write $u|_j \in \mathcal{G}_j$ for the gauge transformation obtained from it by restriction to the sites of $\mathbb{T}^{(j)}$. A function on $\mathcal{V}_j$, or a measure on it, is called invariant if this action leaves it invariant. The same convention applies on the configurations over a set of bonds closed under reversal, and on $\mathfrak{H} \times \mathcal{V}_j$, where the group acts trivially on the finite set $\mathfrak{H}$. Given a bounded Borel function F and a finite positive measure τ on $\mathcal{V}_j$, we define

$$\bar{F}(V) := \int F(V^v)\, dv,$$

$$\int F\, d\bar{\tau} := \int \bar{F}\, d\tau.$$

(ii) The statements. Throughout, β is real, $0 \le s \le K$ and $k = K - s$. The run is assumed to satisfy, through level k, the inductive description of the effective densities (part §4.17.1.45), with $x_0, \dots, x_k \ge \gamma^{-2}$, together with the two-sided flow bound (part § 5.2.1). Of all these data, the proofs use only the fact that the moves of the steps $1, \dots, k$ are formed, that is, they use nothing beyond a reference sequence and a torus that is large compared with the cubes of the levels $\le k$.

1. The step, taken term by term. Let $0 \le j < k$ and $h \in \mathfrak{H}_j$. Then each $\tau_a^{\mathbf{T}}$ with $a|_j = h$ is a finite non-negative measure on $\mathcal{V}_{j+1}$. Moreover, every bounded Borel invariant F on $\mathcal{V}_{j+1}$ satisfies the following identity (the transport identity of the stage $\mathbf{T}$):

$$\sum_{a \in \mathfrak{H}_{j+1}^{\mathbf{T}} :\, a|_j = h} \int F\, d\tau_a^{\mathbf{T}} = \int (F \circ \mathcal{M})\, d\tau_h.$$

Now let a be such that $a|_j = h$, and let F be a bounded Borel invariant function on $\mathcal{V}_{j+1}$ which does not depend on the variables $V(b)$ for which b is a bond of $\mathbb{T}^{(j+1)}$ having at least one end point in $\mathsf{Z}(a)$. Then (the transport identity of the stage $\mathbf{R}$)

$$\sum_{h' \in \mathfrak{H}_{j+1} :\, h'^{\mathbf{T}} = a} \int F\, d\tau_{h'} = \int F\, d\tau_a^{\mathbf{T}}.$$

After summation over $h \in \mathfrak{H}_j$, the first identity expresses the exactness of $\mathbf{T}$ on the whole density. Taking $F \equiv 1$ in both identities gives

$$\sum_{h' \in \mathfrak{H}_{j+1} :\, h'|_j = h} \mathsf{t}(h') = \mathsf{t}(h) :$$

thus the step divides the mass of a history among its continuations. The law of the histories (part §§ 5.20 and 5.22) is based on this identity.

2. Gauge averages. Suppose a compact group $\mathcal{G}$ with Haar probability dv acts continuously on a compact metrisable space $\mathcal{X}$. Define $\bar{F}(x) = \int F(v \cdot x)\, dv$ and $\int F\, d\bar{\tau} = \int \bar{F}\, d\tau$. (a) The function $\bar{F}$ is bounded, Borel and invariant, with $\sup |\bar{F}| \le \sup |F|$, and $\bar{F} = F$ when F is invariant. The measure $\bar{\tau}$ is finite, positive and invariant. It satisfies $\int F\, d\bar{\tau} = \int F\, d\tau$ for invariant F, and $\bar{\tau}(N) = \tau(N)$ for invariant Borel sets N. (b) Every invariant finite positive measure ν satisfies $\int \bar{F}\, d\nu = \int F\, d\nu$. Hence, if two invariant finite positive measures give the same integral to every bounded Borel invariant function, they are equal. (c) Let $r : \mathcal{G} \to \mathcal{G}'$ be surjective, and let $q : \mathcal{X} \to \mathcal{X}'$ be a Borel map with $q(v \cdot x) = r(v) \cdot q(x)$. Then the image under q of any invariant measure is invariant, and $f \circ q$ is invariant whenever f is invariant.

3. Gluing. Let $\mathcal{X}_1, \mathcal{X}_2, \mathcal{Y}$ be compact metrisable spaces and let $p_i : \mathcal{X}_i \to \mathcal{Y}$ be Borel maps. Let λ_i be finite positive measures on $\mathcal{X}_i$ such that $(p_1)_* \lambda_1 = (p_2)_* \lambda_2$. Then $\mathcal{X}_1 \times \mathcal{X}_2$ carries a

finite positive measure λ with the following two properties: its marginals are λ_1 and λ_2, and $p_1(x_1) = p_2(x_2)$ for λ-almost every (x_1, x_2).

4. Clear bonds. (a) One has $c_-, c_+ \in \mathrm{Bl}_j(c)$. (b) Let c be a bond of $\mathbb{T}^{(j+1)}$, and let b be a bond of $\mathbb{T}^{(j)}$ whose two end points lie in the double block $B(c_-) \cup B(c_+)$. Then $\mathrm{Bl}_j(b) \subset \mathrm{Bl}_{j+1}(c)$. (c) Every bond of $\mathbb{T}^{(k)}$ that is far from $Y(h)$ is clear of $Y(h)$.

5. A single step as a transport of the averaged terms. Let $0 \le j < k$. Then $(\mathfrak{H}_j \times \mathcal{V}_j) \times (\mathfrak{H}_{j+1} \times \mathcal{V}_{j+1})$ carries a finite positive measure m_{j+1} with the following properties: (a) the marginal on $\mathfrak{H}_j \times \mathcal{V}_j$ equals $\sum_{h \in \mathfrak{H}_j} \delta_h \otimes \bar{\tau}_h$; (b) the marginal on $\mathfrak{H}_{j+1} \times \mathcal{V}_{j+1}$ equals $\sum_{h' \in \mathfrak{H}_{j+1}} \delta_{h'} \otimes \bar{\tau}_{h'}$; (c) for m_{j+1}-almost every $((h, V), (h', V'))$ both of the following hold: $h'|_j = h$, and $V'(c) = \mathcal{M}(V)(c)$ for every bond c of $\mathbb{T}^{(j+1)}$ that has no end point in $\mathsf{Z}(h'^{\mathbf{T}})$.

6. Exact insertion of block observables. We write $Z = Z_{K,\ell,\beta} = Z(0)$ and $\mu = \mu_{K,\ell,\beta}$, and $\mathbb{E}_{\mathsf{P}}$ denotes the expectation with respect to a probability measure P. (a) On $\mathcal{V}_0 \times \mathfrak{H}_k \times \mathcal{V}_k$ there exists a probability measure P with the following four properties. Its marginal on $\mathcal{V}_0$ equals μ. Its marginal on $\mathfrak{H}_k \times \mathcal{V}_k$ is built from the averaged terms:

$$\bar{\nu}_k := Z^{-1} \sum_{h \in \mathfrak{H}_k} \delta_h \otimes \bar{\tau}_h.$$

Hence this marginal assigns to every bounded Borel function $\Phi(h, V)$ that is invariant in V the integral $Z^{-1} \sum_h \int \Phi(h, V)\, \tau_h(dV)$, and the law of the histories of level k is the marginal of P on $\mathfrak{H}_k$: for $\mathsf{E}_k \subset \mathfrak{H}_k$, $\mathsf{P}(h \in \mathsf{E}_k) = Z^{-1} \sum_{h \in \mathsf{E}_k} \mathsf{t}(h) = \tilde{\nu}(\mathsf{E}_k)$. It is invariant under the maps $(U, h, V) \mapsto (U^u, h, V^{u|_k})$, $u \in \mathcal{G}_0$. Conditionally on (U, h), the third coordinate agrees with $\mathcal{M}^k U$ on every bond that is clear of $Y(h)$, and in particular on every bond far from $Y(h)$. (b) For each bounded Borel invariant function F on $\mathcal{V}_k$, let

$$F^{(h)}(V) := \mathbb{E}_{\mathsf{P}}\big[F(\mathcal{M}^k U) \,\big|\, h, V\big]$$

be chosen among the versions of the conditional expectation as one that is invariant in V. Versions with this invariance exist, and for each h any two of them coincide τ_h-almost everywhere. Each of them satisfies

$$\big\langle F(\mathcal{M}^k U) \big\rangle_{K,\ell,\beta} = \frac{\sum_h \int F^{(h)}\, d\tau_h}{\sum_h \int d\tau_h},$$

$$|F^{(h)}| \le \sup |F| \ \tau_h\text{-almost everywhere},$$

$$\sum_h \int d\tau_h = Z.$$

(c) Suppose F depends only on the variables of bonds that are clear of $Y(h)$; this is the case in particular when its dependence is confined to bonds far from $Y(h)$. Then one has $F^{(h)} = F$ almost everywhere with respect to τ_h. In particular, for every history in which the large-field operation has acted on none of the components, $F^{(h)} = F$. Without this restriction one has, in general, $F^{(h)} \ne F$. Here the depth s is arbitrary, $0 \le s \le K$, and $k = K - s$.

7. Bounded block observables. Take F as in Statement 6 (b) and level-k cells $\mathfrak{c}_1, \dots, \mathfrak{c}_n$, and denote by $\mathsf{E}_k := \bigcup_{i \le n} \mathfrak{lv}_k(\mathfrak{c}_i) \subset \mathfrak{H}_k$ the event that at least one of these cells is contained in the live region of level k. Then

$$\Big| \big\langle F(\mathcal{M}^k U) \big\rangle_{K,\ell,\beta} - \frac{\sum_{h \notin \mathsf{E}_k} \int F^{(h)}\, d\tau_h}{\sum_h \int d\tau_h} \Big| = \Big| \frac{\sum_{h \in \mathsf{E}_k} \int F^{(h)}\, d\tau_h}{\sum_h \int d\tau_h} \Big|$$

$$\leq \sup|F|\;\tilde{\nu}(\mathsf{E}_k) \leq n\,C\,\sup|F|\,e^{-c_{\mathrm{r}}p_0(g_k)}.$$

The final inequality is valid whenever the data satisfy the hypotheses of the one-cell bound of part §§ 5.20 and 5.22, with C and c_{r} the constants of that bound. It holds uniformly in K, β, ℓ and the positions of the cells. In this form the bound applies to an observable of bounded modulus that depends on the block variables of a bounded number of cells at its own scale. In the expectation of such an observable, the part contributed by the histories of E_k is smaller than any power of g_k.

(iii) Proofs.

On 1. All three assertions are contained in part § 5.20. There they are properties of the measures that the moves produce, taken one string at a time. Positivity. All kernels of all moves are non-negative. Hence the measure into which a string turns $\rho_0\,dU \geq 0$ is finite and non-negative. The stage **T**. In its first move, **T** sets $V_{j+1} := \mathcal{M}(V_j)$, and no later move of **T** alters V_{j+1}. The reason is that the Faddeev–Popov draw uses gauge transformations supported on the sites $B(y)\setminus\{y\}$, and these act on V_j without touching V_{j+1}. Hence at this stage the identity is valid for every bounded Borel F. As an equality of measures, $\sum_{a|_j=h}\tau_a^{\mathbf{T}} = \mathcal{M}_*\tau_h$. The stage **R**. Given a class component X, denote by $\Lambda^{\mathrm{pr}}\cap X$ its box. This box lies well inside X, and **R** integrates the block field over it. Denote by $\mathfrak{b}_X$ the set of bonds of $\mathbb{T}^{(j+1)}$ that have an end point in that box. The moves of **R** alter V_{j+1} on the bonds of the sets $\mathfrak{b}_X$ and nowhere else. Hence at this stage the identity is valid for every bounded Borel F that does not depend on these bonds. Each bond of $\mathfrak{b}_X$ has both end points in X. Therefore every function that depends on no bond with an end point in $\mathsf{Z}(a)$ belongs to this class. The property that matters is that F does not depend on $\mathfrak{b}_X$. Gauge invariance by itself is not enough. A counterexample is the plaquette function that appears in two places: in the block of this part that treats the curvature observable as a source (in the proof concerning the steps as stochastic kernels: the two refinements), and in part § 5.20 (stability; in the proof of Statement 2 on exactness: which functions are transported). Why history by history. Each move, once summed over its outcomes, is a probability kernel at each state. For a move consisting of tests, exactly one outcome takes the value 1. For the gauge fixing the property holds because the gauge fixing is carried out as a procedure, namely as a draw. Let $\mathfrak{G}\geq 0$ be normalised by $\int\mathfrak{G}(V^u)\,du = 1$. Then the measure

$$(\tau\kappa_{\mathfrak{G}})(\mathcal{B}) = \int\tau(dV)\int du\,\mathfrak{G}(V^u)\,\mathbf{1}_{\mathcal{B}}(V^u)$$

has the same mass as τ, for every measure τ. The product $\mathfrak{G}\,\tau$, by contrast, has mass $\int\mathfrak{G}\,d\tau$. If τ is invariant under the group with respect to which $\mathfrak{G}$ is normalised, this coincides with the mass of τ, and then $\tau\kappa_{\mathfrak{G}} = \mathfrak{G}\,\tau$. Suppose that the bare weight is invariant under gauge transformations and that the representatives transform covariantly. Then, history by history, the term on which a gauge-fixing move acts has this invariance (see the treatment of the steps as stochastic kernels at the beginning), and for such a term the draw coincides with the product. The invariance meant here is invariance under the group of the move. A term need not be invariant under the full gauge group of the level. For a measure without this invariance, replacing the draw by the product does not conserve the mass in general. The masses considered from here on are the ones produced by the draw, which preserves them for any bounded Borel weight. Likewise, the axial frames are drawn before the tests that use them. The test that follows the gauge fixing along the tree lacks gauge invariance. Therefore the mass a_r that passes it depends on the frame r. Suppose the components that leave kept a single frame e while the survivors were averaged over the frames. Then the mass after the reference laws would be off by $\bar{a}-a_e$, with $\bar{a}$ the average of the a_r, and already for $F\equiv 1$ the identity of the stage **R** would not hold. Part § 5.20 contains both points (exactness: frames first; the product form). Why it does not suffice to have the identities in their form summed over the histories. Let $\mathcal{V}_0=\mathcal{V}_1=\mathcal{V}_2=\{0,1\}^2$, where bond 1 is exterior and bond 2 is the component. Let $\mathcal{M}=\mathrm{id}$, let the gauge group be trivial, and let μ be the uniform law on the diagonal. Level 1

has two outcomes a_1, a_2, with $\tau^{\mathbf{T}}_{a_1} = \tau^{\mathbf{T}}_{a_2} = \mu/2$, and $\mathbf{R}$ acts on bond 2 in a_2 alone. Thus $\tau_{a_1} = \mu/2$, while τ_{a_2} is the product of the marginal of $\mu/2$ on bond 1 with the uniform law on bond 2. At level 2 no $\mathbf{R}$ acts, and every history has a single continuation, a'_i for a_i. We set $\tau_{a'_1} := \tau_{a_2}$, $\tau_{a'_2} := \tau_{a_1}$. Every term is non-negative. The totals are transported exactly, and the masses are conserved history by history, $\mathsf{t}(a'_i) = \mathsf{t}(a_i)$. Moreover, $\mathbf{R}$ replaces a term by the product of its exterior marginal with a probability law. On $\{h = a'_1\}$, however, $Y(a'_1) = \emptyset$ forces $V = U$, which is a point of the diagonal. Yet $\tau_{a'_1}$ assigns mass $\frac{1}{4}$ to the complement of the diagonal. Hence no P exists. The failure lies in the identity of the stage $\mathbf{T}$ applied to the one history a_1 by itself. Below, the two identities are applied to invariant F alone.

