FOUR-DIMENSIONAL SU(2) YANG–MILLS THEORY A PROOF OUTLINE FOR $\mathrm{tr}(F^2)$

Abstract. Under the stated uniform renormalization and short-distance hypotheses, we outline the continuum construction of the renormalized $\mathrm{tr}(F^2)$ observable in four-dimensional Wilson SU(2) theory at sufficiently small reference coupling. The proof follows the source-dependent multiscale integration through uniform correlation estimates, volume-first limits and canonical decomposition to scalar Osterwalder–Schrader reconstruction.

1. Introduction

Theorem 0. Assume the uniform renormalization and short-distance estimates stated below. For sufficiently small reference coupling, the correlations of $\mathrm{tr}(F^2)$ in four-dimensional Wilson SU(2) theory have nontrivial volume-first subsequential continuum limits. In every canonical component, the Schwinger functions satisfy the Osterwalder–Schrader axioms and reconstruct a local Hermitian scalar Wightman theory with positive energy and a unique vacuum. ■□

The precise statements are Thms. A to C.

Here $\mathrm{tr}(F^2)$ is the scalar curvature-squared observable with Wilson normalization. At each lattice cutoff we subtract the expectation of its smeared version $\mathcal{O}(f)$. A volume-first limit takes infinite volume at each fixed spacing before sending the spacing to zero along the weak-coupling sequence defined in § 2.3. The Euclidean functionals are first constructed on tests with separated supports and then extended to Schwartz tests flat on all coincidence diagonals. The reconstructed field generates the scalar sector associated with this observable.

The main task is uniform control of the source-dependent multiscale integration. The background field, its constrained inverse, the polymer sum and the large-field history sum must remain compatible on one analytic domain. In particular, a derivative of the normalizer and a change of exterior configuration must satisfy the same estimates used to bound local correlations. The proof develops these estimates in §§3 and 4 before passing to limits.

§5 controls the number of insertions and extends the limits to diagonal-flat tests. §6 gives the short-distance law and covariance. §7 treats spectral representations, canonical components and scalar reconstruction. Appendix A contains the auxiliary lattice estimates.

2. Lattice fields and the main results

This section fixes the Wilson measure, the normalization of $\mathrm{tr}(F^2)$, the admissible limiting sequences and the test spaces. The two main continuum statements follow the setting. The final subsection states the analytic inputs used in the proof, with their domains and uniformity requirements.

2.1. **Finite-cutoff identities and compactness.** This section establishes the finite-dimensional identities and compactness arguments used throughout the construction. None of its statements assumes a continuum Yang–Mills measure. Uniformity in the cutoff requires constants independent of the number of plaquettes, even though each integral is finite.

2.1.1. *The configuration space and its probability measure.* Let $G = \mathrm{SU}(2)$, the compact group of complex 2×2 matrices U with $U^*U = 1$ and $\det U = 1$. Its normalized Haar probability measure is denoted by dg. Fix a finite oriented graph obtained from a cubic lattice on a four-dimensional torus. Choose one orientation of each geometric bond; write B_+ for this set and impose $U_{\bar{b}} = U_b^{-1}$ for the reverse orientation. The configuration space is the compact space $\mathcal{V} = G^{B_+}$, with product probability measure dU.

A path is an ordered list of consecutive oriented bonds. Its transport is the ordered product of their matrices. For each geometrical elementary square choose one boundary orientation and one starting vertex, and denote its transport by U_p. Define

$$a_p(U) = 1 - \tfrac{1}{2}\,\mathrm{Re}\,\mathrm{tr}\,U_p,$$
$$A(U) = \sum_{p \in P} a_p(U),$$
$$N_P = |P|.$$

Changing the starting vertex conjugates U_p, and reversing orientation inverts it. Both changes preserve a_p.

Proposition 2.1 (Finite-cutoff existence and elementary bounds)**.** For every real $\beta \geq 0$,

$$e^{-2\beta N_P} \leq Z(\beta) := \int e^{-\beta A(U)} dU \leq 1.$$

Consequently $Z(\beta)^{-1} e^{-\beta A(U)} dU$ is a well-defined probability measure. Every bounded Borel observable has a finite expectation. ■

Proof. The eigenvalues of an element of G are e^{it}, e^{-it} for a real t. Thus $\frac{1}{2}\,\mathrm{Re}\,\mathrm{tr}\,U_p = \cos t$ lies in $[-1, 1]$, so $0 \leq a_p \leq 2$ and $0 \leq A \leq 2N_P$. Exponentiate these inequalities and integrate against a probability measure. The lower bound is strictly positive and supplies the normalization. □

The proof uses only compactness and positivity. Its constants degenerate when $N_P \to \infty$. In particular it supplies neither tightness of renormalized local fields nor a useful estimate for a continuum limit.

A gauge transformation is a family (h_x) of group elements indexed by vertices. It acts by $U_b \mapsto h_{b_-} U_b h_{b_+}^{-1}$. Successive factors cancel along a path, so a closed transport based at x is conjugated by h_x. Haar measure on each bond is unchanged by its independent left and right multiplications. This proves gauge invariance of the action and of the probability measure. A permutation of vertices and bonds coming from a lattice isometry also preserves the product measure and permutes the plaquettes. Therefore the finite torus measure has every isometry of that torus. This conclusion concerns these finite torus measures; it is not a proof that every infinite-volume periodic Gibbs state has every reflection.

2.1.2. *The continuum normalization is a local expansion.* Represent the Lie algebra by Hermitian traceless matrices and set $|F|^2 = \frac{1}{2}\operatorname{tr}(F^2)$. For a fixed such matrix,

$$1 - \tfrac{1}{2}\operatorname{Re}\operatorname{tr} e^{itF} = \tfrac{t^2}{4}\operatorname{tr}(F^2) + O(t^4|F|^4) = \tfrac{1}{2}t^2|F|^2 + O(t^4|F|^4).$$

The expansion follows by the matrix exponential series: the linear trace vanishes and the odd powers have zero real trace. If a smooth connection has elementary holonomy $U_p = \exp(ia^2 F_{\mu\nu}(x_p) + O(a^3))$, with all required derivatives uniformly bounded, it follows that

$$a_p = \tfrac{1}{2}a^4|F_{\mu\nu}(x_p)|^2 + O(a^5).$$

Hence, on a fixed compact region, summing $f(x_p)a_p$ over plaquettes gives the corresponding Riemann integral of $\frac{1}{2}f\sum_{\mu<\nu}|F_{\mu\nu}|^2$ as $a \downarrow 0$.

This is a deterministic smooth-field calculation. Typical configurations under a quantum measure have not been shown to satisfy its hypotheses. The calculation fixes the intended normalization of the observable; it does not prove convergence of that observable under the lattice measures.

2.1.3. *Sources, cumulants, and centering.* For bounded functions f_i on the plaquette barycentres put $O_i = \sum_p f_i(x_p)a_p$ and

$$Z(z) = \int \exp\{-\beta A(U) + \sum_{i=1}^{n} z_i O_i(U)\}\, dU,$$
$$z \in \mathbb{C}^n.$$

The estimate $|O_i| \le 2\sum_p |f_i(x_p)|$ gives an integrable uniform majorant on every compact source set. Termwise differentiation of the exponential series is therefore valid, and Z is entire. Since $Z(0) > 0$, continuity gives a sufficiently small polydisc about zero where Z has no zeros. On that polydisc there is a unique holomorphic logarithm W with $W(0) = \log Z(0)$.

The joint cumulant is

$$\kappa(O_1, \dots, O_n) = \partial_{z_1} \cdots \partial_{z_n} W(z)\big|_{z=0}.$$

Its expression in moments is

$$\kappa(O_1, \dots, O_n) = \sum_{\pi \in \mathrm{Part}(n)} (|\pi| - 1)!(-1)^{|\pi|-1} \prod_{J \in \pi} \mathbb{E} \prod_{i \in J} O_i.$$

Indeed, write $Z(z)/Z(0) = 1 + u(z)$ and use $\log(1+u) = \sum_{m \ge 1}(-1)^{m-1}u^m/m$ near zero. The coefficient of $z_1 \cdots z_n$ in u^m sums over ordered partitions into m nonempty blocks. Dividing by m turns their $m!$ orderings into $(m-1)!$. Conversely, expanding $e^{W(z)-W(0)}$ proves the moment–cumulant relation

$$\mathbb{E}\prod_i O_i = \sum_{\pi \in \mathrm{Part}(n)} \prod_{J \in \pi} \kappa((O_i)_{i \in J}).$$

Replacing O_i by $O_i - c_i$ changes the logarithm only by $-\sum_i z_i c_i$. Thus every cumulant of order at least two is unchanged. If $c_i = \mathbb{E}O_i$, every singleton cumulant vanishes. The centered moment functional is consequently

$$\mathbb{E}\prod_i (O_i - \mathbb{E}O_i) = \sum_{\pi \in \mathrm{Part}_{\ge 2}(n)} \prod_{J \in \pi} \kappa((O_i)_{i \in J}).$$

There are finitely many partitions at fixed n. Convergence of every separated cumulant of order at least two therefore implies convergence of the centered moments on the same tuples. Positivity must be applied to these moments, not to the cumulants separately.

The source is exactly a local coupling shift:

$$-\beta A + \sum_i z_i O_i = -\sum_p (\beta - w(x_p)) a_p,$$

$$w = \sum_i z_i f_i.$$

For a constant source c, $Z_\beta(c + w) = Z_{\beta - c}(w)$. This algebraic identity holds before any renormalization procedure is chosen.

2.1.4. *What a mass-preserving transformation preserves.* Let T be a fixed linear map on finite measures on a measurable space, with $(T\nu)(1) = \nu(1)$ for all measures in its domain. If $\nu_z = e^{\sum_i z_i O_i}\nu$ belongs to that domain, then

$$(T\nu_z)(1) = \nu_z(1).$$

This proves exact equality of sourced partition functions, and hence of their derivatives when the analytic dependence can be justified. It does not identify $T\nu$ as the distribution of a predetermined block variable. For that stronger conclusion one needs a measurable map M and the identity $(T\nu)(F) = \nu(F \circ M)$ for every bounded measurable F.