Proof of 2. (a) The map $(v, x) \mapsto F(v \cdot x)$ is bounded and Borel, so Fubini's theorem shows that $\bar{F}$ is Borel. Right invariance of Haar measure gives $\bar{F}(v_0 \cdot x) = \int F(vv_0 \cdot x)\, dv = \bar{F}(x)$. The functional $F \mapsto \int \bar{F}\, d\tau$ is positive and continuous under monotone limits. It therefore defines a measure $\bar{\tau}$. With $F_{v_0}(x) = F(v_0 \cdot x)$, left invariance yields $\overline{F_{v_0}} = \bar{F}$, and this is the invariance of $\bar{\tau}$. The remaining assertions follow from $\bar{F} = F$ for invariant F, applied to indicators as well. (b) If ν is invariant, Fubini's theorem gives $\int \bar{F}\, d\nu = \int dv \int F(v \cdot x)\, \nu(dx) = \int F\, d\nu$. Hence ν is determined by the values it assigns to the integrals of the invariant functions $\bar{F}$. (c) This follows by a change of variables. By this device, the proof converts the two identities of Statement 1 into equalities of measures, namely equalities between the gauge averages of the terms. The proof applies these identities to invariant functions only.

Proof of 3. We apply the disintegration theorem in the following form. Let $\mathcal{X}$, $\mathcal{Y}$ be compact metrisable, let $p : \mathcal{X} \to \mathcal{Y}$ be Borel, let λ be a finite positive measure on $\mathcal{X}$, and let $\nu = p_*\lambda$. Then there exist probability measures $\kappa(y; \cdot)$ on $\mathcal{X}$, Borel in y, such that $\lambda(B) = \int \nu(dy)\, \kappa(y; B)$ and $\kappa(y; p^{-1}\{y\}) = 1$ for ν-almost every y. Set $\nu = (p_i)_*\lambda_i$, and let $\kappa_i(y; \cdot)$ be a disintegration of this kind of λ_i along p_i. Define

$$\lambda(B) := \int \nu(dy)\, \big(\kappa_1(y; \cdot) \otimes \kappa_2(y; \cdot)\big)(B).$$

The integrand is Borel in y, because the sets B with this property form a Dynkin class that contains the products of Borel sets. We have $\lambda(B_1 \times \mathcal{X}_2) = \int \nu(dy)\kappa_1(y; B_1) = \lambda_1(B_1)$, and the second marginal is treated in the same way. The set $\{p_1(x_1) = p_2(x_2)\}$ is Borel and contains $p_1^{-1}\{y\} \times p_2^{-1}\{y\}$. For ν-almost every y, the latter set has full measure under $\kappa_1(y; \cdot) \otimes \kappa_2(y; \cdot)$.

Proof of 4. (a) Every site lies in its own block. (b) For a site y of $\mathbb{T}^{(j+1)}$, its cube is the union, over the sites $x \in B(y)$ of $\mathbb{T}^{(j)}$, of their cubes. After intersection with the bare lattice this becomes $B^{j+1}(y) = \bigcup_{x \in B(y)} B^j(x)$. Consequently $B^j(b_\pm) \subset B^{j+1}(c_-) \cup B^{j+1}(c_+)$. (c) This follows from $Y(h) \subset Y(h)^\sim$.

Proof of 5. The measures τ_h, $\tau_{h'}$, $\tau^{\mathbf{T}}_a$ are all finite and non-negative. Consequently the gauge average of each of them is a finite, positive and invariant measure. Step 1 (the stage $\mathbf{T}$: Radon–Nikodym). Let $h \in \mathfrak{H}_j$ be fixed. The map $\mathcal{M}$ is covariant, $\mathcal{M}(V^v) = \mathcal{M}(V)^{v|_{j+1}}$, as well as Borel measurable, and $v \mapsto v|_{j+1}$ is a surjection of $\mathcal{G}_j$ onto $\mathcal{G}_{j+1}$. Therefore $\mathcal{M}_*\bar{\tau}_h$ is invariant, and $F \circ \mathcal{M}$ is invariant whenever F is. Let F be any bounded Borel function on $\mathcal{V}_{j+1}$. Applying the transport identity of the stage $\mathbf{T}$ to the invariant function $\bar{F}$, we obtain

$$\sum_{a|_j = h} \int F\, d\bar{\tau}^{\mathbf{T}}_a = \sum_{a|_j = h} \int \bar{F}\, d\tau^{\mathbf{T}}_a = \int (\bar{F} \circ \mathcal{M})\, d\tau_h = \int (\bar{F} \circ \mathcal{M})\, d\bar{\tau}_h = \int \bar{F}\, d(\mathcal{M}_*\bar{\tau}_h) = \int F\, d(\mathcal{M}_*\bar{\tau}_h).$$

Hence $\sum_{a|_j = h} \bar{\tau}^{\mathbf{T}}_a = \mathcal{M}_*\bar{\tau}_h$. In particular $0 \le \bar{\tau}^{\mathbf{T}}_a \le \mathcal{M}_*\bar{\tau}_h$. Therefore $\bar{\tau}^{\mathbf{T}}_a = f_a \cdot \mathcal{M}_*\bar{\tau}_h$ for Borel functions $0 \le f_a \le 1$ with $\sum_{a|_j = h} f_a = 1$ almost everywhere. Define $\mathsf{m}^{\mathbf{T}}_a$ as the image of $(f_a \circ \mathcal{M})\, \bar{\tau}_h$ under $V \mapsto (V, \mathcal{M}(V))$. It is a measure on pairs $(V, W) \in \mathcal{V}_j \times \mathcal{V}_{j+1}$. The marginals of this measure are $(f_a \circ \mathcal{M})\bar{\tau}_h$ and $\bar{\tau}^{\mathbf{T}}_a$, and almost surely $W = \mathcal{M}(V)$. What the identity transports is the sum

over the outcomes and nothing more. It does not fix which portion of τ_h goes to which a, and the only splitting it supplies is the one by $f_a \circ \mathcal{M}$. Accordingly, under the coupling just constructed, the outcome a is drawn with probability $f_a(\mathcal{M}(V))$, and it is not determined by the tests. Step 2 (the stage **R**: restriction off the class). Fix a. Let $\mathrm{Bd}(a)$ denote the set of bonds of $\mathbb{T}^{(j+1)}$ having no end point in $\mathsf{Z}(a)$. Let $\mathcal{V}(a)$ be the space of configurations on $\mathrm{Bd}(a)$, and let $\mathrm{res}_a : \mathcal{V}_{j+1} \to \mathcal{V}(a)$ be the restriction map, which commutes with the gauge action. Set $\lambda_a := \sum_{h'^{\mathbf{T}}=a} \delta_{h'} \otimes \bar{\tau}_{h'}$. Let f be a bounded Borel invariant function on $\mathcal{V}(a)$. Then $f \circ \mathrm{res}_a$ is invariant and depends on no bond with an end point in $\mathsf{Z}(a)$. The transport identity of the stage **R** therefore gives

$$\sum_{h'^{\mathbf{T}}=a} \int (f \circ \mathrm{res}_a)\, d\bar{\tau}_{h'} = \sum_{h'^{\mathbf{T}}=a} \int (f \circ \mathrm{res}_a)\, d\tau_{h'} = \int (f \circ \mathrm{res}_a)\, d\tau_a^{\mathbf{T}} = \int (f \circ \mathrm{res}_a)\, d\bar{\tau}_a^{\mathbf{T}}.$$

The measure $(\mathrm{res}_a)_* \bar{\tau}_a^{\mathbf{T}}$ and the image of λ_a under $(h', V') \mapsto \mathrm{res}_a(V')$ are both invariant, so Statement 2 (b) shows that they are equal. The identity says nothing about the bonds with an end point in $\mathsf{Z}(a)$. For this reason the two measures are glued over $\mathcal{V}(a)$. The result is a measure $\mathsf{m}_a^{\mathbf{R}}$ on $\mathcal{V}_{j+1} \times (\mathfrak{H}_{j+1} \times \mathcal{V}_{j+1})$ with marginals $\bar{\tau}_a^{\mathbf{T}}$ and λ_a. Almost surely under it, $\mathrm{res}_a(V') = \mathrm{res}_a(W)$ and $h'^{\mathbf{T}} = a$. Step 3 (composition). On the middle field W, the marginal of $\mathsf{m}_a^{\mathbf{T}}$ and the marginal of $\mathsf{m}_a^{\mathbf{R}}$ are both equal to $\bar{\tau}_a^{\mathbf{T}}$. We glue over $\mathcal{V}_{j+1}$ and discard the middle field. We then attach to V the label $h = a|_j$ and sum over a. The resulting measure is m_{j+1}. (a): $\sum_{a|_j=h} (f_a \circ \mathcal{M}) \bar{\tau}_h = \bar{\tau}_h$. (b): $\sum_a \lambda_a = \sum_{h'} \delta_{h'} \otimes \bar{\tau}_{h'}$, because each h' has exactly one first stage. (c): almost surely $W = \mathcal{M}(V)$, $\mathrm{res}_a(V') = \mathrm{res}_a(W)$ and $h'^{\mathbf{T}} = a$, so that $h'|_j = a|_j = h$.

Proof of 6. For $0 \le j \le k$ we define

$$\mathsf{A}_j := \{(U, h, V) \in \mathcal{V}_0 \times \mathfrak{H}_j \times \mathcal{V}_j : V(b) = (\mathcal{M}^j U)(b) \text{ for every bond } b \text{ of } \mathbb{T}^{(j)} \text{ clear of } Y(h)\},$$

which is a Borel set. Step 1 (induction on the level). We show that, for each $0 \le j \le k$, the space $\mathcal{V}_0 \times \mathfrak{H}_j \times \mathcal{V}_j$ carries a probability measure P_j with the following three properties. Its projection to $\mathcal{V}_0$ is μ. Its marginal on $\mathfrak{H}_j \times \mathcal{V}_j$ equals $Z^{-1} \sum_{h \in \mathfrak{H}_j} \delta_h \otimes \bar{\tau}_h$, which is the family of averaged terms. Finally, $\mathsf{P}_j(\mathsf{A}_j) = 1$. To begin the induction: the measure $\rho_0\, dU$ is invariant, so $\bar{\tau}_\varnothing = \tau_\varnothing$, and we take for P_0 the push-forward of μ under $U \mapsto (U, \varnothing, U)$. Passage from j to $j+1$: by the second property together with Statement 5 (a), the measures P_j and $Z^{-1}\mathsf{m}_{j+1}$ induce the same marginal on $\mathfrak{H}_j \times \mathcal{V}_j$. We glue the two over this space and project the result onto (U, h', V'), which gives P_{j+1}. The first two properties carry over, and Statement 5 (b) is what carries over the second. As for the third, with probability one we have $(U, h, V) \in \mathsf{A}_j$, $h'|_j = h$, and $V'(c) = \mathcal{M}(V)(c)$ outside $\mathsf{Z}(h'^{\mathbf{T}})$. Take a bond c clear of $Y(h') = Y(h) \cup \mathsf{Z}(h'^{\mathbf{T}})$. Both of its end points belong to $\mathrm{Bl}_{j+1}(c)$, so neither lies in $\mathsf{Z}(h'^{\mathbf{T}})$, and therefore $V'(c) = \mathcal{M}(V)(c)$. For each bond b of the double block of c we have $\mathrm{Bl}_j(b) \subset \mathrm{Bl}_{j+1}(c)$. Hence such a bond is clear of $Y(h)$, and $V(b) = (\mathcal{M}^j U)(b)$. Because $\mathcal{M}(V)(c)$ depends on V only through these bonds, we obtain

$$V'(c) = \mathcal{M}(V)(c) = \mathcal{M}(\mathcal{M}^j U)(c) = (\mathcal{M}^{j+1} U)(c).$$

Step 2 (symmetrisation). The group $\mathcal{G}_0$ acts on triples by $(U, h, V) \mapsto (U^u, h, V^{u|_k})$. Averaging P_k over this action gives a measure P, and it is invariant under the action. Since μ and $\bar{\nu}_k = Z^{-1} \sum_h \delta_h \otimes \bar{\tau}_h$ are both invariant, P still has the first two properties. Covariance gives $\mathcal{M}^k(U^u) = (\mathcal{M}^k U)^{u|_k}$, so the condition $V(b) = (\mathcal{M}^k U)(b)$ holds exactly when $V^{u|_k}(b) = (\mathcal{M}^k(U^u))(b)$ does. Thus the set A_k is invariant, and $\mathsf{P}(\mathsf{A}_k) = \mathsf{P}_k(\mathsf{A}_k) = 1$. Let Φ be a function and N a Borel set, both invariant in V, with sections N_h. Then Statement 2 (a) gives

$$\int \Phi\, d\bar{\nu}_k = Z^{-1} \sum_h \int \Phi(h, V)\, \tau_h(dV),$$

$$\bar\nu_k(N) = Z^{-1}\sum_h \tau_h(N_h).$$

This is why the statement is restricted to invariant Φ and F. The marginal of P consists of the averaged terms, and the averaged terms coincide with the terms only on invariant functions and invariant sets. Step 3 (assertion (a)). The marginals and the invariance were obtained in Step 2. A function of h alone is invariant in V, and this yields the law of the histories. Because $\mathsf{P}(\mathsf{A}_k) = 1$, for almost every (U, h) a regular conditional distribution of V given (U, h) is concentrated on the configurations that agree with $\mathcal{M}^k U$ on every bond clear of $Y(h)$, and so in particular on every far bond. Step 4 (invariant versions). Suppose that F is invariant, and set $\mathsf{f}(U) := F(\mathcal{M}^k U)$. This function is invariant under $\mathcal{G}_0$. Take an arbitrary version Ψ of $\mathbb{E}_{\mathsf{P}}[\mathsf{f}(U)|h, V]$ with $|\Psi| \le \sup|F|$, so that $\mathbb{E}_{\mathsf{P}}[\mathsf{f}(U)\phi(h, V)] = \int \Psi\phi\, d\bar\nu_k$ for every bounded Borel ϕ. Each $v \in \mathcal{G}_k$ is of the form $u|_k$, where $u \in \mathcal{G}_0$ takes the value $v(y)$ on the block $B^k(y)$. Using the invariance of P, of f and of $\bar\nu_k$, we get

$$\mathbb{E}_{\mathsf{P}}[\mathsf{f}(U)\phi(h,V)] = \mathbb{E}_{\mathsf{P}}[\mathsf{f}(U^u)\phi(h,V^v)] = \mathbb{E}_{\mathsf{P}}[\mathsf{f}(U)\phi(h,V^v)] = \int \Psi(h,V)\phi(h,V^v)\,d\bar\nu_k = \int \Psi(h,V^{v^{-1}})\phi(h,V)\,d\bar\nu_k.$$

The first equality holds because P is jointly invariant. We integrate over v, apply Fubini's theorem and use the fact that Haar measure is invariant under inversion. It follows that $F^{(h)}(V) := \int \Psi(h, V^v)\, dv$ is also a version, and that it is Borel, invariant in V and bounded by $\sup|F|$. Any two invariant versions differ only on an invariant Borel set N with $\bar\nu_k(N) = 0$. Since the terms are non-negative, this gives $\tau_h(N_h) = 0$ for every h. Step 5 (assertion (b)). Take an invariant version. Then

$$\langle F(\mathcal{M}^k U)\rangle = \int \mathsf{f}\, d\mu = \mathbb{E}_{\mathsf{P}}[\mathsf{f}(U)] = \int F^{(h)}(V)\,\bar\nu_k(dh, dV) = Z^{-1}\sum_h \int F^{(h)}\, d\tau_h.$$

The last equality uses the invariance of $F^{(h)}$ in V. Taken by itself, the defining property of a conditional expectation yields the integral against $\bar\nu_k$ and nothing more. No use can be made at this point of a non-invariant version. Consider a term in which some component has been put into the second class by the large-field operation at level k. By part § 5.20, such a term carries, in the level-k block field, a Dirac distribution on the gauge tree of the box. Consequently τ_h and $\bar\tau_h$ are mutually singular for such a term. A version is determined $\bar\tau_h$-almost everywhere, and in this case the integral against τ_h of a version that is not invariant is then arbitrary. Taking $\Phi \equiv 1$ gives $\sum_h \int d\tau_h = Z$. For every h, any invariant version coincides τ_h-almost everywhere with the version constructed in Step 4, and that version is bounded by $\sup|F|$. Step 6 (assertion (c)). Fix h_0, and suppose that F depends only on bonds clear of $Y(h_0)$. On $\mathsf{A}_k \cap \{h = h_0\}$ we then have $F(\mathcal{M}^k U) = F(V)$. It follows that

$$\mathbb{E}_{\mathsf{P}}[\mathsf{f}(U)\mathbf{1}_{\{h=h_0\}}\phi(V)] = \mathbb{E}_{\mathsf{P}}[F(V)\mathbf{1}_{\{h=h_0\}}\phi(V)]$$

for every bounded Borel ϕ. In other words, $F^{(h_0)} = F$ $\bar\nu_k$-almost everywhere on $\{h_0\} \times \mathcal{V}_k$. The set on which this equality fails is invariant in V and is therefore a τ_{h_0}-null set. When the operation has acted on no component of h_0, we have $Y(h_0) = \emptyset$, and then every bond is clear.

Proof of 7. The equality comes from splitting the numerator of Statement 6 (b) into the part over E_k and the part over its complement. We have $\tau_h \ge 0$, and $|F^{(h)}| \le \sup|F|$ holds τ_h-almost everywhere. Hence $|\int F^{(h)}\, d\tau_h| \le \sup|F|\,\mathsf{t}(h)$. Summing this over $h \in \mathsf{E}_k$ and dividing by $Z = \sum_h \mathsf{t}(h)$ gives $\sup|F|\,\tilde\nu(\mathsf{E}_k)$. Subadditivity together with the one-cell bound $\tilde\nu(\mathfrak{w}_k(\mathfrak{c})) \le C\, e^{-c_{\mathrm{r}} p_0(g_k)}$ of part §§ 5.20 and 5.22 yields $\tilde\nu(\mathsf{E}_k) \le n\, C\, e^{-c_{\mathrm{r}} p_0(g_k)}$. For a history outside E_k, no one of the cells lies in a large-field region that is live at level k.

(iv) What is used.

From other parts. The following results of part § 3.1.1 are used. The map $\mathcal{M}$ is Borel. It is gauge covariant: $\mathcal{M}(V^v) = \mathcal{M}(V)^{v'}$, where v' is obtained from v by restriction to the sites of the coarser lattice. It is local: $\mathcal{M}(V)(c)$ depends on V only through the bonds of the double block of c. From part § 5.20 we use three things. The first is the description of the construction as a chain of moves. The second is that every kernel is non-negative, so that every τ_h and every $\tau_a^{\mathbf{T}}$ is a finite non-negative measure. The third is the pair of transport identities of Statement 1. From part §4.17.1.3 we use the class of the large-field operation, which enters through the recursion $Y(h') = Y(h'|_j) \cup \mathsf{Z}(h'^{\mathbf{T}})$. Statements 1 to 6 use nothing further from the construction: no bound, no analyticity, and no form of a term. Only Statement 7 draws in addition on part §§ 5.20 and 5.22, through the one-cell bound there on the law of the histories.

Where it is used. Statement 7 is obtained by combining Statement 6 with the one-cell bound of part §§ 5.20 and 5.22. The other parts draw on the identity $\sum_{h'|_j=h} \mathsf{t}(h') = \mathsf{t}(h)$, which is the last line of Statement 1. This identity makes the laws of the histories of the levels $j \le K$ a consistent family of probability measures. That family is the law $\tilde{\nu}$ of part §§ 5.20 and 5.22. The bounds on large fields rest on it, and through them so do the laws at one scale. For $k \ge 1$ the observables of the theorem do not have the form $F(\mathcal{M}^k U)$. Indeed, $\mathcal{O}(f) = \sum_p f(x(p))\, a_p(U)$ is a function of the bare plaquettes, and Statement 6 cannot be applied to it. These observables are carried as sources (first block of this part). A single scale is isolated by exactness with sources at depth s:

$$\sum_{h \in \mathfrak{H}_{K-s}} \tau_h^w(\mathcal{V}_{K-s}) = Z(w),$$

whence, at $c = 0$,

$$\Big\langle \exp \sum_i z_i\, \mathcal{O}(f_i) \Big\rangle_{K,\ell,\beta} = \frac{Z(w)}{Z(0)}$$

and this quantity is an expectation, taken over the histories, the block fields and the stored variables at level $K - s$, of the exponential of the sourced exponent minus the unsourced one.

Against Bałaban's papers. Bałaban presents the operation $\mathbf{R}$ in a simplified form in the Introduction of Comm. Math. Phys. 122 (1989) 175, formula (0.3) on p. 176:

$$(\mathbf{R}\rho)(V) = \sum_Z \rho(Z'', V) \int dV|_{Z'}\, \rho(Z, V) / \int dV|_{Z'}\, \rho(Z'', V).$$

This form has the normalisation property $\int dV\, (\mathbf{R}\rho)(V) = \int dV\, \rho(V)$ ((0.4)). In the procedure as actually carried out, the denominators integrate parts of the densities that are localised near Z' (p. 177), and the normalisation property takes the form (1.102), p. 201. The objects treated in Bałaban's papers are densities. On observables, he states that his Theorem 1 "is the basis for many other applications, for example, for an analysis of expectation values of physical observables, like loop variables, averaged loop variables", and calls these problems that "deserve detailed analysis and further publication" (Comm. Math. Phys. 122 (1989) 355, p. 356).

5.20.1.2. Analytic dependence on the source; locality and decay in tame and in wild regions. **Objects.** We write $w(p) := w(x(p))$. When the source is a constant shift $w \equiv \zeta$, the increments $b_j(\zeta)$ are computed on the infinite lattice in the same way as b_j. They therefore do not depend on the torus, and they are real for real ζ. The running shift is $\zeta_k = \zeta + \sum_{j \le k} [b_j(\zeta) - b_j(0)]$, and the inverse couplings are $x_k - \zeta_k$. For a general source, let p_y denote a bare plaquette at y. Then

$$\zeta_k(p; w) = w(p) + \sum_{j \le k} \varphi_j(p) \sum_{y \in \mathbb{T}^{(j)}} h_y^{(j)}(p)\, [b_j(w(p_y)) - b_j(0)]\ :$$

in other words, the coupling counterterm of level j is applied locally, and its coefficient is taken at the local value of the source.

Proposition 5.68 (The format with sources)**.** The density ρ_k^w has the form of §4.17.1.45, with $x_k(\cdot)$ replaced by $x_k(\cdot)-\zeta_k(\cdot;w)$. Its activities $E^{(j),w}, R^{(j),w}, B^{(j),w}$ are holomorphic in (c,z), depend on w only through its values on $X^{\sim 1}$, and obey the bounds valid at $w=0$ up to constants. Moreover $|\zeta_k(p;w)| \le \frac{4}{3}\sup|w|$, and for every constant $|\zeta_*| < 2\varrho$

$$|E^{(j),w}(X,\cdot) - E^{(j),\zeta_*}(X,\cdot)| \le E_0\,\varrho^{-1}\mathsf{m}_j\, e^{-\kappa d_j(X)},$$
$$\mathsf{m}_j := \max\Big\{\sup_{X^{\sim 1}}|w-\zeta_*|,\, CML^{j-K}\,\mathrm{Lip}\,w\Big\}. \qquad \blacksquare$$

Strategy: induction on the levels, on a complex polydisc of data. On a complex polydisc of data (activities, boundary terms, shifts) centred at the real run, a single step (the cluster expansion of § 4.5 together with **R** of §4.17.1.3–§ 4.17) is local, analytic and uniformly bounded. This is the step on the complex class of §4.17.1.45. Its small-field core is the holomorphic map on local families required by the ordinary-step hypothesis. The sourced data remain inside the polydisc, so holomorphy follows by composition. Locality follows because an activity at X depends on the data, and on the outcomes of the history, only near X (locality in the history, §4.17.1.1).

The marginal term. When the source is constant, the step preserves the symmetries of § 4.2, so once $b_{k+1}(\zeta)A$ has been extracted only irrelevant terms remain. The estimate is the one of § 5.2.3. There is a remainder $\le C g_k^{\kappa_0-4}$, coming from the $R^{(j)}$, which is holomorphic in ζ on a disc of radius $C\varrho$. Apart from this remainder, the increment b_{k+1} is holomorphic in the shifts ζ_j of the earlier levels on discs of radius cx_j, where $c \le \sigma_\star$. These discs make up the polydisc of § 4.5, taken along the run's own couplings. On these discs its non-constant part, less the remainder, is bounded by $Cg_k(\log x_k)^{\mathfrak{p}_0}$. Cauchy's estimate together with $x_k \ge g^{-2} + c(K-k)$ yields

$$|b_{k+1}(\zeta) - b_{k+1}(0)| \le \mathsf{a}_{[K-k-1]}|\zeta|,$$
$$\sum_{s<K}\mathsf{a}_{[s]} \le C\sum_k [g_k^3(\log x_k)^{\mathfrak{p}_0} + \varrho^{-1}g_k^{\kappa_0-4}] \le \tfrac{1}{6},$$

where the quantity $\mathsf{a}_{[s]}$ carries a depth index and denotes, for the step that arrives at depth s, the Lipschitz number of its increment (the same letter is used in § 5.2.3 and § 5.2 and appendix A.8). Consequently $|\zeta_k'(0)-1| \le \frac{1}{6}$. On the smaller real interval $|\zeta| \le \varrho$ one obtains $\zeta_k'(\zeta) \in [\frac{2}{3}, \frac{4}{3}]$: on $|\zeta| < 2\varrho$ the holomorphic quotient $[b_j(\zeta)-b_j(0)]/\zeta$ is bounded by $\mathsf{a}_{[K-j]}$, and Cauchy's estimate on the half-disc gives $|b_j'(\zeta)| \le 2\mathsf{a}_{[K-j]}$. The sum was chosen at most $1/6$ for this fixed loss. No derivative bound throughout the full open source disc follows from the radial inequality alone. On X a general source is compared with $\zeta_* = w(p_*)$, where p_* is a bare plaquette of $X^{\sim 1}$. When $\mathsf{m}_j < \varrho$, the slope displayed above comes from the Schwarz lemma, applied along a line of data and not along a line of sources. This line is a family, holomorphic in t, of data of the level below; at $t=0$ it coincides with the data of ζ_*, and at $t=1$ it coincides on $X^{\sim 1}$ with those of w. For $|t| < \varrho/\mathsf{m}_j$ the family remains in the convex polydisc. When $\mathsf{m}_j \ge \varrho$, the slope is simply the sup bound. Subtract from each of the two activities the normaliser part $\mathbf{N}^{(j)}$ of § 4.5, which is common to both; what is left of each is at most $\frac{1}{2}E_0e^{-\kappa d_j(X)}$. The slope is thus a clause that the induction carries along. The defect estimate uses the sharper, normalizer-subtracted bound of the local data-line argument. The induction carries similar slopes for $R^{(j)}$ and $B_{\mathcal{S}}^{(j)}$, and also, among the operations treated below, for the excess exponents Ψ_ω. The slope does not follow, up to the boundary of the class of sources $\{\|w\|_\flat < 2\varrho\}$, from holomorphy in w, from the bound, from locality and from the agreement at constant sources. Moreover, $\mathsf{m}_j \le e^{d_j(X)}L^{-(K-j)}\|w\|_\flat$. The part that

no counterterm renormalises therefore carries a factor $L^{-(K-j)}$, which is summable over the scales. In short, a gradient of the source is irrelevant.

Wild regions. Two kinds of operations act on the sourced exponent. The first kind consists of the operations $\mathbf{T}_k(Z)$ on the components on which $\mathbf{R}$ has not acted. These are built from the choices of the run only, namely delta functions, tests, gauge-fixing factors and conditional Gaussian weights, and they contain no Wilson weight §4.17.1.3. On such components the source appears in the function on which these operations act, that is, in the Wilson weight and in the boundary terms. Taken on its own, $\mathbf{T}_k(Z)1$ carries no small factor: for a component produced by failed plaquette tests, this quantity is $\le \exp[C\sum_{t\le k}\#_t(Z_t\cap Z)]$. Three places carry the small factor §4.17.1.40: the Gaussian forms of the fluctuation fields, the kept gauge-fixing exponents and the Wilson weight. Only the last of these depends on the source; the first two are built from the choices of the run. The pointwise majorant of §4.17.1.40 gives one factor $e^{-cp_0(g_t)^2}$ for each creation, at the coupling of that creation's own step, and one constant for each site. It is used in the form it has at $w=0$; the sourced exponent and the unsourced one are compared further below, on the supports of the tests.