For example, on the two-point set $\{0, 1\}$ let $T\nu = \nu(\{0, 1\})\delta_0$. This positive linear map preserves total mass but changes the expectation of the coordinate from $\nu(\{1\})$ to zero when ν is a probability measure. Thus mass preservation alone contains no statement about observable expectations. Sources must be transported through the exact integral, with the choices of the transformation fixed throughout the source family.

2.1.5. *A fixed-spacing infinite-volume limit.* Consider the countable cubic lattice at a fixed positive spacing. Its configuration space is $\mathcal{V}_\infty = G^{B_+}$ with the product topology. This is a compact metrizable space: enumerate the bonds and use, for example, the sum of 2^{-j} times bounded compatible distances on their group coordinates. The space of Borel probability measures is sequentially compact in the weak topology.

For a finite set of bonds D, define the conditional specification

$$(\gamma_D F)(U) = \frac{\int F(V_D, U_{D^c}) \exp[-\beta A_D(V_D, U_{D^c})]\, dV_D}{\int \exp[-\beta A_D(V_D, U_{D^c})]\, dV_D},$$

$$A_D = \sum_{p : p \cap D \neq \varnothing} a_p.$$

The sum is finite and the denominator is bounded below by $e^{-2\beta N(D)}$, where $N(D)$ is the number of plaquettes meeting D. For continuous cylinder F, numerator and denominator depend continuously on only finitely many boundary bonds; dominated convergence proves that $\gamma_D F$ is another continuous cylinder function.

Proposition 2.2 (DLR existence at fixed lattice parameters)**.** Take torus Wilson measures at fixed spacing and fixed β, and extend their bond configurations periodically to the infinite lattice. Every sequence of torus side lengths tending to infinity has a weakly convergent subsequence. Each limit ν satisfies $\nu(\gamma_D F) = \nu(F)$ for every finite D and bounded Borel cylinder function F. It is invariant under all lattice translations and all lattice isometries preserved by the finite torus measures. ■

Proof. Compactness gives the subsequence. Fix D and a continuous cylinder F. For sufficiently large tori the finite set consisting of D, all adjacent plaquettes and the support of F embeds without identifications. The finite-volume conditional expectation identity then reads $\mu_\ell(\gamma_D F) = \mu_\ell(F)$ after periodic extension. Both integrands are continuous cylinder functions, so the identity passes to the weak limit. Continuous functions on the finite-dimensional compact coordinate spaces determine measures. The identity therefore extends first to bounded Borel cylinder functions, and, if desired, to all bounded Borel functions by the monotone class theorem. Invariance passes to the limit by the same continuous-cylinder argument, since a fixed lattice isometry acts continuously on the product space. □

This proposition does not change the spacing or the coupling. It provides no bounds uniform as the spacing tends to zero and gives no uniqueness or extremality of the limiting state. A theorem about all periodic Gibbs states is stronger than a theorem about these torus limit points.

2.1.6. *Compactness of separated correlation forms.* Let $\mathbb{E}$ be $\mathbb{R}^4$ or a fixed torus. A separated tuple consists of finitely many compactly supported C^1 functions with pairwise disjoint supports. Their compactness makes the minimum distance between nonempty supports positive. Fix the norm $\|f\|_1 = \max(\|f\|_\infty, \|\nabla f\|_\infty)$.

Proposition 2.3 (A diagonal extraction principle)**.** Suppose $T_{n,j}$ are symmetric multilinear forms on separated tuples and for every fixed n, $R < \infty$ and $d > 0$ there is a finite $C(n, R, d)$, independent of all sufficiently large j, such that

$$|T_{n,j}(f_1, \dots, f_n)| \le C(n, R, d) \prod_i \|f_i\|_1$$

whenever the supports lie in $B(0, R)$ and are separated by at least d. Then a subsequence converges at every separated tuple, simultaneously for all n. The limits obey the same bounds. ■

Proof. Choose all finite families of finite unions of rational closed boxes with positive mutual distance. The C^1 functions supported in each union form a separable normed space, being a subspace of a finite product of spaces of continuous functions on a compact set. Choose countable dense subsets. There are countably many finite tuples drawn from these subsets. Each sequence of values is eventually bounded by the assumed estimate. Bolzano–Weierstrass and a successive diagonal extraction give a common subsequence on which all these values converge.

Given any separated tuple, enclose its supports in pairwise separated finite unions of rational boxes, still inside a fixed bounded region. Approximate each function in C^1 by elements of the chosen dense sets. The telescoping multilinear identity

$$T(f_1, \dots, f_n) - T(g_1, \dots, g_n) = \sum_{i=1}^{n} T(g_1, \dots, g_{i-1}, f_i - g_i, f_{i+1}, \dots, f_n)$$

and the uniform bound make the approximation error uniformly small along the extracted subsequence. This proves the Cauchy property for the original tuple. Multilinearity, symmetry and the bound pass to the limit on each product of spaces with separated supports. □

The difficult Yang–Mills input is the hypothesis supplying $C(n, R, d)$. Finite-cutoff boundedness with a constant involving the number of plaquettes does not meet it. An exponentially large dependence on the physical torus volume also does not supply a bound uniform on $\mathbb{R}^4$. These are different compactness problems.

2.1.7. *Reflection positivity and closed limits.* Let θ be a geometric reflection, and let $\overline{X}$ denote componentwise complex conjugation of a test tuple. Real reflection-invariant centering preserves reflection positivity: replacing each $O_j(f)$ by $O_j(f) - m_j(f)$ maps every positive-half polynomial to another such polynomial and commutes with reflection when $m_j(\theta f) = m_j(f)$. Suppose for each cutoff a centered moment functional σ_j satisfies

$$\sum_{r,s=1}^{m} \overline{c_r} c_s \, \sigma_j(\theta \overline{X}_r \cdot X_s) \geq 0$$

for every finite collection of tuples X_r in the positive half-space. Within each X_r the supports are separated; the reflected negative tuple and the positive tuple are automatically separated from one another. Overlap between supports from X_r and X_s on the same side causes no problem, because these supports do not occur together in the same concatenated pair $\theta X_r \cdot X_s$.

If all the entries converge, the finite sum converges and remains nonnegative. Thus the limiting moment functional is reflection positive on this vector space of separated monomials. This elementary closedness statement is the precise sense in which positivity passes to limits. Passing from that domain to a Schwartz test space requires a density result and a continuous bound for the limiting distributions; it cannot be justified by closedness alone.

The algebraic form $\langle F, G\rangle = \sigma(\theta\overline{F} \cdot G)$ is positive semidefinite. Positivity of $\langle F + zG, F + zG\rangle$ for every complex z gives $|\langle F, G\rangle|^2 \leq \langle F, F\rangle\langle G, G\rangle$. Consequently a null vector is orthogonal to every vector. The quotient by the null space is an inner-product space, and its completion is a Hilbert space. Defining translations on this quotient additionally requires that they preserve the null space and satisfy the appropriate bounds. Strong continuity and a nonnegative generator are later conclusions with their own hypotheses.

2.1.8. *Two limits of what scalar correlations prove.* Let X be a real standard Gaussian variable and put $Y = X^2 - 1$. For $t < 1/2$ near zero,

$$\log \mathbb{E} e^{tY} = -t - \tfrac{1}{2}\log(1 - 2t) = \sum_{n \geq 2} \frac{2^{n-1}}{n} t^n.$$

It follows that $\kappa_n(Y) = 2^{n-1}(n-1)!$ for every $n \geq 2$. In particular a nonzero connected four-point function of a quadratic observable is compatible with a Gaussian underlying theory. For distinct centered jointly Gaussian variables the same conclusion is expressed by the connected cycle contractions of their Wick squares.

Accordingly a non-Gaussian $\mathrm{tr}(F^2)$ field is an important property of that field, but is not by itself a characterization of an interacting Yang–Mills gauge theory. Reconstruction from the $\mathrm{tr}(F^2)$ correlations produces the cyclic sector generated by that observable. Identifying a richer gauge-invariant algebra requires additional observables and compatibility arguments.

A polynomial cluster estimate likewise gives no positive mass gap. In a Hilbert space with a nonnegative self-adjoint H, a connected time correlation has the spectral form $\langle v, e^{-tH} v\rangle = \int_0^\infty e^{-tE}\, d\mu_v(E)$ for a vector orthogonal to the vacuum. If $d\mu_v(E) = Ee^{-E}\, dE$, the integral is $(1 + t)^{-2}$. It decays, yet its spectral measure meets every interval $(0, \varepsilon)$. The support condition required for a gap would instead exclude all such intervals below one fixed positive threshold.

These examples delimit the conclusions of the conditional construction. They do not contradict the proposed ultraviolet estimates, and they do not replace the work of proving those estimates.

2.2. **Renormalisation objects and norms.** The renormalisation step must represent the same integral after one scale is integrated, with local interactions whose bounds remain uniform in the number of scales. We describe those interactions by their local functions and measures, their field domains, and their norms. This gives a precise meaning to preservation of the class under a step.

Constructing backgrounds and keeping every substituted field inside its stated domain require analytic estimates beyond these definitions.

2.2.1. *Lattices, currents, and auxiliary geometric data.* The normalization in this section is that of $G = \mathrm{SU}(2)$. Its Lie algebra is represented by traceless Hermitian matrices, with $\langle A, B\rangle = \frac{1}{2}\operatorname{tr}(AB)$ and complexification $\mathfrak{g}^{\mathbb{C}}$. Fix an odd integer $L > 1$. The level-j lattice, denoted $\mathbb{T}^{(j)}$, consists of the sites retained after j blockings of a periodic bare lattice. Its bare spacing, expressed in level-j units, is $\eta_j = L^{-j}$. A bond configuration satisfies $U(\bar{b}) = U(b)^{-1}$. Products along oriented paths are ordered in path order. Positive coordinate bonds suffice to specify a configuration. All suprema over bonds below use these bonds. In the left multiplication chart, reversal is $J(\bar{b}) = -\operatorname{Ad}(U_b^{-1})J(b)$. The complex configuration group is $\mathrm{SL}(2,\mathbb{C})$.