The second kind concerns a component X on which $\mathbf{R}$ has acted at some level i (whether it was healed, remained as an island, or dropped out because a test of a stage or of the main step failed). For such a component the source enters inside its operation $\mathbf{T}'_i(X)$. Except for a drop-out, this operation contains the Wilson factor of the core. When the component is healed or is an island, the operation coincides with that of Bałaban, Comm. Math. Phys. 122 (1989) 355, (1.71). Let ω run over the local histories of X, let ξ be the stored variables and $\mu_\omega\ge 0$ their measures, and let $\mathbf{p}=(\mathbf{U},\mathbf{J})$ be the pairs on $X^\sim$ at which a term evaluates the factor of X §4.17.1.40. For each ω, e^{Φ_ω} is replaced by $e^{\Phi_\omega+\Psi_\omega}$, with an *excess exponent*

$$\Psi_\omega = A\big(\hat\zeta\,\phi_{\mathrm{c}}\mathbf{1}_X, U''(\xi)\big) + [V^w - V^0](X^\sim) + \sum_{\omega'}\Psi_{\omega'}\,:$$

its summands are the Wilson term, weighted by the shift $\hat\zeta$ of the prepared regions ($|\hat\zeta|\le C\varrho$, and $0\le\phi_{\mathrm{c}}\le 1$ is the cut-off on the old core, § 4.17) and evaluated at the background $U''(\xi)$ of the inner region, which is constructed from the stored fields; the difference between the interaction terms V of $\mathbf{R}$ with and without the source; and the exponents of the inner histories ω', namely those of the swallowed islands and drop-outs. The operation modified in this way is written $\mathbf{T}'_i(X;w)$. (In the case of a drop-out, the operation §4.17.1.40 is taken to include the Wilson weight that the carrying term has over X. The operations that are kept are built from the choices of the run only, and none of their factors depends on the source, which appears in that Wilson weight and in the boundary terms. The exponent is then $\sum_{\omega'}\Psi_{\omega'}$ alone, the contribution of the swallowed islands, and it obeys the bound given below.) The exponent Ψ_ω is holomorphic in (c,z), is real for real pairs and real sources, vanishes at $w=0$, and depends on w only on $X^{\sim 2}$. The background U'' is real, and its regularity holds only at the scale on which the respective layer was stored. Where $\phi_{\mathrm{c}}\ne 0$, one has $|\partial U''-\mathbf{1}|\le C\check R_n^2\varepsilon_n\eta_n^2\le C\eta_n^2$ on $\Omega_n\setminus\Omega_{n+1}$, so the bound $a_p\le C\eta_n^4$ balances the $C\eta_n^{-4}$ plaquettes per site of level n (on the bare layer $a_p\le 2$, since G is compact). Each layer therefore contributes $O(\varrho)$ for each site of its own scale:

$$|\Psi_\omega|\le \bar f\,\#(\omega),$$
$$\bar f = C(1+\varrho),$$

where, as in §4.17.1.45, $\#(\omega)$ is the number of stored sites, each being counted at its own level. Since $\#(\omega)$ is additive over the inner histories, the constant after a step is the maximum of $\bar f$ and the constant of the new term, not their sum. Hence the constant does not increase with the level. The perturbation is extensive and must therefore be paid in advance. This is done by the

mass bound of §4.17.1.40, §4.17.1.45, which the induction maintains with a reserve weight $e^{c\mathsf{v}(\omega)}$, where $c = c_{\mathrm{r}}$ is the reserve constant of §4.17.1.45, one fixed number (the same constant stands in every weight $e^{c\mathsf{v}}$ of this part except the raised one in the bound of the whole label, whereas in the exponents that contain p_0 the letter c denotes a generic constant). Here the space-time volume $\mathsf{v}(\omega)$ counts $\log x_j$ for each stored site of level j:

$$\mathsf{M}(i,X) := \frac{1}{|W_4|}\sum_{\omega} e^{c\mathsf{v}(\omega)} \int \sup_{\mathbf{p}} \left|e^{\Phi_\omega(\xi;\mathbf{p})}\right| \mu_\omega(d\xi) \le e^{-(2-c')p_0(g_i)},$$

with the supremum over the complex pairs taken inside the integral and the sum. This form applies to a healed component and to an island. In the case of a drop-out, the integral contains the Wilson weight of the carrying term over X. The supremum is then taken over the evaluations at ξ, that is, over the real configurations which are compatible with the stored variables, are regular layer by layer, and give the listed tests their recorded values, with the exception of the test whose failure made X a drop-out; these evaluations form a set fibred over ξ §4.17.1.40. A product set contains a flat $\mathbf{U}$, at which $e^{-A} = 1$, and the supremum over such a set removes the factor. Bałaban's bound is $\mathbf{T}'_k(X)1 \le e^{-(2-c')p_0(g_k)}$ (ibid., (1.89), where Bałaban has $2(1+\beta_0)^{-1}$ in place of $2-c'$), for each fixed pair and without the weight. If g is small enough once ϱ has been fixed, then $c\log x_j \ge 2\bar{f}$. Consequently $|e^{\Psi_\omega}| \le e^{c\mathsf{v}(\omega)}$, and for every bounded function F of the stored variables and every evaluation of this kind

$$\left|\mathbf{T}'_i(X;w)F\right| = \left|\frac{1}{|W_4|}\sum_{\omega}\int F\, e^{\Phi_\omega+\Psi_\omega}\, d\mu_\omega\right| \le \sup|F|\,\mathsf{M}(i,X) \le \sup|F|\, e^{-(2-c')p_0(g_i)}.$$

Under a positive measure, the modulus of a complex factor serves as a bound for it; in the case of the small complex term produced by a complex pair, this is the device of Bałaban, Comm. Math. Phys. 122 (1989) 355, (1.73). The estimate just displayed is made on the moduli, and a sourced component retains the small factor of the unsourced one. That $\mathbf{T}'_i(X;w)F$ is holomorphic follows from dominated convergence together with the theorems of Morera and Fubini. For a healed component, the exponentiation of § 4.17 produces its local terms from this bound, each at most $e^{-p_0(g_i)}e^{-\kappa d_i(Y)}$ on a domain Y, just as at $w = 0$.

The whole label. Bounds on the individual components cannot be multiplied together, even though each is uniform in the variables outside its own component, because the background couples the components. (For $\mathbf{1}\{|\xi_1 - \xi_2| < \epsilon\}$ on $[0,T]^2$, every integral in one variable is $\le 2\epsilon$, while the double integral equals $2\epsilon T - \epsilon^2$.) By Tonelli, what does multiply is a product of functions of disjoint groups of variables; here the factors of this one product are the pieces of the pointwise majorant together with the integrands of the masses. For this reason the supremum is placed inside the integral. The result is the integrated bound of §4.17.1.40, with one factor for each creation and one mass for each outermost component on which $\mathbf{R}$ has acted. If every e^{Φ_ω} in $\mathbf{T}'_k(\mathcal{S})$ is replaced by $e^{c\mathsf{v}(\omega)}|e^{\Phi_\omega}|$, then

$$\int \mathbf{T}'_k(\mathcal{S})\Big[\chi_{k,\mathcal{S}}\, e^{-A(x_k(\cdot),U_k(\mathbf{V}))}\Big]dV_k \le \exp\Big[C\sum_{j\le k}(1+\log x_j)\,\#_j(Z_j)\Big]\prod_{(t,\mathfrak{c})} e^{-cp_0(g_t)}\prod_{(i,X)}\mathsf{M}(i,X),$$

where the first product runs over those creation cells, outside these components, that belong to a single history with the label $\mathcal{S}$, namely the history for which this product is largest (the creation cells are not determined by the label, §4.17.1.40). The second runs only over the outermost ones among the components on which $\mathbf{R}$ has acted and which remain in the label. (In §4.17.1.40 the bound carries $p_0(g_t)^2$ and has no logarithm. The sum over the labels needs only the present weaker form, because $CM^4\check{R}_t^5\log x_t \le \frac{1}{2}c\,p_0(g_t)$ (the logarithmic cost allowed in the rarity hypothesis): half of the exponent pays the cost and the other half is kept. Inside a drop-out the mass has

consumed the factors of the creations, and whatever the label still shows there is paid for by the weight. The masses are required at a weight that exceeds the $e^{c\mathsf{v}(\omega)}$ spent by the sources by a constant; this constant is determined by the per-site cost of the part of the label visible inside the drop-out, and its choice comes after that of ϱ and before the ceiling on g is set (the mass bound is valid at every weight $c \geq 0$, §4.17.1.40, and the masses $\mathsf{M}(i, X)$ in the display are understood at the raised weight). The surplus comes from that part of $\mathsf{M}(i, X)$ which is made up of the local histories admitted by the label; on these, $\mathsf{v}(\omega)$ is bounded below by the volume shown §4.17.1.40, §4.17.1.45.) Once its vacuum constant is set aside, the sourced term of the label is dominated by the left-hand side multiplied by $e^{C(1+\varrho)}$ for each bond of the determining set, for three reasons. The moduli are taken inside the integrals. In the operations, $|e^{\Psi_\omega}| \leq e^{c\mathsf{v}(\omega)}$. On the supports of the tests, what remains of the sourced exponent once the Wilson term $-A(x_k(\cdot), U_k)$ and the vacuum constant are set aside is at most $C(1 + \varrho)$ for each bond of the determining set § 5.20. Consider the weighted sum over the labels of §4.17.1.45, that is, the total masses summed over $\mathcal{S}$, where the credit pays the costs. In it every component C of Z_k keeps a factor

$$\exp\big[-cp_0(g_k) - \kappa_1 |C|_k\big],$$

where $|C|_k$ is measured in cells. In §4.17.1.40 the factor is taken per site, with $\#_k(C) \geq d_k(C)$ in place of $|C|_k$. This contains the form "with the additional term $-\kappa_1 d_k(X)$", which Bałaban gives for a general region (ibid., p. 387).

The cost of the reserve. A factor $e^{c \log x_j}$ for each site amounts to at most $e^{cM^4 \check{R}_j^5}$ for each cell. Its form is that of the volume costs $CM^4 \check{R}_n^5$ per cell and per step, which, until $\mathbf{R}$ acts on a component, are covered by the credit $\kappa_j(Z)$ of that component: an amount $p_0(g_j)^2$ for each cube, deposited at its creation, pays for $\check{R}_j^6$ for each cube (ibid., (1.79)–(1.81), in which both the deposit and the cost are measured by the linear size $d'_j(Z) + 1$, counted in MR_j-cubes, and (1.89); these bound $\mathbf{T}'_k(X)1$ for the operation of (1.71), which contains the Wilson factor). Bałaban already pays $O(1) \log g_j^{-2}$ for each site of Z_j, on account of the normalisation constants (ibid., p. 380). The spare weight, whose constant c is free, holds once g is small enough, the constant c being chosen first §4.17.1.40.

Proposition 5.69 (Sources along a frame)**.** Let $(\theta_j)_{j \leq n}$ be a frame such that $\theta_j \geq \gamma_J^{-2}$ throughout, and let (x_j) be the run along it starting from a real β, as in the frame setting of § 5.2. The cube sizes are $\check{R}_j = R(\min_{i \leq j} \theta_i)$. All the other auxiliary choices of level j (the reference laws, the thresholds, the gauge-fixing weight and the scaling of the fluctuation field) are made with θ_j, whereas the weight of the action obeys its own recursion. The reference line is a frame. A first-passage run, that is, the run starting from a first-passage datum (K, β), is the run taken along its own couplings. The run is said to stay in the tube if $|\theta_j - x_j| \leq \mathsf{t}_j$ for all j, and to have room r if $|\theta_j - x_j| + r \leq \mathsf{t}_j$. Suppose that the run has room $2r$ for $r = \varrho$ or for $r = 2\varrho$. Then, for all sources with $\|w\|_\flat < r$ and for the steps of the frame, Props. 5.63, 5.65, 5.67 and 5.68 are valid, with upper stability and the floor holding with $C(1 + \log \theta_n)$ for each site of $\mathbb{T}^{(n)}$. They hold on every admissible pair (ℓ, K) of a torus and a cutoff, admissibility meaning $K \geq n$ and $\ell L^{K-i} \geq CM\check{R}_i$ for $i \leq n$, as in § 5.2.2; all of this is uniform in ℓ, in K, in n, in β and in the frame. Moreover

$$\mathsf{z}_j(\zeta) := (\theta_j - x_j) + \zeta_j(\zeta) \in D(0, \mathsf{t}_j),$$

$$\sum_{j \leq n} \sup_{0 < |\zeta| < r} \frac{|b_j(\zeta) - b_j(0)|}{|\zeta|} \leq \tfrac{1}{3}. \qquad \blacksquare$$

The mechanism is as follows. A step depends separately on the choice θ_j and on the weight $x_j - \zeta_j$. For given remainders, its small-field part is holomorphic in their difference $\mathsf{z}_j(\zeta)$ on $D(0, \sigma_\star \theta_j) \supset D(0, \mathsf{t}_j)$ (the small-field holomorphy hypothesis in the ordinary step, on the disc

stated here); this difference is the deviation $\mathsf{z}_j = \theta_j - x_j$ displaced by the running shift. The full step is formed at a real deviation in the tube, together with a complex shift about it of modulus at most $\bar{c}$ (the complex class of §4.17.1.45). Consequently, as far as the increments are concerned and with the remainders $R^{(i)}$ held fixed, a deviation from the frame and a constant source are the same variable. The remainders depend on the source as well, and the activities in the two presentations of Prop. 5.67 need not coincide term by term. The room is what keeps the complex excursion $|\zeta_j| \le \frac{4}{3}|\zeta|$ inside the disc. The objects constructed do not depend on the tube. A single statement therefore serves the first-passage runs, the comparison of two cutoffs in appendices A.8 and A.9, and the runs with frozen choices that occur in § 5.2.3 and Prop. A.15; it is used with $r = \varrho$, where the room is 2ϱ, and with $r = 2\varrho$, where the room is 4ϱ (which is the room $C\varrho$ of Prop. 5.63).

Reading at depth s. For the run stopped at level $K-s$, everything above holds with the following changes. The norm $\|f\|_{\sharp,s} = \max\{\|f\|_\infty, CML^{-s}\,\mathrm{Lip}\,f\}$ replaces $\|f\|_\sharp$, the Lipschitz constant being measured at scale L^{-s}. The sums are restricted to $j \le K-s$. Either normaliser may be used, each with exponents of its own: E of the whole run, or the vacuum constant $E_{(K-s)}$ of the first $K-s$ steps. The number of sites of $\mathbb{T}^{(K-s)}$ replaces ℓ^4, and $L^{-(K-s-j)}$ replaces $L^{-(K-j)}$. The exponents of the two global bounds also depend on s §6.1.1.2.

Proposition 5.70 (Large fields are rare uniformly in the volume)**.** (Live regions, creation sets, lineages, marks and ages, as well as the law $\tilde{\nu}$ of the histories, are defined in §4.17.1.1, and the prepaid bounds are stated in §4.17.1.45. They have here the meaning given there.) For g small, for every level $0 \le k \le K$ (with $\mathcal{Z}_0 = \emptyset$) and every level-$k$ cell $\mathfrak{c}$, one has uniformly

$$\tilde{\nu}\big(\mathfrak{lv}_k(\mathfrak{c})\big) = \tilde{\nu}\big(\mathfrak{c} \subset \mathcal{Z}_k\big) \le Ce^{-cp_0(g_k)},$$

$$\tilde{\nu}\big(\mathfrak{c} \text{ is created at step } k\big) = \tilde{\nu}\big(\mathfrak{c} \subset \mathcal{W}_k^{\wedge}\big) \le Ce^{-cp_0(g_k)}. \qquad \blacksquare$$

The second bound ($k \ge 1$) is a consequence of the first, because creation cells are live. Indeed, $\mathbf{R}$ touches a component only if no creation has occurred in it during the last N_k steps. Hence a component of Z_k containing a creation cell of step k is not healed at step k, which gives $\mathcal{W}_k^{\wedge} \subset \mathcal{Z}_k$. The same inclusion also bounds the event that $\mathfrak{c}$ lies in a live component in which a creation occurs at step k. The theorem relies on the following point. A label's determining set starts from a neighbourhood of its first region, $\Omega_0 = \Omega_1^{\sim}$, and not from the whole torus. Its background therefore requires the bare field to be regular only on that neighbourhood (see under Lem. 5.72). If regularity is required at every bare plaquette of T_ℓ, then a single rough plaquette, wherever it lies, leaves the step-1 background undefined. By totality §4.17.1.1, every test formed with that background then fails at every place, so that Z_1 equals the whole torus and is never healed. Moreover, at fixed (β, g), the probability that such a plaquette is present tends to 1 as $\ell \to \infty$. The theorem concerns only the law of the histories of the run; it gives no bound on the law that $\mu_{K,\ell,\beta}$ induces on the bare plaquettes inside a box of fixed physical size.

The proof is a first-moment argument. For a level-n cell $\mathfrak{z}$, let $\mathcal{E}_{\mathfrak{z}}^{(n)}(k)$ be the survival event of §4.17.1.1, namely $\mathfrak{z} \subset \mathcal{Z}_i$ for $n \le i \le k$. The event $\mathcal{E}_{\mathfrak{c}}^{(k)}(K) \subset \mathfrak{lv}_k(\mathfrak{c})$ is the never-healed event. (i) If healing takes place at a level $j > k$, the relative removal comparison of §5.20.2.6 gives the factor $Ce^{-cp_0(g_k)-cp_0(g_j)}$, summable in j. This use requires the outer-operation comparison on the actual completed positive terms. (ii) We use Vol_i, Dep_i, the mark $\Theta^{(i)}$ with its dials w, c_a, and the end mark $\Theta = \Theta^{(K)}$, all as in §4.17.1.1. For a component live at level i, along its lineage Vol_i charges every live cell, at every level $j \le i$, with twice the weight $\mathsf{r}_j = M^4\check{R}_j^5$, while Dep_i contributes $cp_0(g_j)^2(d'_j(W)+1)$ for every component W that is created. By §4.17.1.45, the upper bound of § 5.20 stays valid once the mark is prepaid: for the run stopped at an arbitrary level when the dial is $\mathsf{w} = 0$, and at the last level when the dial is $\mathsf{w} > 0$. In the form needed here, the prepaid bound takes up the large-field bound one lineage at a time and consists of two statements,

independent of each other. *Volumes are paid by events.* Let $\mathsf{r}_j = M^4 \check{R}_j^5$. For every history, and for every component X of Z_k, whether live or healed at step k, one has

$$\sum_{(j,C)} \mathsf{r}_j \, |C|_j \le c_G \sum_{(j,C)} \mathsf{r}_j \check{R}_j \, e(j,C),$$

$$e(j,C) := \big(|\operatorname{pred}| - 1\big)^+ + |\operatorname{pred} \cap \operatorname{Act}_{j-1}| + \sum_W \big(d'_j(W) + 1\big),$$

where both sums run over the components of the lineage of X. Here pred denotes the set of components live at level $j-1$ that are contained in C; Act_{j-1} is the set of those components that are live even though $\mathbf{R}$ of level $j-1$ has acted on them; W ranges over those components of the step-j creation set that lie in C; and the constant c_G is determined by L, M and the remaining constants fixed ahead of the ceiling γ imposed on the couplings, and by nothing else. The coupling $\gamma_\star$ is taken small. The inequality is a statement on the geometry of the regions alone; neither a field nor a measure enters. At levels where nothing happens, a component, measured in cells of its own level, shrinks geometrically until it becomes small; and once a component has stayed small over $\check{R}_j + 1$ levels without any event, it belongs to the class of $\mathbf{R}$. *Masses by lineage traces.* The lineage trace $\mathfrak{l}$ of X is the list of the regions $\mathsf{Z}_j(X)$, of the sets created in them, and of the sets Act_j. We set

$$\operatorname{wt}(\mathfrak{l}) := \exp\big[C_{\mathrm{chg}} \operatorname{Vol}_k - \operatorname{Dep}_k - \sum_{(j,W)} 2p_0(g_j) - \sum_j |\operatorname{Act}_j| \, p_0(g_j)\big]$$

, where C_{chg} is the charge constant; it is defined by the requirement that, for each cell of level j, the sums over the admissible regions, the Gaussian integrals, the normalisation constants and the vacuum-energy counterterms contribute a factor no larger than $e^{2C_{\mathrm{chg}}\mathsf{r}_j}$. This constant is determined by the parameters of the construction alone, and it is fixed before $\gamma_\star$. Let $\mathscr{L}$ be any set of lineage traces of level k, and sum over those histories of level k whose live components carry the lineage traces $\mathscr{L}$. Then

$$e^{-E_{(k)}} \sum_h \mathsf{t}(h) \le e^{C|\mathbb{T}^{(k)}|} \prod_{\mathfrak{l} \in \mathscr{L}} \operatorname{wt}(\mathfrak{l}) :$$

indeed, one unfolds the majorants of §4.17.1.40, passing through the components that $\mathbf{R}$ has acted on, as far as the creations, and one sums the entropy with the lineage trace held fixed. No factor arises from a joining, since a creation at a leaf of the lineage pays for it (Prop. 4.63, move (3)). The relation $\mathsf{r}_j \check{R}_j = M^4 \check{R}_j^6 \ll p_0(g_j)$ is valid for all couplings not exceeding the anchor coupling $\gamma_\star$. This anchor coupling is fixed small only once L, M, the dials w and c_a, and the rate c' introduced below (a constant of this proof only, different from the small c' of the mass bound) have been fixed, and it does not exceed γ_J; g is subsequently taken small depending on $\gamma_\star$. Consequently the volumes, the entropy of the lineage traces and the mark are all paid for by the events. Precisely, take the rate $c' \ge 0$, which is fixed before $\gamma_\star$ and may be given any value; the value $c' = 1$ already outweighs the number $C^{|X|_k}$ of connected sets X of cells containing a given cell, because $\mathsf{r}_k \ge M^4$. Then for every set of lineage traces ending in X,

$$\sum_{\mathfrak{l}} \operatorname{wt}(\mathfrak{l}) \, e^{\mathsf{w} \operatorname{Dep}_k + c_a \operatorname{Vol}_k} \le e^{-c' \mathsf{r}_k |X|_k} \, e^{-2 \min p_0(g_{j_0})}$$

, where j_0 denotes the first level of a lineage. It is this bound that prepays the mark. There are two reasons for carrying out the argument at the last level, with the end mark. The first reason applies already at $\mathsf{w} = 0$. The gain obtained from the first moment in (iii) is the quotient of two

quantities: the exponent in the moment bound, equal to $\mathsf{B}(y) = C(1 + \log y)$ for every site of the lattice on which the run stops, and the product of $c_a \mathsf{r}_k$ with the count of level-k cells. When the run is stopped at level k, the quotient equals $\mathsf{B}(x_k)(M\check{R}_k)^4/(c_a\mathsf{r}_k) \approx \log x_k/(c_a\check{R}_k)$, and this carries no smallness of order $e^{-cp_0(g_k)}$. At the last level there are fewer sites, by the factor $L^{-4(K-k)}$. The second reason concerns the alternative of (iv) in which the torus shrinks. There a single deposit is weighed against the volume, and this requires $\mathsf{w} > 0$. Whatever value the dial takes, the end mark registers only lineages of components still live at the last level, that is, only the never-healed lineages. This is why the healed part is split off in (i). Together with the floor one obtains $\mathbb{E}_{\tilde{\nu}} e^{\Theta} \le e^{C_g \ell^4}$, hence $\mathbb{E}_{\tilde{\nu}}\Theta \le C_g \ell^4$ by Jensen's inequality. On the other hand Vol_K charges every never-healed cell, so $\sum_{\mathfrak{c}} \mathbf{1}_{\mathcal{E}_{\mathfrak{c}}^{(k)}(K)} \le \Theta/(c_a \mathsf{r}_k)$, where $c_a > 0$. (iii) Translations by level-k cells commute with the steps up to level k; therefore $\tilde{\nu}(\mathfrak{w}_k(\mathfrak{c}))$ is the same for every $\mathfrak{c}$. The event $\mathcal{E}_{\mathfrak{c}}^{(k)}(K)$, by contrast, depends on coarser partitions and is not covariant. Averaging gives

$$\tilde{\nu}\big(\mathfrak{w}_k(\mathfrak{c})\big) \le \max_{\mathfrak{c}'} \tilde{\nu}\big(\mathfrak{w}_k(\mathfrak{c}') \setminus \mathcal{E}_{\mathfrak{c}'}^{(k)}(K)\big) + \frac{C_g \ell^4}{c_a \mathsf{r}_k \, \#\{\mathfrak{c}'\}} \le C e^{-cp_0(g_k)} + C_g L^{-4(K-k)}.$$

(iv) To make $K - k$ large, the run is extended on the same bare lattice up to a larger reference coupling, not exceeding the anchor coupling $\gamma_\star$. This is a fixed upper limit for the reference couplings. It is chosen small once the dials w and c_a are fixed, in such a way that (i), (ii) and the comparison made in the first alternative below are valid at each reference coupling up to $\gamma_\star$; only afterwards is g chosen small, depending on $\gamma_\star$. This continuation leaves the law up to level k unchanged § 5.2.4. Steps (i)–(iii) are applied to the continued run, with Θ the mark at its last level.

Let $K^\dagger$ be the largest admissible continued first-passage level, $g^\dagger$ its reference coupling, and $m^\dagger = m - (K^\dagger - K)$ its torus exponent. Write $K_\star$ for first passage at the anchor coupling and $X_\star = \gamma_\star^{-2}$. Choose $c_{\mathrm{gap}} = \lceil c_5/\lambda_\sharp \rceil + 1$. If $K^\dagger + c_{\mathrm{gap}} \le K_\star$, the lower flow bound produces a strict new record low within those c_{gap} steps. A strict record low is a first-passage level for a reference threshold there. For a record q, use $g' = (x_q - B_\sharp)^{-1/2}$, or the anchor if $x_q - B_\sharp < X_\star$, in which case $q = K_\star$. The new reference coupling is at least $g^\dagger$ and at most the anchor. The admissible side floor $m_\star(g')$ is nonincreasing with g'. Thus the record would still be admissible if $m^\dagger \ge m_\star(g^\dagger) + c_{\mathrm{gap}}$. Maximality gives the opposite inequality. The terminal site count is then at most $C(1+\log(g^\dagger)^{-2})^{4r}$ by the side floor. Every surviving lineage carries a birth, with mark at least $\mathsf{w} c_{\mathsf{D}}(p_0(g_k) - 1)^2$ by the drift. For the chosen anchor ceiling this mark pays the terminal moment exponent and leaves $cp_0(g_k)$, since $2\mathfrak{p}_0 > 4r + 1$.

Otherwise $K^\dagger > K_\star - c_{\mathrm{gap}}$. The upper flow bound and the first-passage windows give

$$p^\dagger := K^\dagger - K > \frac{g^{-2} - X_\star - B_\sharp}{B_\sharp} - c_{\mathrm{gap}}.$$

The continued exponent $m^\dagger = m - p^\dagger$ is nonnegative. In particular every side with $m \le m_V(g) = \lfloor (g^{-2} - X_\star - B_\sharp)/B_\sharp \rfloor - c_{\mathrm{gap}}$ falls in the volume case. This gives the horizon $\ell_V(g) = 2L^{m_V(g)}$. Use the averaged never-healed bound at this terminal level. Writing $u = K - k$, division by the number of level-k cells gives

$$\frac{\mathsf{B}(x_{K^\dagger})}{2c_a \check{R}_k} L^{-4(p^\dagger + u)}.$$

Here $x_{K^\dagger} \le g^{-2} + B_\sharp$ while $x_k \le (g^{-2} + B_\sharp)(1 + u)$. Consequently the required extra depth is at most $C(1 + \log g^{-2})^{\mathfrak{p}_0}$, uniformly in u: the u-dependent part of $cp_0(g_k)$ is bounded by $4u \log L + C$ because $(\log(1+u))^{\mathfrak{p}_0} = o(u)$. The available depth $p^\dagger$ exceeds this bound for small g. The average is thus at most $Ce^{-cp_0(g_k)}$. Combine it with the pointwise healed estimate by averaging the live-prefix

events, whose probabilities are translation invariant at level k. This uses the common prefix of the two runs.