For a positively oriented plaquette p, based at its chosen corner, write U_p for its holonomy and set

$$a_p(U) = 1 - \tfrac{1}{2}\operatorname{tr} U_p,$$
$$A(U) = \sum_p a_p(U),$$
$$A(c,U) = \sum_p c(x(p))a_p(U).$$

Here $x(p)$ is the plaquette midpoint. On real configurations this is the real Wilson action; the same formula is its holomorphic extension. For definiteness the current on a lattice of spacing η is specified by its variational normalization:

$$\frac{d}{dt}A(e^{i\eta tB}U)\Big|_{t=0} = \eta^4 \sum_b \langle J_\eta(U)(b), B(b)\rangle. \tag{2.i}$$

The sum is over positive bonds and B is arbitrary. This identity defines every component of J_η, also for complex U by analytic continuation. It fixes the transports and factors implicit in the notation $D_U^* F_U$. One must use the plaquette divergence associated with eq. 2.i in that notation; the adjoint of the site gradient alone has a different domain. At $U = \mathbf{1}$, differentiation in the potential coordinate $U(t) = e^{i\eta tB}$ gives $J'_\eta(\mathbf{1})B = \mathrm{d}_\eta^* \mathrm{d}_\eta B$, where d_η here is the oriented plaquette difference on one-forms divided by η. If the numerical mesh changes from η to $\eta' = L^m\eta$ while the group configuration stays fixed, potentials are multiplied by L^{-m} and currents by L^{-3m}. This follows directly from eq. 2.i and the chart $e^{i\eta A}$, and specifies the direction of the unit change. The current variable of a complex pair, introduced below, is independent of this particular function of U.

Fix powers of L called $\mathfrak{M}, M_1', M$, a gap $\rho = R_1\mathfrak{M}$, and constants $C_{\mathrm{box}}, C_{\mathrm{pot}}$. They are part of the auxiliary data, selected before domains or norms are formed. The first two sizes concern backgrounds and walks; M is the localization cube size. They are not interchangeable. The partition π_j consists of the centered, half-open M-cubes in level-j units. Boundary conventions are fixed once on every lattice. For a cubical region Y, $Y^{\sim n}$ means addition of n layers in the partition currently named; $Y^{\sim -n}$ means removal of those layers. A hull is the smallest union of cubes of the named partition containing the set. These operations include their periodic versions.

The two erosion assignments are fixed as follows. Take $L \geq 13$ odd, $R_1 \geq L$, $M_1' \geq R_1\mathfrak{M}$ and $M \geq L^4 M_1'$, in addition to the background floors. For $Z \in \mathcal{D}_{p-1}$ put $\Omega_0^{(1)} = \Omega_0^{(2)} = Z$. In bare

units their successive members are

$$\begin{aligned}\Omega^{(1)}_{q+1} &= \bigcup_{\substack{C \text{ of side } \mathfrak{M}L^{q+1}\\ C\subset\Omega^{(1)}_q,\ \mathrm{dist}_\infty(C,(\Omega^{(1)}_q)^c)>R_1\mathfrak{M}L^q}} C,\\ \Omega^{(2)}_{q+1} &= \bigcup_{\substack{C \text{ of side } M_1'L^{q+1}\\ C\subset\Omega^{(2)}_q,\ \mathrm{dist}_\infty(C,(\Omega^{(2)}_q)^c)\geq M_1'L^{q+1}}} C, \qquad 0\leq q<p.\end{aligned} \tag{2.ii}$$

Each union contains every cube of the named aligned partition satisfying its test. A tower of depth $n \leq p$ is the truncation of this construction at n. These definitions commute with the allowed translations and common lifts. Empty members remain empty; for a full torus the complement distance is infinite and the members remain full. The maximal-cube rule is essential: it gives the upper bound on total erosion proved in Lem. 3.126.

Here is the determining set of a nested sequence. Work temporarily in level-k units, so the spacing of level j is $\xi_j = L^{j-k}$. Let $\Omega_0 \supset \cdots \supset \Omega_k$ and $\Omega_{k+1} = \varnothing$. The set Γ_j consists of bonds of $\mathbb{T}^{(j)}$ whose endpoints lie in Ω_0, at least one endpoint lies in Ω_j, and neither lies in Ω_{j+1}. Thus inward bonds crossing into the next layer are excluded. Put

$$\mathbf{B} = \bigcup_j \Gamma_j,$$

$$M_{\mathbf{B}}(U) = (\mathcal{M}^j U|_{\Gamma_j})_j. \tag{2.iii}$$

The endpoints of these bonds are the nodes. They are the tops of the blocks, or pillars, partitioning the determining region. A residual gauge function equals $\mathbf{1}$ at all nodes. In particular, imposing additional inward-bond constraints changes this problem.

The averaging map $\mathcal{M}$ used in eq. 2.iii is the symmetric contour average. For group elements V_i of small diameter their mean is the unique nearby V satisfying $\sum_i \log(V_i V^{-1}) = 0$. The contour transport $U(y,x)$ is the mean over the shortest paths from y to x in its centered block that traverse the coordinate directions in one of their orders. Set $U(x,y) = U(y,x)^{-1}$. For a coarse bond c, $x' = x + (c_+ - c_-)$, and straight transports $U[c]$ and $U([x,x'])$,

$$\mathcal{M}(U)(c) = \exp\left(L^{-4}\sum_{x\in B(c_-)} \log\{U(c_-,x)U([x,x'])U(x',c_+)U[c]^{-1}\}\right) U[c]. \tag{2.iv}$$

All logarithms in regular neighborhoods are their near-identity branches. Away from those neighborhoods a measurable extension of the contour means and logarithms is auxiliary input. Exact identities using that extension require its gauge covariance; small-field analyticity concerns only the displayed branches. Existence of a globally symmetric extension with every desired property is not asserted merely by writing eq. 2.iv.

For every determining sequence and real regular datum $\mathbf{V}$, the background input is a regular critical orbit for $\sum_{p\subset\Omega_0} a_p$ on $\{U : M_{\mathbf{B}}(U) = \mathbf{V}\}$, together with a chosen analytic continuation $\Phi_{\mathbf{V}}(B)$ at datum $e^{iB}\mathbf{V}$. The representatives, gauge, analytic domain and transport under local charts are included in this input. Uniqueness, existence and uniform estimates for these maps are separate background theorems. The word "background" does not substitute for them.

2.2.2. *Hereditary domains and their shifts.* A triple of level j on X is defined on the bare mesh η_j when lengths are expressed in level-j units. It is $P = (U, A', \mathbf{J})$, with U real and $A', \mathbf{J}$ complex Lie-algebra-valued bond forms. Its pair is $\mathbf{p}(P) = (\mathbf{U}, \mathbf{J})$, where $\mathbf{U} = e^{i\eta_j A'}U$. A triple is a splitting of its pair. Fix positive radii a_0, a_1, a_2. The simple conditions are

$$\begin{aligned} &|\partial U - \mathbf{1}|, |\partial \mathbf{U} - \mathbf{1}| < a_0 \eta_j^2, \qquad |A'|, |\nabla_U A'| < a_1, \qquad |\mathbf{J}| < a_2; \\ &|A|, |\nabla A| < C_{\text{pot}} M a_0 \quad \text{in the real gauges described below.} \end{aligned} \tag{2.v}$$

For each cubical box contained in X with side at most $C_{\text{box}} LM$, such a real gauge must exist, with $U = e^{i\eta_j A}$. The norms are maximum matrix norms in the named local units. For a one-form component A_μ based at its initial site, fix the forward convention

$$(\nabla_\nu^U A)_\mu(x) = \eta_j^{-1}\{\mathrm{Ad}(U_\nu(x))A_\mu(x + \eta_j e_\nu) - A_\mu(x)\}.$$

The maximum of these component norms defines $|\nabla_U A|$. In the usual two-radius notation $a_2 = a_0$.

For every subdomain $Z \subset X$ at every level $p \le j$, for both erosion assignments, and every truncation depth $1 \le n \le p$, form its determining set $\mathbf{B}'$. Define its tower configuration by

$$U_n(Z; P) = \Phi_{M_{\mathbf{B}'}(U)} \left(\frac{1}{i} \log\{M_{\mathbf{B}'}(\mathbf{U}) M_{\mathbf{B}'}(U)^{-1}\} \right). \tag{2.vi}$$

This expression is required to exist in the chosen continuation domain. On Z with two layers of the M-cubes of level $p-1$ removed, require

$$\begin{aligned} |\partial U_n(Z; P) - \mathbf{1}| &< a_0 L^{-(j-p)} \eta_p^2, \\ |J(U_n(Z; P))| &< a_0 L^{-(j-p)} L^{2(n-p)}. \end{aligned} \tag{2.vii}$$

The current in the second line is formed in level-n units. Impose the same conditions with $\mathbf{U}$ replaced by U. These are quantifiers over every allowed Z, p, n, not just the domain on which an activity is eventually evaluated. The hereditary core $\mathcal{U}_j^\circ(X; a_0, a_1, a_2)$ is the set of triples satisfying eq. 2.v–eq. 2.vii. Its pair image is the analytic pair domain; holomorphy means holomorphy in $(A', \mathbf{J})$ on every open slice with U fixed. The inequalities are strict. Requiring the tower maps to exist in their open continuation domains is part of membership.

An activity on this core must have the tie: its values at any two splittings of the same complex pair agree. Gauge invariance means invariance under simultaneous transformation of both entries of the pair; the current at a bond is based at its initial site and transforms by conjugation there. The core itself is not saturated by complex gauge transformations. Extension of a function to the union of complex orbits requires equality on all intersections and holomorphic descent; it is an additional statement when used.