Proposition 5.71 (Ages)**.** Denote by C the component live at level k that contains $\mathfrak{c}$, by $\mathsf{Z}_j(C)$ its lineage regions, and by j_0 the least level at which these regions are non-empty. The three ages of C are the age read in the label, the age of the lineage, $\mathrm{age}_k(C;h) = k - j_0$, and the seed age. These ages and the events $\mathfrak{lw}_k^{=a}(\mathfrak{c})$, $\mathfrak{lw}_k^{\geq a}(\mathfrak{c})$, $\mathfrak{sd}_k^{=a}(\mathfrak{c})$ are defined as in §4.17.1.1. The age read in the label refers to the oldest region of the label that appears in C: $\mathrm{age}^{\mathrm{lab}}(C) = k - \min\{t : C \cap Z_t \neq \emptyset\}$, where $Z_t = \Lambda_t^c$ is the large-field region of scale t in the label $\mathcal{S}(h)$ of the history. The proposition states that the three ages are ordered,

$$\mathrm{age}^{\mathrm{lab}}(C) \;\leq\; \mathrm{age}_k(C;h) \;\leq\; \text{seed age},$$

and it gives a decay in the second of them. For the first inequality, note that every point of $C \cap Z_t$ belongs to the live region at each level between t and k. It therefore belongs to $\mathsf{Z}_t(C)$, and so $t \geq j_0$. For the second inequality, no component of $\mathsf{Z}_{j_0}(C)$ contains a component that is live at the preceding level. Each such component is therefore created at step j_0, and it is contained in C. The second inequality may be strict. Suppose a region created at a step $t < j_0$ is contained in C. Then it was healed at some step before k, and the live region of some later level covers its place anew. As a point set it counts for the seed level. It contributes no factor, however, since no cell of it stays live through all the levels from t to k. In terms of events, $\mathfrak{sd}_k^{=a}(\mathfrak{c}) \subset \bigcup_{a' \leq a} \mathfrak{lw}_k^{=a'}(\mathfrak{c})$. Let $b \geq 1$, let $c_a \geq C(b)\log L$ (a floor on c_a, which is chosen after L), and let g be small depending on b and c_a. Then, uniformly, with constants C on the right-hand sides that may depend on b and c_a,

$$\tilde{\nu}\big(\mathfrak{lw}_k^{=a}(\mathfrak{c})\big) \leq C e^{-c p_0(g_k)} (2L^b)^{-a},$$

$$\tilde{\nu}\big(\mathfrak{lw}_k^{=a}(\mathfrak{c}) \cap \mathcal{E}_{\mathfrak{c}}^{(k)}(K)\big) \leq C (2L^b)^{-a-(K-k)}.$$

Both bounds decay in the age of the lineage, and so does the age series given further below. Suppose the seed level is formed only from regions that are healed at no step before k. Then the two bounds and the age series hold in the seed age as well, that is, for $\mathfrak{sd}_k^{=a}(\mathfrak{c})$: the seed level equals j_0, the two ages coincide, and $\mathfrak{sd}_k^{=a}(\mathfrak{c}) = \mathfrak{lw}_k^{=a}(\mathfrak{c})$. When the seed level is formed from all regions, the price of survival yields no decay. Two facts show this. First, a level-k cell contains of the order of $L^{4(k-t)}$ cells of level t, whereas the bound per creation has an exponent that is merely polylogarithmic in $k - t$. Second, take $k = K$ and $a = K - 1$. Applied there, the bound gives at most $C(2L^b)^{-(K-1)}$, at fixed g and for every K, for the probability that a fixed cell at the final level is live and occupies the place of a region created at step 1. Yet the tests of the last step depend only on $x_{K-1}, x_K \approx g^{-2}$. A first-moment argument yields only a density, and never a factor per level for a single cell. For this reason the chessboard estimate is now applied to the large fields, which is a second use of reflection positivity.

■

Lemma 5.72 (Chessboard for the law of the histories)**.** Put $q_a = e^{-c_a}$, where $c_a \geq c^{-1}\log(2L^4)$, equivalently $L^4 q_a^c \leq \frac{1}{2}$. In this condition, in the two bounds below and wherever these bounds are quoted, the constant is $c = \frac{1}{16}$; it is fixed before c_a, and it arises as the root, taken over the tiles, of the bound for a pattern that is repeated in one tile out of 2^4. Fix $\epsilon > 0$ and take g small depending on c_a, ϵ. A *tiling* is a translate, by a multiple of the side length of a level-k cell, of the partition of the torus into cubes of side $\mathsf{l}_\square$, called *tiles*, whose faces lie in mirror planes that pass through midpoints of bonds. In each tile, the cube with the same centre and with side $\frac{3}{4}\mathsf{l}_\square$ is called its *core*. A cell, of whatever level, is called *deep* in a tile when the level-k cell containing it lies in the core of that tile. Then for each level $k \leq K$ there is a tile side $\mathsf{l}_\square \approx M\check{R}_k$, measured in level-$k$ units, which

is a power of L and spans at least sixteen level-k cells, with the following property. Let $n \le k$, let $\mathfrak{z}$ be a level-n cell situated deep inside a tile $\square_0$ of a tiling, and let $\square_1, \dots, \square_r$ be further tiles, all distinct. Then

$$\tilde{\nu}\big(\mathcal{E}^{(n)}_{\mathfrak{z}}(k)\big) \le \mathsf{l}_{\square}^{-4}\, q_a^{c(k-n+1)},$$

$$\sum_{\mathfrak{c}_1,\dots,\mathfrak{c}_r} \tilde{\nu}\Big(\mathcal{E}^{(n)}_{\mathfrak{z}}(k) \cap \bigcap_{i\le r} \mathfrak{fv}_k(\mathfrak{c}_i)\Big) \le \mathsf{l}_{\square}^{-4}\, q_a^{c(k-n+1)}\, \epsilon^r,$$

where the sum runs over the level-k cells $\mathfrak{c}_i$ lying deep inside $\square_i$. The first bound is valid for every level-n cell on every torus, including tori too small to carry a tiling with tiles of this side. The bounds are independent of how many tiles the torus contains. Survival costs a factor q_a^c per level, and every further tile that contains a deep live cell costs a factor ϵ. ■

5.20.2. *Radial windows and bare-field witnesses.* This section supplies the conditional-density and witness steps in Lem. 5.72. It concerns the actual positive law of a finite history prefix, at zero source. The all-history hypotheses $\mathcal{H}_{\mathrm{step}}$ of §3.1.1.1 remain in force. In particular, the background and Gaussian estimates below are required on the actual determining regions and stored-field fibres. A regular homogeneous construction does not supply these hypotheses on its own.

The collar cutoff used here is the component-local cutoff specified in §4.17.1.3. Its exponentially close global variant can support analytic estimates, but it cannot replace this sharp cutoff in a comparison of two runs. With the local cutoff, the comparison needs windows only at the ordinary split of each step. No window at a preparatory completion or collar test will be removed.

5.20.2.1. The finite prefix and its real estimates. Fix k, and measure lengths in level-k units. Write

$$s_j = M\check{R}_j L^{-(k-j)}, \qquad r_j = M^4\check{R}_j^5, \qquad N_j = \check{R}_j, \qquad q_a = e^{-c_a}, \qquad \widehat{q} = q_a^{1/16}.$$

The cells are nested, $s_j/s_{j-1} \in \{1, L\}$, and the flow satisfies

$$c(j-i)-C \le x_i - x_j \le C(j-i)+C, \qquad \check{R}_i = R\Big(\min_{t\le i} x_t\Big), \qquad (\log x)^r \le R(x) \le L\max\{1, (\log x)^r\}.$$

All constants below may depend on the fixed construction parameters, including L, but not on the depth, the torus or the chosen history.

We record the real estimates that enter the argument. These are formation and mass estimates, rather than the class-invariance target. The background response on a regular collar has the form

$$\big|V^{\mathrm{bg}}(b)V^{\mathrm{bg}\prime}(b)^{-1} - 1\big| \le C_{\mathrm{dec}} e^{-\delta_{\mathrm{dec}} d(b,A^c)} \varepsilon_{\mathrm{rim}}. \tag{5.cdxii}$$

The two determining sets and their data must coincide in A, its rim must lie in the common top domain, and the actual data must lie below the regularity ceiling. Near the top domain, $\varepsilon_{\mathrm{rim}} \le C\varepsilon_j$. A factor $C(\log x_j)^r$ on rebuilt distant layers is allowed; two additional cells of collar pay for it. The first determining region is $\Omega_0 = \Omega_1^{\sim}$, rather than the whole torus.

In the literal nonpivot coordinates at a split, the smooth real exponent satisfies

$$|\partial_{a_b}\mathcal{F}| \le C_{\mathrm{sl}} p_0(g_j). \tag{5.cdxiii}$$

This estimate includes the Haar, coarea and nonlinear terms. Its quadratic contribution follows from an exponentially summable precision row applied to fields bounded by Cp_0. For the ordinary remainder, the domains through the tested bond have a bounded rooted sum with the ordinary decay. A complex margin $c/p_0(g_j)$ in the scaled coordinate thus suffices by Cauchy's inequality. For the preparatory remainder, use the coordinate $a_b = (\mathrm{i}g_i)^{-1}\log(V_i(b)C_b^{-1})$ at its actual collar level i, with C_b its test centre. The stage domains meeting the tested bond also meet the preparatory collar. Their relative length does not charge the class box of side $O(n_{\mathrm{sm}}\check{R}_j)$ cells. Rooting at one of its cells and summing the exterior continuations therefore costs $C(n_{\mathrm{sm}}\check{R}_j)^4$. The complex margin in this collar coordinate is $c\delta_i'/g_i$, bounded below by a fixed constant. Cauchy's inequality with

the formed activity bounds on that disc gives a contribution bounded by $C(n_{\mathrm{sm}}\check{R}_j)^4 g_i/\delta_i'$. The waiting-window bounds compare the scales, and $\mathfrak{p}_0 > 4r$ makes this at most $Cp_0(g_j)$. This uses the admitted collar margin with the relative rooted sum, and the ordinary margin with the ordinary rooted sum.

For an isolated box of free coordinates, write its conditional exponent as

$$H_e(y) = \tfrac{1}{2}\langle y, K_{II} y\rangle + \langle y, K_{IO} A_O\rangle - P_e(y). \tag{5.cdxiv}$$

Here I is the set of free bonds touching e^{+1}, whereas the marked bonds touch e. The real Gaussian estimates and nonlinear formation bounds give

$$K \geq a_- I, \qquad |K(b,b')| \leq a_+ e^{-c|b-b'|}, \qquad |A_O| \leq Cp_0(g_{j-1}), \tag{5.cdxv}$$

$$\sup_I |\nabla P_e| \leq \epsilon_{\mathrm{nl}}, \qquad \|\nabla^2 P_e\|_{\ell^2\to\ell^2} \leq a_-/2, \qquad \epsilon_{\mathrm{nl}} \longrightarrow 0. \tag{5.cdxvi}$$

Distances in these formulas are in level-$(j-1)$ lattice units. The bounds are needed after conditioning on the exterior datum. Positivity of Haar measure alone supplies none of them.

Finally, let $t(h) \geq 0$ be the masses of the prefix and $Z = \sum_h t(h)$. The marked upper bound and the all-small lower bound, with the same vacuum constant E_k, are

$$e^{-E_k}\sum_h t(h) e^{\Theta_k(h)} \leq e^{C_+ V_k}, \qquad e^{-E_k} Z \geq e^{-C_-(x_k)V_k}, \qquad C_+ + C_-(x) \leq B(x) := C_B(1+\log x). \tag{5.cdxvii}$$

Here $V_k = |\mathbb{T}^{(k)}|$, and

$$\Theta_k = c_a \sum_{X \text{ live at } k} \mathrm{Vol}(X), \qquad \mathrm{Vol}(X) = 2\sum_{j\leq k} r_j |\mathsf{Z}_j(X)|_j.$$

The charge dial in the mass estimate has been increased before choosing the coupling ceiling. Dividing the two inequalities in eq. 5.cdxvii cancels E_k and gives

$$\mathbb{E}_{\widetilde{\nu}} e^{\Theta_k} \leq e^{B(x_k)V_k}. \tag{5.cdxviii}$$

In particular, if n_j distinct level-j cells are forced into surviving lineages, their probability is at most $e^{B(x_k)V_k} q_a^{2\sum_j r_j n_j}$.

5.20.2.2. The coordinates read after a split. The independent split coordinates are the actual nonpivot link logs

$$a_b = g_i^{-1} i^{-1} \log\left(V_i(b) V_i^{\mathrm{bg}}(b)^{-1}\right), \qquad i = j-1.$$

They are not coordinates obtained by a global nonlinear Landau projection. The next field V_j is held fixed, and the literal averaging constraint determines the pivots.

Lemma 5.73 (The split coordinate and the later decisions)**.** Fix all other stage coordinates. On either one-sided shell about any of the three split thresholds, the conditional likelihood of a joint survival event and of later ordinary-split no-window conditions is constant along each radial ray. Existing sharp factors are constant there as well. This statement uses the actual outward determining rows and the margins of the ordinary step. ■

Proof. We describe the readsets, including the pivots. In a single averaging step the pivot for a coarse bond is the middle fine bond of its central line. Internal block contours contain no pivot. A pivot therefore occurs in its own coarse constraint only. The local implicit-function theorem solves that constraint, with the other nonpivot variables held fixed. Changing a_b changes only b and the face pivots in its one-step contour carrier. All constants in this finite-dimensional calculation are C_L; no lower bound uniform in L is being asserted.

The ordinary split reads cubes in $\Omega_j^{\sim -1}$. Their full one-step carriers stay inside Ω_j, with a cell margin. Consequently none of the changed bonds belongs to the actual row Γ_i, whose bonds have no endpoint in Ω_j. The background datum, the coarser field, and the older retained data are

unchanged. The same is true of data used by joined strip backgrounds: their additional tower data are coarse lifts, and their inherited fine rows are these same outward rows. Thus other stored nonpivot coordinates acquire no hidden change through a background centre.

The plaquette tests depend on V_j. The approximate fluctuation tests exclude pivots, use the threshold $2\delta_i$, and have exponentially small centre offsets. They remain constant throughout the shells about $\delta_i^{\flat}, \theta_c\delta_i, \delta_i$. The soft contour cutoffs are identically one there, since their contours remain within $C_L\delta_i$ and the parameter order gives $C_L\delta_i \ll \varepsilon_i$. For the density tests one needs the quantitative new-test implication in Lem. 4.57, not merely their previously recorded answer. With the new coarse plaquette and approximate fluctuation tests passed, that implication gives, on each old density cube in the one-cell enlargement,

$$|\partial U_{i,\square}(V_i) - 1| \le \left(C_0 L^{-2} + C_L A_1/A_0 + Ce^{-c\delta_0 M_2 \check{R}_j}\right)\varepsilon_i\eta_i^2 \le \tfrac{1}{4}\varepsilon_i\eta_i^2.$$

The construction fixes these quantitative margins in this order: the coarse-curvature floor on L, the sufficiently small ratio A_1/A_0 after the finite-L response and pivot constants, and the coupling ceiling after the collar constants. The shell enlarges the fluctuation threshold by $g_i W_\sigma = o(\delta_i)$, so the same bound remains below $\varepsilon_i\eta_i^2/2$. Here η_i is the bare spacing in level-i units. At $i = 0$, $U_{0,\square}(V_0) = V_0$ on the tested plaquettes, so these are the bare P_0 tests on the full changed carrier. Thus fixing the earlier P_0 entry imposes no additional shell cut. Old tests near a changed pivot are either removed in the strip operation or identically one by its one-cell margin.

Now compare two states on the same ray, on the same side of a threshold. All three interval flags agree. The ordinary recursion uses only these flags, so its geometry, its creation entries and its integration region agree. If the coordinate is integrated, its slot is deleted and no subsequent move reads it.