Restriction ρ_X discards bonds and variables outside X without extending them across the boundary. If an evaluation changes its numerical mesh from η_j to $\eta' = L^m \eta_j$, the coordinate change is explicitly

$$\begin{aligned} (U, A', \mathbf{J}) &\longmapsto (U, L^{-m} A', L^{-3m} \mathbf{J}), \\ m &\ge 0. \end{aligned} \tag{2.viii}$$

For a shift $(\mathbf{H}, \mathrm{j})$ on the same lattice define

$$\begin{aligned} P \dotplus (\mathbf{H}, \mathrm{j}) &= (U, A' \boxplus \mathbf{H}, \mathbf{J} + \mathrm{j}), \\ e^{i\eta_j (A' \boxplus \mathbf{H})} &= e^{i\eta_j \mathbf{H}} e^{i\eta_j A'}. \end{aligned} \tag{2.ix}$$

The logarithm defining $\boxplus$ is the small branch; inclusion in its domain is required. The independent current is shifted additively. Replacing it by $J(e^{i\eta_j \mathbf{H}}\mathbf{U})$ at every complex argument would change the construction.

The decoupled response on a cubical region Y is the pair of maps $\mathfrak{h}_Y(s;P,B') = (\mathbf{H},\mathsf{j})$, holomorphic in complex cube parameters $|s(\Delta)| < e^{\bar\kappa}$, the complex triple variables, and the datum B'. It vanishes at $B' = 0$. Its first component is the solution of the actual background equations with the propagators decoupled by these parameters:

$$\begin{aligned} \mathbf{H} &= \mathbf{a} - \mathsf{H}(s)\mathsf{D}, \qquad & \mathsf{D} &= C_k(\mathbf{a} - \mathsf{H}(s)\mathsf{D}), \\ \mathbf{a} &= \mathsf{H}_1(s)B' + \mathbf{A}_1, \qquad & \mathbf{A}_1 &+ \mathfrak{G}(s)\mathsf{W}_s(\mathbf{a}) = 0. \end{aligned} \tag{2.x}$$

Here C_k is the nonlinear part of the straightened constraint map; H, H_1 are the constrained linear minimizers; $\mathfrak{G}$ is the inverse on the simultaneous Landau and zero-average slice; and W_s is the nonlinear gradient remainder. The actual raw-coordinate force and complete carrier prescription are given in Prop. 3.171 and Lem. 3.172 and eq. 3.mccxv. Their first-order regular-pair domain, independent current radius, and parameter discs are part of that construction. The reduced current is the multiplier expression eq. 3.mccxviii, with the uniform bound eq. 3.mccxix. At one change of units its value is $L^{-3}\mathbf{J} + \mathsf{j}$.

The response has realness, gauge covariance, compatibility under restriction to wall-components, and transport by common lifts. A wall-component is a component of cubes sharing three-dimensional faces. When s vanishes on separating cubes, the equations split over the remaining components, and the response on a component with no datum is zero. In local first-order norms its size is at most $Ce^{C\bar\kappa}\sup|B'|$; a response viewed $k-j$ levels below has the additional potential factor $L^{-(k-j)}$. At the whole-sequence all-one point over a physical critical real reference, its shifted pair is the corresponding background and its own current, with the recorded node gauge factor, by Prop. 3.176. Existence, uniqueness and the stated properties are proved in Props. 3.174 and 3.175.

For a term F on X let X_0 be its hull in the cubes of the decoupling scale. The interpolation is

$$\Phi_Y[F](s,\nu) = F\big((\rho_X P) \dot{+} \nu\mathfrak{h}_Y(s;P,B')\big). \tag{2.xi}$$

Every occurrence of eq. 2.xi requires a domain-inclusion hypothesis: for all the indicated s and $|\nu| < \varrho_F$, its triple lies in the core of F. One sufficient quantitative hypothesis, with a fixed constant $c_F > 0$, is inclusion throughout

$$|\nu| < c_F L^{k-j} a_{0,j}\delta(\theta_k)^{-1}e^{-C_F\bar\kappa} =: \varrho_F > 1. \tag{2.xii}$$

In inner and removed substitutions separate inclusion bounds and their own radii are required. eq. 2.xii is not a consequence of the formal shift law in eq. 2.ix.

For disjoint finite cube sets $\mathcal{K},\mathcal{N}$ define

$$F[\mathcal{K}\mid\mathcal{N}] = \sum_{\mathcal{K}'\subset\mathcal{K}} (-1)^{|\mathcal{K}|-|\mathcal{K}'|}F(\mathbf{1}_{\mathcal{K}'\cup\mathcal{N}}). \tag{2.xiii}$$

This equals the integral of $\prod_{\Delta\in\mathcal{K}}\partial_{s(\Delta)}F(s+\mathbf{1}_{\mathcal{N}})$ over the unit cube, by iterating the one-variable fundamental theorem of calculus. Summing eq. 2.xiii over subsets gives its exact resummation identity. For the rooting assertion, use the wall-components of $\mathcal{K}\cup\mathcal{N}\cup X_0$. If such a component contains a cube of the differenced set $\mathcal{K}$ and misses the base X_0, then locality and splitting make the function independent of that component's parameters, so the alternating bracket is zero. An additional component made only of fixed $\mathcal{N}$ cubes need not make a bracket zero. For $\Phi_Y[F](s,\nu) - \Phi_Y[F](s,0)$ the expression vanishes if the component of the base has no datum for the shifted

response, since that response is then zero on the base. These conclusions require the stated splitting and support properties of the actual response. If $|\Phi_Y[F]| \le M_F$ on the stated polydisc, Schwarz's lemma gives $|\Phi_Y[F](s,1) - \Phi_Y[F](s,0)| \le 2M_F/\varrho_F$. Cauchy's formula on the s discs then bounds the bracket of this excess by $2M_F\varrho_F^{-1}(e^{\bar\kappa}-1)^{-|\mathcal{K}|}$. For $\bar\kappa \ge 1$ this is at most $2M_F\varrho_F^{-1}e^{-(\bar\kappa-1)|\mathcal{K}|}$. When $\mathcal{K}$ is nonempty, this also bounds the bracket of $\Phi_Y[F](s,1)$ itself: its value at $\nu = 0$ is the s-independent constant $F(\rho_X P)$, which the bracket annihilates. For an empty differenced set, an un-subtracted constant does not acquire ϱ_F^{-1}. Thus the algebraic bracket bound is proved once the response and inclusion hypotheses have been supplied.

2.2.3. *Pointed families, marginal coefficients, and list norms.* Let $\mathcal{D}_j$ be the connected unions of cubes of π_j. Set $d_j(X) = M^{-1}$ times the length of a shortest tree in X meeting each cube; it is zero for one cube. A pointed family is the collection $E(X, \mathbf{p}, z)$ for $X \in \mathcal{D}_j$ and unit sites $z \in X \cap \mathbb{T}^{(j)}$, with each term analytic on its core, gauge invariant and tied. Its norm is

$$\|E\|_{j,\kappa} = \sup_{\text{admissible tori and their companion}} \sup_{X, z\in X} e^{\kappa d_j(X)} \sup_{P\in\mathcal{U}_j^\circ(X)} |E(X, \mathbf{p}(P), z)|. \tag{2.xiv}$$

The supremum in z is not a sum over base points. For an unpointed family omit z from this formula. Sums over domains require the separate lattice-animal summability bound at the chosen decay rate.

A companion is a single family $\widehat{E}$ on $\mathbb{Z}^4$, agreeing with every torus term on every common lift of a non-wrapping domain with the necessary collar. For a fixed level, fixed frame prefix and fixed initial weight, the same companion serves every cutoff on which those input data coincide. Its existence is compatibility between tori, not a property that can be tested on just one torus. Individual terms are required to be covariant under the translations preserving π_j. The pointed total has the stronger property

$$\mathcal{P}_z^{\mathsf{T}}(W) = \sum_{X\ni z} E(X, \mathbf{p}_W, z),$$
$$\mathcal{P}_{rz}^{\mathsf{T}}(rW) = \mathcal{P}_z^{\mathsf{T}}(W) \tag{2.xv}$$

for every lattice isometry r, including unit translations. Here

$$\mathbf{p}_W = (U_j(W), J(U_j(W))).$$

The covariance class consists of the W for which these backgrounds exist, every restriction lies in the required core, and

$$L^{2j} \max_p |\partial U_j(W)(p) - \mathbf{1}| < c \min\{\varepsilon(\theta_{j-1}), \varepsilon(\theta_j)\}. \tag{2.xvi}$$

Both W and rW must be in this class. Invariance of the sum over z alone is weaker than eq. 2.xv.

The site tent is $h_z(x) = \prod_{\mu=1}^4 \max\{1 - |x_\mu - z_\mu|, 0\}$. Evaluate it at bond and plaquette midpoints. Then $\sum_z h_z(x) = 1$ and $h_{rz}(rx) = h_z(x)$. A bond-rooted term is pointed by $E(X, \cdot, z) = \sum_b h_z(x_b) E(X, b; \cdot)$; its collar must contain the supports of these tents. The pointed Wilson family has terms $A(h_z, \mathbf{U})$ on the cube of z enlarged by one layer, and zero elsewhere. This convention distributes a coupling counterterm by the same base points as the regular family.

To define the coefficient, use the chart $\mathsf{e}_X(A, J) = (e^{i\eta_j A}, J)$ at $(\mathbf{1}, 0)$. Directions are pairs of complex bond forms, with norm $\max\{\sup|A|, \sup|\nabla A|, \sup|J|\}$. Let H_∞ be the derivative of the infinite-lattice background map at its trivial datum, in its fixed gauge, and put

$$\mathfrak{h}_\infty B = (\mathsf{H}_\infty B, \mathrm{d}^*\mathrm{d}\mathsf{H}_\infty B).$$

This linear response is an input from the background theory; it must include its domain and decay estimates. Choose an orthonormal color basis t_1, t_2, t_3, and let δ_c^a be t_a on the unit bond c and zero elsewhere. With Hessians taken in the displayed chart,

$$\begin{aligned} \Pi^E(c,c';z) &= \tfrac{1}{3}\sum_{a=1}^{3}\sum_{\widehat{X}\ni z} \mathrm{Hess}\,\widehat{E}(\widehat{X},\cdot,z)[\mathfrak{h}_\infty\delta_c^a, \mathfrak{h}_\infty\delta_{c'}^a], \\ \Pi^E(c,c') &= \sum_z \Pi^E(c,c';z) =: \Pi^E_{\mu\nu}(c'_- - c_-), \\ b[\widehat{E}] &= \sum_{u\in\mathbb{Z}^4} \Pi^E_{\mu\nu}(u)u_\mu u_\nu, \qquad \mu\neq\nu. \end{aligned} \tag{2.xvii}$$

The coefficient is defined only when all these sums converge absolutely, the middle expression depends just on directions and displacement, and the last value is independent of the distinct directions chosen. Gauge independence, the Ward identities and the reduction of the second-moment tensor to this scalar require proof. They are not incorporated by declaring an arbitrary Hessian to have a coefficient. In particular, a claim that the Wilson tent family has coefficient one requires the linear-response identities with the normalization in eq. 2.i.

A member is a triple $(E, \widehat{E}, e)$ satisfying eq. 2.xiv–eq. 2.xvii, with $e = b[\widehat{E}]$. Activity bounds and coefficient bounds use their declared physical radii, including the inverse-square readout factor of § 4.23. A list at step $k+1$ contains such members for $j \le k$ and unpointed slot families $H^{(j)}$ with no coupling counterterm. Its action is

$$\begin{aligned} S[\mathfrak{f}](U) = &\sum_{j\le k}\left[\sum_z\sum_{X\ni z}\{E^{(j)}(X,U,z) - E^{(j)}(X,\mathbf{1},z)\} - e_j A(U)\right] \\ &+ \sum_{j,X}\{H^{(j)}(X,U) - H^{(j)}(X,\mathbf{1})\}. \end{aligned} \tag{2.xviii}$$

Every evaluation uses the background and units appropriate to its level. Slot families have companions, term covariance under the localization translations, and invariant totals on the stated background class, but no requirement of a pointed coefficient. For $0 < \alpha_{\mathrm{H}} < 1$ their list size is

$$\begin{aligned} N_{\mathfrak{a}}(\mathfrak{f}) &= \sum_{j\le k}(k+2-j)^{3/2} L^{-\alpha_{\mathrm{H}}(k-j)}\|E^{(j)}\|_{j,\kappa} + \sum_j \varrho_j^2 \|H^{(j)}\|_{j,\kappa}, \\ \varrho_j &= \max_\iota \frac{(1+\beta_{\mathrm{s}})a_{\iota,k+1}}{a_{\iota,j}}. \end{aligned} \tag{2.xix}$$

All three radii, including the independent-current radius, enter this maximum. Admissible radius systems require $CMa_{0,j} < a_{1,j}$, $a_{1,j}^2 \le Ca_{0,j}$, $a_{\iota,j} \le (1+\beta_{\mathrm{s}})a_{\iota,k+1} \le C(k+2-j)^{1/2}a_{\iota,j}$, and a fixed small upper bound on the absolute radii. They also require $\mathsf{s}_{\mathfrak{a}} := \delta(\theta_k)/a_{0,k+1} \le c$. The constants and the admissible systems are specified before taking eq. 2.xix. For the running system use $a_{\iota,j} = \check{\alpha}_{\iota,j} := \min\{\alpha_{\iota,j-1}, \alpha_{\iota,j}\}$ at $j \le k$ and $a_{\iota,k+1} = \alpha_{\iota,k}$. For the absolute system use fixed α_ι at $j \le k$ and $a_{\iota,k+1} = \alpha_\iota/(1+\beta_{\mathrm{s}})$.

2.2.4. *Frames, histories, structures, and stored variables.* A frame is a real sequence $\theta_0, \dots, \theta_k \ge \gamma^{-2}$, with $0 < \gamma < e^{-1/2}$, such that, for $i \le j$,

$$\underline{\lambda}(j-i) - c_5 \le \theta_i - \theta_j \le \bar{B}(j-i),$$
$$\check{R}_j = R(\min_{i\le j} \theta_i),$$
$$\check{R}_j \le L\check{R}_{j+1}, \tag{2.xx}$$

where $R(y)$ is the smallest power of L not below $(\log y)^r$. Set $\bar{g}_j = \theta_j^{-1/2}$, $p_0(g) = A_0(\log g^{-2})^{\mathfrak{p}_0}$, $p_1(g) = (\log g^{-2})^{\mathfrak{p}_1}$, $\varepsilon_j = \bar{g}_j p_0(\bar{g}_j)$, $\delta_j = (A_1/A_0)\varepsilon_j$ and $\alpha_{\iota,j} = C_\iota \theta_j^{-1/2}(\log\theta_j)^q$. Here $\mathfrak{p}_0 > \mathfrak{p}_1$, $A_1 < A_0$, and all constants are fixed. The waiting depth is $\mathsf{N}_j = \check{R}_j$. The barred couplings belong only to the auxiliary frame. The actual running couplings $x_j^{-1/2}$ are separate. The weights x_j are separate entries, with $x_0 = \beta$ and $x_j = x_{j-1} - b_j$. A tube requires

$$|\theta_j - x_j| \le \mathsf{t}_j,$$
$$\mathsf{t}_j \le c\theta_{j+1}(\log\theta_{j+1})^{-2q_{\mathrm{t}}},$$
$$q_{\mathrm{t}} \ge q,$$
$$2q_{\mathrm{t}} > q + \mathfrak{p}_0. \tag{2.xxi}$$

Its radii are non-increasing. At a terminal frame with no next member the radius must instead be supplied explicitly; for a one-member frame require $\mathsf{t}_0 \le 2c\theta_0(\log\theta_0)^{-2q_{\mathrm{t}}}$. All tests, regions and kernels are formed from θ, not from the unknown entries x_j.

A history is a finite record of every outcome of the tests of the steps and of the operations inside large-field components, including coordinate frames in the signed-permutation group W_4. The formation data assign to each record its regions, stored bonds and integration variables. In particular they give total tests $\chi, 1-\chi$ as Borel functions on the actual variable space, with each value in $\{0,1\}$. A plaquette test is $\mathbf{1}\{|\partial U_{j,\square} - \mathbf{1}| < \varepsilon_j\eta_j^2\}$; a fluctuation test is $\mathbf{1}\{|\mathcal{A}_j| < \delta_j\}$. The local background map, the neighborhoods of each test, and the collar and rim tests with their sharper thresholds are part of the formation data. Listing the names of tests does not define them.

The label is $\mathcal{S} = (\Omega_j, \Lambda_j, S_j)_{j\le k}$ with $T_\ell \supset \Omega_1 \supset \Lambda_1 \supset \cdots \supset \Lambda_k$; $S_j \subset \Omega_j \setminus \Lambda_j$ records strips and failed fluctuation regions. Write $Z_j = \Lambda_j^c$. The step creates unions of $M\check{R}_j$-cubes, with gaps at least $cM\check{R}_j$ in local units. Nests inside an operation may have gaps of only one M-cube of the later level. The formation data must state the actual enlargements and test neighborhoods; bounds described by a fixed number of layers leave that number as a required datum.

An operation at level t acts on the prescribed class of components which are small, quiet for N_t steps, and satisfy the waiting and quarantine conditions. It first integrates stored fields in N_t stages, then tests extension of the exterior field, integrates the inner box in an axial gauge with frame in W_4, restores block variables through normalized reference laws, localizes the exponent, and performs its last test. A healed component leaves the label; an island passes the earlier tests and fails the last; a drop-out fails after $n \le \mathsf{N}_t$ stages and keeps those stages. These alternatives and every operation kernel must be given as measurable maps and positive measures. Their exactness is a separate equality of represented measures.

An operation can use its waiting window only when $t_\flat = t - \mathsf{N}_t \ge 0$. Before then it is not eligible; no negative-level history is introduced. A drop-out C records its former regions $\Omega_l^\circ \cap C$ and its stage boxes $Z_l''(C)$. For each integer $0 \le \nu(C) \le n(C)$ define

$$\Omega_l^{\boldsymbol{\nu}} \cap C = \begin{cases} C \setminus Z_l''(C), & t_\flat < l \le t_\flat + \nu(C), \\ \Omega_l^\circ \cap C, & t_\flat + \nu(C) < l \le t_\flat + n(C). \end{cases} \tag{2.xxii}$$

Outside the affected levels retain the label regions. The choice $\boldsymbol{\nu} = n$ is the determining sequence; it governs backgrounds. The choice $\boldsymbol{\nu} = 0$ is the action sequence; it governs the sums and the coupling profiles. Standing marks record the analogous Λ_l, S_l data. Their waiting windows are required to be disjoint at a point, and old marks disappear when swallowed by a healed component or an island. These geometric facts require verification for the actual operation.

A structure $\sigma = (\mathcal{S}, \boldsymbol{\nu}; t, \phi)$ also records a phase. Its phase weight is 0 at output, 1 at the step input, and $1 - n/(2\mathsf{N}_t)$ after n stages. A structure precedes another if it counts no more completed stages and has lower level, or the same level with larger phase weight. At an index $0 \le m \le t$ the radius coefficient is

$$c_\sigma(x \mid m) = 1 - \beta_{\mathrm{s}}(1 - 2^{-(t-m)}) + \varpi_\phi \mathsf{g}_t(m) - \beta_{\mathrm{R}} \sum_{l \in \mathrm{Re}_\sigma(x)} 2^{-|m-l|},$$
$$\mathsf{g}_t(m) = \begin{cases} \theta_{\mathrm{s}}\beta_{\mathrm{s}} 2^{-(t-m)}, & m < t, \\ \beta_{\mathrm{s}}, & m = t. \end{cases} \tag{2.xxiii}$$

Here $0 < \theta_{\mathrm{s}} < 1$ and $\beta_{\mathrm{R}} = c_{\mathrm{R}}\beta_{\mathrm{s}}$ are fixed fractions; $\mathrm{Re}_\sigma(x)$ consists exactly of the levels of the first $\nu(C)$ stages of each drop-out containing x. The layer-radius formation data give the original regularity layer and the layer after each stage. Their nonnegative difference is $e_\sigma(x)$. The lift is $L_\flat^{2e_\sigma(x)}$ for a fixed $L_\flat \ge 1$. The layer-m radii are multiplied by this lift and, except for the real-potential gauge bounds, by eq. 2.xxiii. Unfinished structures here have $t \ge 1$: at layer zero use level-one radii; at the unfinished top use level-$t-1$ radii. The initial $t = 0$ base structure is separate input with its own specified radii. The data must ensure $c \le c_\sigma \le 1 + \beta_{\mathrm{s}}$.