If it is retained, it is still excluded from all later determining data: the old domains only expand. Preparatory gauge reads lie in the outer collars and use these datum rows and fixed coarser fields. The other preparatory tests use backgrounds localised to the actual component. A completion test can read the stored coordinate itself, but then it tests the same previously stored modulus at the old threshold. At a passed original cube test that answer is already one. A failed original cube test is a creation; while its level remains in the preparatory window, the class condition prohibits acting on its component. Once it leaves that window, its old coordinate is below the levels of those completion tests. No recomputation with a new centre is permitted.

The remaining moves are fixed-law gauge or Haar draws, a frame draw, coarse tree maps, or the coarse reference draw. The reference draw and its normalizer read the exterior coarse datum and the fixed component frame; they read no omitted fine row. Their read coordinates have already been shown to agree. Its final density test therefore has the same answer when the later coins agree. The old retained values can remain as passengers; the assertion is about future decisions, not about a full state kernel that carries such passengers unchanged.

Induction through the finite list of moves proves that the indicated future events have equal indicators for equal later coins. Integration over those independent coins gives the asserted constant likelihood. This argument would fail if a retained fine staple were admitted into a later datum row. Fixed coarse means by themselves would not exclude that possibility. □

5.20.2.3. A deterministic family of split tests. At step j, after Ω_j and its single global fluctuation field have been formed, record the three interval flags for every candidate nonpivot bond read by a cube in $\Omega_j^{\sim -1}$. Then run the original recursion using these flags. It uses exactly the flags it would have queried before. Forgetting the unused flags recovers the original history at every configuration, so this refinement changes neither its law nor the moment eq. 5.cdxviii. It introduces no new coin and no sum over possible recursion branches.

This precomputation is legitimate because the split uses one global field, not a field recentered at a hypothetical explored component. No such refinement is made for the context-dependent

preparatory collar cutoffs. Order the diagnostic split sites by step and then by a fixed bond order. Each potential lattice bond now has one position in this list; an inactive site has $T_\sigma = 0$.

Write $p_i = p_0(g_i)$, and set

$$W_\sigma = (C_{\mathrm{sl}} p_i)^{-1}, \qquad \mathfrak{t}_\sigma = \{\mathfrak{b}_i^\flat, \theta_c \mathfrak{b}_i, \mathfrak{b}_i\}, \qquad \mathfrak{b}_i = \delta_i / g_i.$$

Choose the ceiling so that every distinct threshold is at least $2W_\sigma$ from the other thresholds and is itself at least $2W_\sigma$. Let $W_\sigma(u)$ denote the event that the site is active and its modulus is within u of a threshold.

Lemma 5.74 (The conditional radial estimate)**.** Let E be a joint survival event, intersected with any set of no-window conditions at diagnostic sites later in this deterministic order. Then

$$\mathbb{P}(E \cap W_\sigma(u)) \le C \, \frac{u}{W_\sigma} \, \mathbb{P}(E), \qquad 0 \le u \le W_\sigma. \tag{5.cdxix}$$

■

Proof. Disintegrate the stage law in the independent coordinates (s, a_σ). It has density $e^{\mathcal{F}_s(a)} \chi_s(a) \Pi(ds)\, da$, including all its Haar and coarea factors. By Lem. 5.73, the product of χ_s and the conditional future likelihood is constant on every one-sided shell. Conditions at other diagnostic sites of the same step depend on their fixed nonpivot coordinates, so they have the same property. The stage slope is bounded by

$$C_{\mathrm{sl}} p_0(g_j) \le C_{\mathrm{sl}}(p_i + 1) \le 2/W_\sigma.$$

Along a ray in a shell of length W_σ, the exponential density changes by at most e^2, and the radial Jacobian r^2 by at most four. Its initial portion of length u therefore carries at most $4e^2 u / W_\sigma$ times the full shell mass. Apply this separately above and below each threshold. The shells are disjoint. Integration over the angle and s proves eq. 5.cdxix. □

For a tile of side $\ell_\square$, put

$$\begin{aligned} \bar{p}_j &= \max_{\max\{0, j-N_j-1\} \le i \le j} p_0(g_i), \\ \delta_{\mathrm{dec}} D_j &= C + 4 \log \ell_\square + (4 \log L + \log 2)(k-j) \\ &\quad + 4(N_j + 1) \log L + 2 \log \bar{p}_j, \\ u_\sigma &= 2 C_{\mathrm{dec}} e^{-\delta_{\mathrm{dec}} \lceil D_j \rceil} \varepsilon_j / g_{j-1}. \end{aligned}$$

The diagnostic sites of a tile satisfy the more economical count

$$|\mathfrak{S}_j^{\mathrm{split}}[\square]| \le C \ell_\square^4 L^{4(k-j+1)} \le C \ell_\square^4 L^{4(k-j+N_j+1)}.$$

Thus the original, stronger schedule still pays them. The flow over $N_j + 1$ levels gives $\varepsilon_j / g_i \le C \bar{p}_j$, and hence

$$\sum_{\sigma \in \mathfrak{S}_j^{\mathrm{split}}[\square]} C u_\sigma / W_\sigma \le C e^{-C} 2^{-(k-j)}. \tag{5.cdxx}$$

This displays the cancellation of all four count factors, including the retained allowance $L^{4(N_j+1)}$. Before making any removal, enlarge the additive constant C so that the same calculation gives $u_\sigma / W_\sigma \le C' e^{-C} \le \min\{1, (2C_{\mathrm{shell}})^{-1}\}$ at every carried site, where $C_{\mathrm{shell}} \ge 1$ is the constant in eq. 5.cdxix. Thus both $u_\sigma \le W_\sigma$ and $\eta_\sigma = C_{\mathrm{shell}} u_\sigma / W_\sigma \le 1/2$ hold uniformly, including at large levels.

Let $\mathrm{NoWin}^{\mathrm{split}}(\square)$ exclude these diagnostic windows. Remove them in reverse deterministic order. Applying eq. 5.cdxix at each removal and using $1 - \eta \ge e^{-2\eta}$, with $\eta \le 1/2$, gives

$$\mathbb{P}\left(E \cap \bigcap_{\ell=1}^{r} \mathrm{NoWin}^{\mathrm{split}}(\square_\ell) \right) \ge C_{\mathrm{win}}^{-r} \mathbb{P}(E) \tag{5.cdxxi}$$

for distinct tiles. The constant in D_j can make $C_{\mathrm{win}} > 1$ as close to one as desired. This multiplicative estimate uses the conditional denominator in eq. 5.cdxix; an unconditional estimate on the probability of each window would not give eq. 5.cdxxi.

5.20.2.4. The bare-field witnesses. Realise every normalized measurable draw by an independent uniform coin, in the fixed relative chart of its site or component. There are finitely many potential draw sites in a finite prefix. Unused coins are ignored. The resulting run is Borel, has the prescribed kernel law, and, in the tiling regime, commutes with translations by $s_k\mathbb{Z}^4$. Here is the convention needed for the last assertion. The torus side is at least $2\ell_\square$, and $\ell_\square > \max\{128, 2n_{\mathrm{sm}}\}s_k$. Every component on which $\mathbf{R}$ draws fits in a nonwrapping aligned box of side at most $n_{\mathrm{sm}}s_j$, less than half the torus side. Its bounding box has a unique centre modulo the torus and has no nontrivial translation stabilizer. Number its bonds by their offsets from that centre, in the fixed frame. For each such shape and frame choose one Borel coordinate isomorphism, and use the same isomorphism for every translate. Translated states then have identical coordinate laws; their quantile maps with the translated centre coin agree exactly. Site and bond draws use the corresponding fixed local charts.

Induction over the moves proves covariance with this convention; it does not follow from Borel quantile existence alone. On a smaller torus an arbitrary Borel realization suffices for the direct moment argument below, and no covariant realization for a component with a nontrivial stabilizer is asserted. Integration is the deletion of a slot; no later move may read a deleted slot.

Let $m = dU \otimes d\xi$ be product Haar times Lebesgue, and $\mathbb{P} = \mu_{\mathrm{Wilson}} \otimes d\xi$. Since the Wilson action is nonnegative, $\mathbb{P} \le Z^{-1}m$. The tile coordinates contain only bare bonds whose two endpoints are strictly inside the tile and coins placed strictly inside it. For a Borel event A, define

$$F_\square(A) = \left\{x_\square : m^\square\{y : (x_\square, y) \notin A\} = 0\right\}, \qquad \phi_{\square,A}(U) = \int \mathbf{1}_{F_\square(A)}(U|_\square, \xi_\square)\, d\xi_\square.$$

Tonelli's theorem proves that these are measurable. The cylinder over $F_\square(A)$ is contained in A modulo a $\mathbb{P}$-null set, and $0 \le \phi_{\square,A} \le 1$. For distinct tiles,

$$\mathbb{P}\left(\bigcap_\ell \mathrm{pr}_{\square_\ell}^{-1} F_{\square_\ell}(A_\ell)\right) = \left\langle \prod_\ell \phi_{\square_\ell,A_\ell} \right\rangle_{\mathrm{Wilson}}. \tag{5.cdxxii}$$

The exterior measure in the definition is the product reference measure, not a conditional Wilson measure.

These functions need not be gauge invariant. If the chosen statement of chessboard positivity is restricted to gauge-invariant functions, average each ϕ over the gauge variables at all endpoints it reads. Those site sets are disjoint between tiles. Wilson gauge invariance makes the product expectation in eq. 5.cdxxii unchanged. This averaging preserves the support, the interval $[0, 1]$, and translation covariance. No reflection covariance of an individual coin realization is needed.

5.20.2.5. The isolated-cell payment. Suppose $e^{+2} \cap Z_j = \varnothing$. With I as in eq. 5.cdxiv, varying its free coordinates inside $\prod_{b\in I}\{|y_b| < \mathfrak{b}_{j-1}\}$ changes no explored collar or rim answer: every actual such query touches a stage set $Z^{[n]} \subset Z_j$, at index distance at least three from e, and therefore reads no bond of I. The original split queries that do read I are the full-threshold cube tests, which stay passed. The precomputed lower-threshold diagnostic flags may change, but none of them is read by this recursion. Sum over these unused flags before taking the warm-cell conditional law. The isolation factorization concerns the original geometry and column event, not the artificially refined diagnostic string. The approximate tests stay passed by their factor-two margin and their centre offset. At $j = 1$, the bare density margin used in Lem. 5.73 also applies. Thus isolation factors as the indicator of this product window times an exterior indicator. The region, the later run, and a column event are fixed by that exterior datum. Earlier gauge coins must be integrated out: fixing them would constrain the free coordinates to contour level sets. Later coins are independent of the current stage.

Here is the quantitative conditional estimate. Fix a marked bond b of e, and let $w(b') = e^{-\mu|b'-b|}$. For small fixed $\mu > 0$, eq. 5.cdxv gives

$$\left\| \tfrac{1}{2}(wKw^{-1} + w^{-1}Kw) - K \right\| \le C\mu, \qquad \tfrac{1}{2}(wKw^{-1} + w^{-1}Kw) \ge a_- I/2.$$

The same estimates hold for the full principal compression K_{II}. The exterior force has weighted norm at most $Cp_0(g_{j-1})e^{-cLM\check{R}_j}$; the nonlinear force has norm at most $C\epsilon_{\mathrm{nl}}$. In particular both together are small, even though the unweighted exterior force need not be small.

For completeness, a product of convex windows admits the comparison

$$|\nu_{H_1}(f) - \nu_{H_0}(f)| \le \lambda^{-1}\mathrm{Lip}_w(f)\, \|w \sup |\nabla H_1 - \nabla H_0|\|_2$$

when the conjugated symmetric part of H_0'' is at least λI. To see this, approximate the windows by separate convex walls in each bond coordinate and couple the two overdamped Langevin diffusions with the same Brownian motion. Weighted squared distance contracts under the first drift; the remaining force is bounded by the displayed weighted norm. The convex wall terms have the same sign because the weight is scalar on each bond. Pass to stationary couplings and then to hard walls. No convexity of H_1 is needed for this comparison.

Compare eq. 5.cdxiv with the even centered quadratic form on the same symmetric window. The comparison gives $|\nu_{H_e}(y_b^\alpha)| \le 1$ after reducing the coupling ceiling. By eq. 5.cdxvi, $H_e'' \ge a_- I/2$. Comparing it with $H_e - ty_b^\alpha$ and integrating in t yields

$$\nu_{H_e}\left(|y_b^\alpha - \nu_{H_e} y_b^\alpha| \ge u\right) \le 2e^{-a_- u^2/4}.$$

There are at most $C(LM\check{R}_j)^4$ marked bonds. A union bound therefore gives

$$\nu_{H_e}(e \text{ warm}) \le C(LM\check{R}_j)^4 e^{-c(\mathfrak{b}_{j-1}^{\flat\flat}/\sqrt{3}-1)^2} \le q_a^{r_j}.$$

The last inequality uses $2\mathfrak{p}_0 > 5r$, with c_a chosen before the coupling ceiling. Peeling disjoint boxes gives the product of these factors, relative to any column event. No derivative of the curvature or independent-current matching is used in this concentration argument.

5.20.2.6. From the witnesses to the chessboard bound. The remaining geometric and mass ingredients are the following ones of the actual history construction. First, the boxing/cascade recursion is local in its interval flags. Its pieces belong to the c_{lay}-clusters of hot cells, and each piece stays within $c_h = n_{\mathrm{sm}} + 1$ cells of its cluster. This follows by keeping an original seed in every component: a small bounding box is within $n_{\mathrm{sm}} - 1$ cells of that seed, at every round. No monotonicity of the boxing map is required. The same recursion on two common clusters gives the same labelled piece even if distant clusters require more stages.

Second, retain the following exact representation premise on the actual completed positive terms at a healing step. With the live region and its internal histories fixed, the term for a family $\mathfrak{I}$ of healed components is

$$\mathbf{O}_{\mathfrak{I}}[W(\mathfrak{I})], \qquad W(\mathfrak{I}) = \left[\prod_{X\in\mathfrak{I}} \mathbf{T}'_X\right] \exp \sum_Y V_{\mathfrak{I}}(Y).$$

Each $\mathbf{T}'_X$ integrates against a nonnegative measure. To see heredity in the native history, restrict to the clusters of all roots other than X. At each level the separation of distinct clusters exceeds the reach of the bond tests, pivots and collars. Hulls and enlargements are taken on the separated regions, and boxing acts on one component at a time. The class test also reads births in $(j - \mathsf{N}_j, j]$ and marks in $[j - \mathsf{N}_j, j)$. A birth at s can have been healed at an earlier level $i < j$ only if $s \le i - \mathsf{N}_i$; for a mark the inequality is strict. Since $\mathsf{N}_i \ge \mathsf{N}_j$, $i - \mathsf{N}_i < j - \mathsf{N}_j$, so no item read by the class test can have been erased in this way. These two facts give the same tests and classes on the remaining components. Each old component belongs to the cluster of its last successor. For $l \le j$, healing X fills X into Ω_l and Λ_l and removes it from S_l. Omitting the cluster leaves these same completed

label entries on X. The family parametrization over this label drops just X and its isolated inner history.