The space $\widetilde{U}^c_\sigma(X)$ imposes the simple, tower and small-field-core clauses with those layer radii, with one splitting, on every subdomain and every preceding structure. The layer assignments, erosion rules, continuation maps and recorded remade levels are thus indispensable parts of its definition. The claims that restriction or a stage substitution maps one such space into another are analytic inclusion hypotheses. They require the specified radii and constants; a formal partial order by itself does not prove them.

2.2.4.1. Pointwise and local gauge clauses. For a structure with first member Ω_0, let $\mathsf{i}(Y)$ consist of the bare bonds with both endpoints in $Y \cap \Omega_0$. The pointwise part of the structured space imposes the real and complex curvature bounds on every plaquette formed by these bonds. The complex potential, its covariant differences on their retained stencils and the independent current have their layer bounds on the same carrier. In particular the pointwise bounds extend through $\Omega_0 \setminus \Omega_1$, with the layer-zero radii above.

In addition to the running gauge bounds, for each address (σ'', i, Z) of a preceding or current structure with $Z \subset Y$, the structured space requires good real gauges on a fixed family of cubes in two consecutive layers of that address. Each cube lies in $Z \cap \Omega_0$ for the corresponding first member. In using the strip response choose this fixed family to include all its gauge cubes of side at most $12\mathfrak{M}\xi_n$ at index n, including cubes contained in layer $n+1$. The gauge radius $a_\flat$ is below the response ceiling. The width and radius are fixed before the coupling ceiling, which is chosen for that family. In original bare units the good gauge is $U^v = e^{i\mathsf{v}}$ with $L^n|\mathsf{v}|, L^{2n}|\delta\mathsf{v}| \le a_\flat$. The same condition in level units uses $\xi_n|A|$ and $\xi_n^2|\nabla^\xi A|$, with $\mathsf{v} = \xi A$.

Use an address whose domain covers the full carrier of the response, then restrict its gauges and stencils to the active union of parameter cubes. When applying a substitution or taking a restriction, we must verify that the resulting triple has these clauses on that address. The layered bounds on $Y \cap \Omega_1$ alone give only that part of this verification. In particular an independent current at a layer-zero bond is unconstrained by those bounds, even if the configuration and the tower backgrounds are flat.

Stored fluctuation variables are real bond forms $\mathcal{A}_l^{\mathrm{s}}(b)$ belonging to the kernels outside the exponent. They transform by $\operatorname{Ad} u(b_-)$. Near bonds are the bonds in collars, rims and the nonanalytic cutoff zone; all other stored bonds are far. Fix $\lambda_l^{\mathrm{st}} = (\log \theta_l)^{6r+1} > 1$. A stored-field function is Borel in the near variables and is the value at $\mu_b = 1$ of a function jointly analytic in the pair, the far variables, and switches $|\mu_b| < \lambda_l^{\mathrm{st}}$. It is independent of a near variable when its switch is zero, and independent of that switch when the variable is zero. For far variables the analytic ball has radius λ_l^{st} times their specified real range. That range is part of the kernel data. The pair tie is required at every switch value.

2.2.5. *Presentations, standing operations, and their bounds.* A real presentation consists of the frame and formation data above, weights x_j, regular members $(E^{(j),\mathrm{u}}, E^{(j),\mathrm{m}}, \widehat{E}^{(j)}, b_j^{\mathrm{u}}, b_j^{\mathrm{m}})$, remainder families $(R^{(j)}, \widehat{R}^{(j)})$, boundary functions $B_{\mathcal{S}}(j, X, o)$, and the standing-operation exponents below. Here $E = E^{\mathrm{u}} + E^{\mathrm{m}}$, $b_j = b_j^{\mathrm{u}} + b_j^{\mathrm{m}} = x_{j-1} - x_j = b[\widehat{E}^{(j)}]$. Boundary origins o range over five types: the step, the last layer of a regular family, a step remainder beside an island, a stage, and exponentiation. A slot is the tuple (j, X, o) together with the structure-domain on which the function was formed. It retains that domain at later steps.

For a finite exempt family H of nonempty regions, define $d_{j,\mathsf{H}}^{\natural}(X)$ by minimizing M^{-1} times tree length also over subfamilies $\mathsf{F} \subset \mathsf{H}$ contained in X: the tree meets each cube outside $\bigcup \mathsf{F}$ and each member of F, but need not fill those members. For a label use the level-j hulls of its standing islands as H. Denote the result by $d_j^{\natural}(\mathcal{S}; X)$. It is at most $d_j(X)$ and asserts no decay across an exempt island. The real class requires

$$\begin{aligned} \|E^{(j)}\|_{j,\kappa} &\le E_0, \\ \|R^{(j)}\|_{j,\kappa} &\le \bar{g}_j^{\kappa_0}, \\ |B_{\mathcal{S}}(j, X, o)| &\le \mathsf{B} e^{-\kappa d_j^{\natural}(\mathcal{S}; X)}. \end{aligned} \tag{2.xxiv}$$

Boundary functions have the stored-field property. All entries are real on real arguments and invariant under the fixed simultaneous action on pairs and stored data. For regular families in eq. 2.xxiv is evaluated at $\check{\alpha}_{\iota,j}$; for the unmarked family also require a member of size at most E_0 on fixed absolute radii. The whole-lattice step is additional formed data: its positive tame kernel is $\mathbf{T}_{j-1}^{\mathrm{sf}}[\theta_{j-1}]$, with its non-pivot bond coordinates and sharp fluctuation box. For a list action S its step functional is

$$\begin{aligned} \mathcal{E}^{(j)}[\theta; x; S](W) = {} & \log \left(\mathbf{T}_{j-1}^{\mathrm{sf}}[\theta] e^{-xA(U_{j-1}) + S(U_{j-1})} \right)(W) \\ & + xA(U_j(W)) - S(U_j(W)). \end{aligned}$$

The kernel, the fibre coordinates, the normalization and the near-real logarithm branch must be given for this definition. The localization rule producing a pointed family from this functional is supplied once, for every torus and list; it is not determined by its total. The identification clause requires $E^{(j)}$ to be exactly this localized output from the earlier entries. Its unmarked version is the same output using only their unmarked entries.

The formed data also contain pointed Gaussian families $\mathbf{N}_j^{\circ}$ and $\mathbf{G}_{j,\tau}$ on those absolute cores, the first localizing the Gaussian logarithmic normalizer and its trivial-field local numbers, and the second localizing the change of its quadratic form when $x/\theta = \tau$. Their finite-dimensional covariance matrices, localization maps and logarithm branches are typed input data, so the following conditions have definite meanings. Set $b_j^0 = b[\mathbf{N}_j^{\circ}]$ and $\tau_{j-1} = x_{j-1}/\theta_{j-1}$. Require, for fixed constants $C_{\mathrm{m}}, C_{\mathrm{u}}, C_b$,

$$\|E^{(j),\mathrm{u}} - \mathbf{N}_j^\circ - \mathbf{G}_{j,\tau_{j-1}}\|_{j,\kappa} \le C_{\mathrm{u}} \bar{g}_{j-1} (\log \theta_{j-1})^{\mathfrak{p}_0},$$
$$\|E^{(j),\mathrm{m}}\|_{j,\kappa} \le C_{\mathrm{m}} \bar{g}_{j-1}^{\kappa_0 - C_{\mathrm{m}}},$$
$$|b_j^{\mathrm{m}}| \le C_b \bar{g}_{j-1}^{\kappa_0 - 4}, \qquad |b_j^{\mathrm{u}} - b_j^0| \le C_b \bar{g}_{j-1} (\log \theta_{j-1})^{\mathfrak{p}_0}.$$

No universality formula or asymptotic-freedom estimate for b_j^0 is implied by calling these families Gaussian. Their covariance construction and coefficient estimates are separate analytic input.

A standing operation at an island (t, Y) has a countable or finite local-history index ω, a Borel subset S_ω of a finite product of group variables, real bond variables and finite frame sets, and a positive Borel measure μ_ω on that set. These sets and measures are formed independently of the entries. Its exponents are Borel in $\xi \in S_\omega$, holomorphic in the pair, real at real arguments, and have the form

$$\mathbf{T}'_t(Y) F = \frac{1}{|W_4|} \sum_\omega \int_{S_\omega} F(\xi) e^{\Phi_\omega(\xi;\mathbf{p})} \mu_\omega(d\xi),$$
$$\Phi_\omega = \Phi_\omega^\circ(\xi) + \sum_f \Phi_{\omega,f}(\xi; \mathbf{p}|_{R_f}). \tag{2.xxv}$$

Each carrier $R_f \subset Y^\sim$ supports both dependencies of its factor. The finite factor index set, the measurable coordinate projections onto stored variables in each carrier, and any nested island variables are part of the data. No variable is integrated twice: swallowed-operation variables retain their earlier labels inside the product assigned to the swallowing component.

If (s, D) ranges over the forest of nested stored components, set $v(\omega) = \sum_{(s,D)} \log \theta_s \, \#_s(D)$, where $\#_s$ counts sites in their own level. For a fixed creation-time complex domain $\mathcal{K}_{t,Y}$ require

$$\frac{1}{|W_4|} \sum_\omega e^{c_{\mathrm{r}} v(\omega)} \int_{S_\omega}^* \sup_{\mathbf{p} \in \mathcal{K}_{t,Y}} |e^{\Phi_\omega(\xi;\mathbf{p})}| \mu_\omega(d\xi) \le C e^{-2\mathfrak{p}_0(\bar{g}_t)/(1+\beta_0)},$$
$$\sum_{f : R_f = R} \operatorname{osc} \Phi_{\omega,f} \le \mathsf{B}_\Phi (\log \theta_t)^{2\mathfrak{p}_0} e^{-\kappa d_t^\natural(\mathcal{S};R)}. \tag{2.xxvi}$$

The first integral is an upper integral, allowing a nonmeasurable supremum. The oscillation is the supremum of $|\Phi_{\omega,f}(\xi; p) - \Phi_{\omega,f}(\xi; p')|$ over ξ and both pairs in that fixed domain. The domain is supplied from the data at creation and must contain every later evaluation; this last inclusion is an independent requirement. $c_{\mathrm{r}} \ge 0$ is fixed before the coupling ceiling, and $\beta_0 > 0$ satisfies $\mathfrak{p}_0(\bar{g}_m) \ge (1+\beta_0)^{-1} \mathfrak{p}_0(\bar{g}_n)$ for $m < n$. The supremum remains inside the integral and sum. There is no asserted small factor in the size of Y. A drop-out has no new free entry of type eq. 2.xxv: it keeps its partially formed operation, and its carrying Wilson factor is included in its separate majorant. Such a majorant must be supplied to use a drop-out estimate.

The effective exponent additionally requires finite index maps and vacuum numbers, which are formed data. At label $\mathcal{S}$ the map $\mathcal{I}_j^E(\mathcal{S})$ is a subset of $\{(z, X) : z \in \Lambda_j \cap \mathbb{T}^{(j)}, \ X \in \mathcal{D}_j, z \in X\}$; it gives the actual enlarged-region rule for the regular terms. The enlargement width and treatment of boundary-crossing domains must be included in that map. The remainder index map is $\mathcal{I}_j^R(\mathcal{S}) = \{X \in \mathcal{D}_j : X \subset \Lambda_j^{\sim -1}\}$. The boundary index map selects the slots meeting the one-layer enlargement of Z_j. These maps use the action sequence in eq. 2.xxii. The profiles use the small-field regions of the action sequence. Fix a nonnegative smooth function ψ on $\mathbb{R}^4$, invariant under signed coordinate permutations, supported in $\{|u|_\infty \le 1/4\}$, and normalized by $\int \psi = 1$. For example,

normalize the product of the four functions $b(u_\nu)$, where

$$b(v) = \begin{cases} \exp[-1/(1-16v^2)], & |v| < 1/4, \\ 0, & |v| \geq 1/4. \end{cases}$$

At level j, put $\mathsf{s}_j = M\check{R}_j$ when Λ_j is a union of those cubes, and $\mathsf{s}_j = M$ otherwise. The latter region is a union of M-cubes. Measure distances and translations in level-j units and set $D_j(x) = \mathrm{dist}_\infty(x, \Lambda_j^c)$, with $D_j = +\infty$ when $\Lambda_j = T_\ell$. Define on the torus

$$\varphi_j(x) = \int_{\mathbb{R}^4} \psi(u) \mathbf{1}\{D_j(x - \mathsf{s}_j u) \geq \mathsf{s}_j/2\}\, du, \tag{2.xxvii}$$

and evaluate it at plaquette midpoints in the action. The geometry and this rule are held fixed as a source varies.

The distance function is one-Lipschitz when the complement is nonempty. Thus $0 \leq \varphi_j \leq 1$, it vanishes where $D_j \leq \mathsf{s}_j/4$, and it equals one where $D_j \geq 3\mathsf{s}_j/4$. Indeed, wherever $\psi(u) \neq 0$ one has $|u|_\infty < 1/4$, so the argument of D_j moves its value by strictly less than $\mathsf{s}_j/4$. In particular $\varphi_j = 1$ one layer inside Λ_j, with that layer taken in the s_j-cube partition. Its support is contained in $\{D_j \geq \mathsf{s}_j/4\}$, which is a compact subset of the interior of Λ_j. For the whole torus the formula gives $\varphi_j = 1$. On the periodic lift, changing variables in the convolution and differentiating its smooth kernel gives, for every multi-index,

$$\|\partial^\alpha \varphi_j\|_\infty \leq \mathsf{s}_j^{-|\alpha|} \|\partial^\alpha \psi\|_{L^1(\mathbb{R}^4)}.$$

This also proves smoothness, since the indicator is bounded and each kernel derivative has compact support. Cross-level ordering, where used below, is an additional condition. It follows, for example, if $\Lambda_{j+1} \subset \{D_j \geq 3\mathsf{s}_j/4\}$: then $\varphi_j = 1$ throughout the support of φ_{j+1}. With $x_k(p) = \beta - \sum_{j \leq k} b_j \varphi_j(p)$, the exponent is

$$\begin{aligned} A_{k,\mathcal{S}}(U) = & -A(x_k(\cdot), U) + \sum_{j,(z,X) \in \mathcal{I}_j^E(\mathcal{S})} \{E^{(j)}(X, U, z) - E^{(j)}(X, \mathbf{1}, z)\} \\ & - \sum_{j \leq k} b_j A(\varphi_j, U) + \sum_{j, X \in \mathcal{I}_j^R(\mathcal{S})} \{R^{(j)}(X, U) - R^{(j)}(X, \mathbf{1})\} \\ & + \sum_{(j,X,o) \text{ in boundary index map}} B_{\mathcal{S}}(j, X, o; U, \text{stored data}) - \mathcal{E}_{k,\mathcal{S}}. \end{aligned}$$

The real scalar $\mathcal{E}_{k,\mathcal{S}}$ is supplied with its vacuum bookkeeping rule, including the stage numbers retained by drop-outs. The pointwise identity $x_k(p) + \sum_{j \leq k} b_j \varphi_j(p) = \beta$ is exact. It does not authorize changing the index maps or the vacuum rule. These definitions specify the objects; their construction and uniform estimates remain hypotheses where no proof is given.

Erase every healed component together with its ancestral cluster from a history h; the result is its standing part $h^\flat$. Erasure being an admissible history with the same label, and the hard-core decomposition used to sum healed clusters, are structural requirements on the formation data. They are not assumed merely from the word "erase." The never-large standing part has $\Omega_j = \Lambda_j = T_\ell$. The presentation gives finite positive measures $\widehat{\tau}_{h^\flat}$ on V_k, stored fields and coordinate frames, with marginals $\tau_{h^\flat}$ on V_k. It also retains the individual-history measures $\widehat{\tau}_h$ produced by the exact kernels. Their identities are

$$\begin{aligned} \rho_k(V_k) dV_k &= \sum_{h^\flat} \tau_{h^\flat} = \sum_h \tau_h, \\ \sum_h \tau_h(\mathcal{V}_k) &= Z. \end{aligned} \tag{2.xxviii}$$

The first equality uses the summed healed operations; the exponent of an individual h need not have the effective-action form.

The reading at X records the standing regions, outcomes, marks, stored test bonds and frames within the hull of X enlarged by one level-l cell at every scale l. A chart is a translation by top-level cells, a common lift between tori, or their composite. Coherence requires a chart matching readings to carry the terms, carriers, Borel sets and measures to their counterparts. Factorwise,

$$\Phi_{\iota\omega,\iota f}(\iota\xi;\iota p)=\Phi_{\omega,f}(\xi;p). \tag{2.xxix}$$

Unit translations not preserving the partitions are covered by the pointed-total requirement eq. 2.xv, not by this chart definition. The simultaneous lattice symmetries preserving level-j cells must also transport the measures with their variables.

For a datum at a just below a pillar top y, let $\tau[U](a)=(\mathcal{M}^{m-1}U)(y,a)$ be its contour transport. An adapted background satisfies $\tau[U](a)=\mathbf{1}$ at every stored datum site. To define $\widehat{\tau}$ require that all backgrounds exist on its support, every argument belongs to its entry's domain, and the exponential has one value at all adapted representatives. The last clause is independent of simultaneous gauge invariance: an orbit transformation need not fix every datum site. These are part of class membership, not formal consequences of the norm bounds.

Finally let $\mathcal{Z}_k(h)$ be the live region after healing. For a live component X, define its lineage downwards by $\mathsf{Z}_k(X)=X$ and by taking at level j all live components contained in $\mathsf{Z}_{j+1}(X)$. Write $|C|_j$ for its number of level-j cells and $d'_j(W)$ for tree length in those cells. The created sets in a lineage are the components W of the step's creation set there; operation marks do not enter its deposit. With one fixed deposit constant $c>0$, set

$$\begin{aligned}
\mathrm{Vol}_k(X;h)&=\sum_{(j,C)\text{ in its lineage}} 2M^4\check{R}_j^5|C|_j,\\
\mathrm{Dep}_k(X;h)&=\sum_{(j,W)\text{ created in its lineage}} cp_0(\bar{g}_j)^2(d'_j(W)+1),\\
\Theta^{(k)}(h)&=\sum_{X\text{ live at }k}\{w\,\mathrm{Dep}_k(X;h)+c_a\,\mathrm{Vol}_k(X;h)\},\quad 0\le w<1,\quad c_a\ge 0.
\end{aligned} \tag{2.xxx}$$

The end mark is $\Theta^{(K)}$. Label marks and this numerical weight are different objects. Prepaid stability would assert $\sum_h e^{-E}\tau_h(\mathcal{V}_k)e^{\Theta^{(k)}(h)}\le e^{E_+\ell^4}$, with the stipulated normalization and dials; it requires a proof from creation deposits and the operation majorants. Nothing in eq. 2.xxx establishes that assertion.

Thus the class $\mathfrak{C}_k(\theta)$ is the set of these complete typed presentations satisfying eq. 2.xiv–eq. 2.xxx, all their stated structural and positivity clauses, and the specified analytic domains. A step-closure theorem must provide the next presentation, prove those clauses with the same constants and margins, and prove equality of the represented measures under its kernels. The background, response, substitution, island-mass, drop-out-majorant and closure hypotheses remain the substantive unresolved inputs where independent proofs have not been supplied.

2.3. **The weak-coupling sequence and continuum statements.**

2.3.1. *The object of the construction and the source of its difficulty.* We state the continuum and phase theorems. The coupling flow fixes the physical scale, and source derivatives define the connected correlations.