Write $\mathbf{O}_{\mathfrak{I}}$ for the positive outer operation on the common real exterior variables. For removal of X we need

$$\mathbf{O}_{\mathfrak{I}} \le \mathbf{O}_{\mathfrak{I}\setminus\{X\}}$$

on nonnegative inputs. In the completed-output representation, fix the final determining sequence $\bar{\mathbf{\Omega}}$, its datum and the standing components, including the second-class components Y_ι. The outer plaquette factor in the native output formula is

$$\chi_j\left(\left(\bar{\Omega}_j \cap \bigcap_{\iota} (Y_\iota^c)^{\sim 2}\right)^{\sim 4}\right).$$

On the healed branch the passed inset test is incorporated in this output factor. The preparation's shell guards occur in the island integral. In both terms of the comparison, evaluate the output at the same retained datum, including the restored top field. The completed determining rows and the live-component operations are then common, as are this outer factor and the action factored outside the bracket. The localized interactions that read the inner history remain inside $W(\mathfrak{I})$. In a representation with a top mask depending on the family, we must compare the preparation and ordinary masks on the same level-j cubes at the actual exterior field. The implication from the preparation mask to the ordinary mask is sufficient, since multiplication by these ordered indicators is composed with the same positive maps. Resetting the coupling profile identifies the scale of the tests. The comparison also needs their actual readouts and supports.

Removal leaves the terms away from X unchanged and independent of its integration variables. For the near terms on the insertion side, follow a chain of cubes from the enlarged strip of X to a cube outside the exempt strips. Such a cube exists for the interaction domains of the bracket. The first exit from the strip touches X's strip and is outside every other strip by their separation. On the removal side, root the term at a cube of X's enlarged strip, now outside the remaining exempt strips. In either case the interaction tree meets its root cube. There are $C\check{R}_j^4$ possible roots. The rooted entropy bound and the strict decay reserve give a finite geometric sum per root. Thus the sum of the absolute near terms in the two brackets is bounded by $C\check{R}_j^4$ on their common admitted core. This uses the actual localized interaction domains and the strip separation.

Consequently, pointwise inside the bracket, inserting X, with its internal history in $\mathscr{H}$, costs at most $t_X(\mathscr{H})e^{C\check{R}_j^4}$, where $t_X(\mathscr{H}) = \sum_{\mathfrak{h}\in\mathscr{H}} \mathbf{T}'_{X,\mathfrak{h}}1$. The trace mass bound of Props. 4.63 and 4.64, with its charge dial increased by c_a, gives

$$K_H \sup_X t_X(\mathscr{H})e^{C\check{R}_j^4} \le \sup_{\mathfrak{h}\in\mathscr{H}} q_a^{2\sum_{i\le j} r_i|\mathsf{Z}_i(\mathfrak{h})|_i}.$$

Here the unspent factor $e^{-cp_0(g_j)}$ pays both the strip exponent and the finite shape count K_H. The condition $\mathfrak{p}_0 \ge 6r+1$ pays every increased lineage charge, whose logarithmic degree is at most $6r$. The supremum in this estimate is on that same actual core and is taken before the outer integration.

More precisely, let $E_{c,\mathscr{H}}$ specify a healed member at the cell c, and let E_c allow any internal history there. If B ignores earlier healed members and is unchanged by deleting the member at c, heredity and the pointwise comparison give

$$\widetilde{\nu}(B \cap E_{c,\mathscr{H}}) \le \left(\sup_{\mathfrak{h}\in\mathscr{H}} q_a^{\mathrm{Vol}(\mathfrak{h})}\right)\widetilde{\nu}(B \setminus E_c).$$

Apply $\mathbf{O}_{\mathfrak{I}}$ to the bracket bound and dominate it on the reduced bracket by $\mathbf{O}_{\mathfrak{I}\setminus\{X\}}$. Then apply the same subsequent positive kernels to the two sides. A joint survival event has the required blindness: healing removes an entire component, so its earlier lineage cannot also be the ancestor of a component still live later. Peeling in increasing healing time therefore proves the product bound

for several exclusive healed members. A bound on total polymer mass alone would not justify this relative comparison.

Use the collar lengths

$$\begin{aligned} f_j &= \left\lceil \frac{M_1(\lceil D_j \rceil + C)}{M\check{R}_j} \right\rceil, \\ c_{\mathrm{adj}}(j) &= 2c_h + c_{\mathbf{R}} + f_j + C, \\ m(j) &= 1 + 2(k-j), \qquad m_0(j) = 6(c_{\mathrm{adj}}(j)+1)m(j). \end{aligned}$$

At each level reserve $m_0(j)+f_j+C(c_h+c_{\mathbf{R}})$ additional cells, beyond the preceding depth expressed in the new units. The additional two buffers have this same order. The total physical width is bounded by

$$CM\check{R}_k + CM_1 \sum_{n\ge 0} (1+n) L^{-n} \big(\log \ell_\square + n + \check{R}_{k-n} + \log \bar{p}_{k-n} \big).$$

Since $\check{R}_{k-n} \le C(1+n)\check{R}_k$, it is at most

$$M\check{R}_k \left[C_1 + C_2 \frac{\log \ell_\square + C + \log\log x_k}{\check{R}_k} \right].$$

Choose a power of L with $\ell_\square \asymp M\check{R}_k$, with its fixed constant large enough for $\ell_\square > \max\{128, 2n_{\mathrm{sm}}\}s_k$ and $\ell_\square \ge 32 \max_j B_j s_j$. The width bound above allows this choice, since $\log \ell_\square / \check{R}_k$ tends to zero. The core of side $3\ell_\square/4$ leaves every ancestor of a deep cell at depth at least $4B_j$ in its level-j partition.

The comparison of runs is an induction on the level. Measure the preceding common depth in level-j cells and round up to T_0. The double blocks for a level-j average stay in the cells of their centres, so the current field is common on this inner lattice. Its inherited live hull Z' is also common from T_0 on. A cell of this hull can be touched by a component of the preceding live region from outside the inner lattice. The induction therefore keeps the entire preceding components that meet the common region, including those that only touch it.

At a step $j \ge 2$, a plaquette test is inserted outside $Z'^{\sim 4}$. Its localized background, including the existence check, uses only the full four-layer cube, which lies in the cell and its neighbours. Thus the failure set P_j is common from T_0+4, its hull from T_0+5, and the gauge region $(P_j'^{\sim 1} \cup Z'^{\sim 5})^c$ from T_0+6. The gauge draws use their own blocks before any draw and the same tile coins at the drawn sites. For a tested bond b both runs therefore obtain $u(b_-)V_{j-1}(b)u(b_+)^{-1}$ with the same factors. The approximate test reads this field and the background of its local test cube. Its one-cell neighbourhood puts Q_j at depth T_0+7 and Q_j' at T_0+8. The union defining Ω_j^c is common from T_0+10.

At $j=1$ the inherited live hull is empty. Start at $T_0 = 1$ with P_0'. A failed bare cube contributing to its hull there has side at most $L^{-1}s_1$. Its density test adds at most $L^{-2}s_1$ to the read, so the bare plaquettes tested there are at distance at least $(1-L^{-1}-L^{-2})s_1 > 0$ from the tile boundary. The bare bonds of the tile determine this first hull. With the first-step masks above, the depths for P_1, P_1', the gauge region, Q_1 and Q_1' are $T_0+1, T_0+2, T_0+3, T_0+4, T_0+5$, respectively. The first Ω_1^c is therefore common from T_0+7. The bare regularity test supplies regularity on the first determining region $\Omega_0 = \Omega_1^{\sim}$.

Call the common depth for Ω_j^c A_0. The components of Ω_j^c truncated to depths at least A_0 that touch its outer layer are common. One with diameter exceeding $m_0(j)$ is a first kind of trigger. Otherwise these components lie at depths at most $A_0 + m_0(j)$. From the region of depth at least A_0 remove their closed $4M_1$-neighbourhoods and take the resulting union of M_1-cubes. Its $4M_1$ inner rim lies in Ω_j: a bad cell meeting the rim would either touch the outer layer or be adjacent to a removed cluster, because $10M_1 < M\check{R}_j$ in level-j units. In either case it would itself have been

removed. The region contains depth $A_1 = A_0 + m_0(j) + 2$. At depth $A_2 = A_1 + f_j$ the tested bonds have distance at least $f_j M \check{R}_j - 5M_1 \geq \lceil D_j \rceil$ from its complement.

Use the common retained determining rows and data in this region and the regular rim in eq. 5.cdxii. At the first step the determining region includes $\Omega_1^{\sim}$. A retained bad cell in the comparison region is in a component disjoint from the outer layer, so its touching cells are still in the common Ω_1 data. In either case the post-draw link is common. Bi-invariance of the SU(2) angle bounds the difference of the two relative angle moduli by $\frac{\pi}{2}|V^{\mathrm{bg}}(V^{\mathrm{bg}\prime})^{-1} - 1|/g_{j-1}$, which is strictly less than the excluded window width u_σ. A relative group element at the cut locus has angle π, and the perturbed angle is still above the largest small-field threshold. Thus the split interval flags and the hot-cell clusters at depth A_2 are common. A long boundary cluster of these hot cells gives the second kind of trigger.

Use the depth t in level-j cells. Set $h_j = m_0(j) + c_{\mathrm{adj}}(j) + c_h + 3$ and reserve the two depths $A_\alpha = A_2 + h_j$ and $B_j = A_\alpha + h_j$. These layers are included in the width estimate above. If there is no trigger, a cluster of hot cells at adjacency range $c_{\mathrm{adj}}(j)$ meeting $t < \theta + c_{\mathrm{adj}}(j) + 1$ has its c_h-hull in $t < \theta + h_j$, for $\theta = A_2, A_\alpha$. This follows by adding its diameter budget $m_0(j)$ and the hull enlargement. In particular any cluster reaching the c_h-neighbourhood of a cell at depth A_α or greater stays beyond $A_2 + c_{\mathrm{adj}}(j)$. Thus exterior hot cells cannot join it at the smaller boxing adjacency c_{lay}.

Let $\mathcal{K}$ be the union of the common hot clusters meeting $t < A_\alpha + c_{\mathrm{adj}}(j) + 1$. Its c_h-hull stays below B_j. If a boxing cluster meets $\mathcal{K}$ or leaves the common region $t \geq A_2$, its output pieces stay in this hull or within c_h of $t < A_2$. The other clusters, their labels and their earlier-stage data are common by the induction. They have separation greater than $c_{\mathrm{adj}}(j)$ from $\mathcal{K}$. An output piece is within c_h of its cluster, so its distance from $\mathcal{K}^{+(c_h+1)}$ is at least $c_{\mathrm{adj}}(j) + 1 - c_h - (c_h + 1) = c_{\mathrm{adj}}(j) - 2c_h$. Choose the fixed additive constant in $c_{\mathrm{adj}}(j)$ so that this is at least $c_{\mathbf{R}} + f_j + 4$. The same depth buffer separates the piece from the unmatched outer data. Thus the $c_{\mathbf{R}}$-enlargement used by a component-local preparatory read is inside the common data. To apply this at a preparatory stage, keep the fields before the operation as well as the fields after each draw. The latter can overwrite a field whose earlier value the next test reads.

For a component X in the common inner region, the initial record consists of those incident fields, the trace of the label, the current failed tests and cascade cells, the earlier live components with their records, and the coins assigned to X. Append the answers in their order of use. Equality of this record compares physical link values and discrete decisions. Relative coordinates formed with different global centres can still differ. Their later uses must be through an original recorded answer or a local read, as in the completion test below. The waiting, quietness and single-component tests are functions of this trace. For an eligible component the boxes $X \cap Z_i$ and $X \cap \Omega_i^c$ in the waiting window give the prepared nest and every collar. Hence their row masks, including the incident rows, are common.

At stage zero and at each successor stage, the regularity test uses the localized background with the joined datum of X and its prescribed lifts of the top field there. Its determining rows and their stored values are common. An undefined local background gives the same failure on both sides. For a stage integrating level ι, the gauge draw reads complete blocks with centres in $((\Omega_{\iota+1}^{\sim 3})^c \setminus Z''_{\iota+1}) \cap X$ that lack the earlier gauge factor. That mask is common. Their contours are computed from the original retained V_ι links of these blocks, which are stored as Haar links. The common contour and the same normalized draw coin give the same gauge transformation at each site. The resulting incident links agree and the coarse centres are fixed. The approximate test then reads these links against the common local background.

Consider an ordinary completion test at a stage with stored level ι, and put $t = \iota + 1$. The completion reads a free bond with an endpoint in Ω_t from a test cube of the ordinary boundary layer inside the quiet component X. Its full bond read lies in $\mathrm{Box}_t(X)^{+2} \subset X \cap Z_t$, where $\mathrm{Box}_t(X) = \Omega_t^c \cap X$. The waiting condition excludes creations there in the stage window. The hull of the failed

cubes at level t is at distance at least five level-t cells from $\mathrm{Box}_t(X)$. Since the read of a failed cube stays in its own cell and the touching cells, the completion bond is outside the failed cube masks. It therefore belongs to a previously passed mask or to the plain strip. On the passed mask the recorded ordinary bound makes the completion indicator one.

In the plain strip the test reads the stored relative logarithm $\frac{1}{i}\log(V_\iota(b)V_\iota^{\mathrm{bg,loc}}(b)^{-1})$. The centre is the axial representative outside the nodes of the joined problem on the corresponding strip component of $\Lambda_t^c \cap \Lambda_\iota$. The strip nodes fix this representative at the test bond. The joined problem uses the pre-operation V_t, V_ι of $X \cap Z_t$. The lineage in the waiting window stayed live through each intermediate operation, so none of those operations wrote its fields. The level-$t+1$ gauge draw writes outside the enlarged live region. Hence the inputs have their stored values and are common in the two runs. This gives the same completion answer even when the test fails. It is used before testing the new sharp ball. The latter uses the localized next-stage centre and the post-draw link, both common. On each outcome keep its actual prefix.

On a passing stage the deleted slots are the stored nonpivot fluctuations on $Z_{\iota+1} \cap \Omega_{\iota+1} \cap X$ and the collar nonpivots on $(\Omega_{\iota+1}^c \setminus Z''_{\iota+1}) \cap X$. The translation to the expansion centre is an integration coordinate for the latter group. The real weight can use the global expansion background here. The physical retained state keeps the prescribed $V_{\iota+1}$ row and the surviving slots in their own charts. On a failure of the local sharp test, the stored prefix uses the untransformed real variables. Thus the two runs agree on the retained physical record through either branch. If a later read uses a translated coordinate that is actually retained, its dependence must be checked separately.