Objects. We take $G=\mathrm{SU}(2)$ and $N=2$. Put $T_\ell=(\mathbb{R}/\ell\mathbb{Z})^4$ and $\Lambda_{K,\ell}=a_K\mathbb{Z}^4/\ell\mathbb{Z}^4$, where $a_K=L^{-K}$. The compatible sides are $\mathfrak{L}=\{2L^m : m\in\mathbb{Z}_{\ge 0}\}$. At reference coupling g we use $\mathfrak{L}(g)=\{\ell\in\mathfrak{L}:\ell\ge\ell_\star(g)\}$; the floor in eq. 5.lii makes room for the localization cubes at every level. On such a torus we consider the following objects: the lattice $\Lambda_{K,\ell}$, whose spacing is $a_K=L^{-K}$;

the configurations U on it; the quantity $a_p(U) = 1 - \frac{1}{2}\operatorname{Re}\operatorname{tr} U_p$; Wilson's measure; the smeared curvature density; and the connected correlation functions of that density:

$$\mu_{K,\ell,\beta}(dU) = Z_{K,\ell,\beta}^{-1}\, e^{-\beta \sum_p a_p(U)}\, dU,$$

$$\mathcal{O}(f) = \sum_p f(x(p))\, a_p(U),$$

$$S^T_{n;K,\ell,\beta}(f_1, \dots, f_n) = \langle \mathcal{O}(f_1); \dots; \mathcal{O}(f_n)\rangle_{K,\ell,\beta}.$$

In view of $a_p \approx \frac{1}{2} a_K^4 |F_U(p)|^2$, the sum $\mathcal{O}(f)$, which carries no prefactor involving the spacing, is a Riemann-sum approximation of $\frac{1}{2}\int f \sum_{\mu<\nu} |F_{\mu\nu}|^2$. It is therefore the $\operatorname{tr}(F^2)$ observable. The test functions are restricted to separated tuples $(f_i) \in \mathfrak{S}_n(\mathbb{E})$: tuples of real C_c^1 functions with pairwise disjoint supports. We use $\|f\|_\sharp = \max\{\|f\|_\infty, c_M \operatorname{Lip} f\}$, where $c_M > 0$ is the fixed multiple of the localization size M used in § 5.20. The reason is given under "The frame" in Thm. A.

The cutoff is tied to the coupling. The renormalisation group of §§ 3.1 and 4.17 assigns to $\beta = g_0^{-2}$ a sequence of running inverse couplings $x_0 = \beta$, $x_k = x_{k-1} - b_k$, whose increments satisfy $b_k \le B_\sharp$. These increments are independent of the torus § 5.2.2, and also of the cutoff $K' \ge k$ used to carry out the steps § 5.2.4. We fix a small reference coupling g. As the unit of length we take the scale at which the flow reaches, for the first time, the reference window $g^{-2} \le x \le g^{-2} + B_\sharp$ belonging to g:

$$K(\beta, g) = \min\{k : x_k(\beta) \le g^{-2} + B_\sharp\},$$

$$\mathcal{W}_K(g) = \{\beta \ge g^{-2} + B_\sharp : K(\beta, g) = K\};$$

a pair (K, β) such that $\beta \in \mathcal{W}_K(g)$ is called a first-passage datum.

The remaining pairs with $\beta \ge g^{-2} + B_\sharp$ are accounted for as follows. Suppose that $K \ge K' = K(\beta, g)$, put $b = K - K'$, and let $f^{[b]}(x) = f(L^{-b}x)$ on $T_{L^b\ell}$. Then

$$\langle \mathcal{O}(f_1); \dots; \mathcal{O}(f_n)\rangle_{K,\ell,\beta} = \langle \mathcal{O}(f_1^{[b]}); \dots; \mathcal{O}(f_n^{[b]})\rangle_{K',\, L^b\ell,\, \beta}$$

holds exactly, for all bounded f_i. To see this, note that the dilation $x \mapsto L^b x$ maps $\Lambda_{K,\ell}$ onto $\Lambda_{K',L^b\ell}$, plaquettes to plaquettes and barycentres to barycentres. Wilson's weight depends only on the plaquette variables and on Haar measures, and no power of the spacing enters $\mathcal{O}$. The same identity holds between a periodic Gibbs state at β on $\mathbb{L}_K$ and its image on $\mathbb{L}_{K'}$ § 5.2.4. Consequently a pair with $K > K(\beta, g)$ amounts to the first-passage datum of β on a dilated torus, on which $\|f^{[b]}\|_\sharp \le \|f\|_\sharp$ and every distance is multiplied by L^b. The restriction to first passage therefore loses none of these lattice measures; its only effect is to fix the unit of length. (When $K < K(\beta, g)$ the identity is used in the opposite direction, on a contracted torus. This requires a lower bound on ℓ, and the norms grow by at most the factor $L^{K(\beta,g)-K}$ § 5.2.4.)

The final value $x_K(\beta)$ lies in the window but is not fixed at g^{-2}. This is why (a)(ii) passes to subsequences, and it is the purpose of clause (d). On each torus, provided the conditions of (d)(1) are satisfied, that clause dispenses with the subsequences as soon as the renormalised coupling, defined below, converges along the sequence. On $\mathbb{R}^4$, in (a)(iii), a subsequence is taken in every case, including the case in which the renormalised coupling converges (as stated in Thm. A(a)(iii)). The renormalised inverse coupling $x_K^\natural(\beta)$ is the final value of a particular run of K steps starting at β. In that run, the auxiliary choices of level k that depend on the coupling are made with $\theta_k = g^{-2} + c_0(K - k)$ instead of x_k, where $c_0 = \frac{11N^2}{12\pi^2}\log L$. Here and in all steps, log denotes the natural logarithm. A second kind of run is needed for the following reason. Continuity and holomorphy in the bare coupling are established by setting the constructions at two bare couplings

side by side and comparing them entry by entry, and by letting a single fixed linear operation act on a whole family of bare densities. Each of these two devices needs the choices to coincide at the two couplings. In a run made with its own couplings, however, the choices vary with β. Some of them, namely the cube sizes $\check{R}_k$, change through integer values § 5.2.3. Freezing the choices leaves $Z_{K,\ell,\beta}$ and S_n^T unchanged, since these are quantities of the measure. At first-passage data, and under the conditions of (d)(1), the shift that freezing produces in the couplings is at most g times a power of $\log g^{-2}$ § 5.2.3, § 5.2 and appendix A.8. By a continuum limit at g we mean a family $S = (S_n)_{n\geq 2}$ with

$$S_n(X) = \lim_{j\to\infty} S^T_{n;K_j,\ell_j,\beta_j}(X),$$
$$\beta_j \in \mathcal{W}_{K_j}(g),$$
$$K_j \to \infty,$$

taken either on T_ℓ (with all $\ell_j = \ell$) or on $\mathbb{R}^4$ (with $\ell_j \to \infty$). Limits on a torus along the tuned couplings of (a)(i) are also counted as continuum limits. A volume-first limit at g is a limit $\lim_j S_n^T[\nu_j]$, taken along first-passage data (K_j, β_j) with $K_j \to \infty$. In it each $\nu_j \in \mathcal{G}^{\mathrm{tor}}_{K_j,\beta_j}$ is a limit point of the periodically extended torus measures as $\ell \to \infty$, with spacing and coupling held fixed. Thus the volume is removed first and the spacing only afterwards.

The two theorems in brief. The exponents are fixed first. Then L is taken large, then the remaining constants are chosen in their order, and finally g is taken small. Thm. A states the following. The two assertions below hold uniformly in the first-passage datum, and the left-hand one holds also uniformly in the torus as soon as $\ell \geq Cn(R+1)$:

$$|S^T_{n;K,\ell,\beta}(f_1,\dots,f_n)| \leq C_n^\infty(\mathsf{d};R)\prod_i \|f_i\|_\sharp,$$
$$S_2(f,h) = \frac{3(N^2-1)}{\pi^4}\Big(\frac{12\pi^2}{11N^2}\Big)^2 \frac{\mathcal{K}_{\mathrm{free}}(f,h)}{(\log(1/\mathsf{d}))^2}\,(1+\eta) > 0.$$

In the left-hand bound, $n \geq 2$, and the supports lie in balls of radius R and are pairwise at distance $\geq \mathsf{d}$. In the right-hand formula, S is a limit along first-passage data, $f, h \geq 0$ are bumps whose size and separation are of the order of a small d, and $\mathcal{K}_{\mathrm{free}}(f,h) = \iint f(x)h(y)|x-y|^{-8}\,dx\,dy$. The factor $1+\eta$ is bounded above and below by positive constants, and on each torus $\eta \to 0$ as $\mathsf{d} \to 0$; on $\mathbb{R}^4$ the clause consists of the bounds by the two constants and nothing more. The five clauses of this theorem are the following:

- limits exist on the tori and on $\mathbb{R}^4$ (a);
- they inherit translation and hypercubic invariance, reflection positivity, symmetry, regularity and growth (b);
- they are non-trivial and have, at short distance, the normalisation of asymptotic freedom (c);
- on a torus they depend only on the renormalised coupling (d);
- on $\mathbb{R}^4$ they are rotation invariant if and only if a flux through far shells vanishes (e).

Thm. B states that a volume-first limit S is O(4)-invariant. Its centred functional $\sigma_S = \sum_{\pi\in\mathrm{Part}_{\geq 2}} \prod_{J\in\pi} S_{|J|}$ is precisely the system of moments obtained when the one-point function is set to zero, which is to say the moments of the centred density. This functional admits a canonical decomposition, which consists of a probability measure λ, carried by a compact set $\mathsf{X} = \operatorname{supp}\lambda$, together with a continuous injective map $\xi \mapsto \sigma_\xi$ such that

$$\int_{\mathsf{X}} \prod_{i=1}^{q} \sigma_\xi(X^i)\,\lambda(d\xi) = \lim_{|v_q|\to\infty} \cdots \lim_{|v_2|\to\infty} \sigma_S\big(X^1 \cdot \tau_{v_2} X^2 \cdots \tau_{v_q} X^q\big)$$

$$(q \geq 1),$$

so that

$$\sigma_S = \int_{\mathsf{X}} \sigma_\xi\,\lambda(d\xi).$$

Each ergodic component σ_ξ satisfies the full set of axioms of Osterwalder and Schrader.

2.3.1.1. The theorem, stated clause by clause. There exist a shape constant $\vartheta_0 \in (0,1]$ and, for each source radius $\varrho > 0$ (§ 5.20) and each shape $\vartheta \in (0,1]$, thresholds $0 < \gamma_{U'} \leq \gamma_U \leq \gamma_J$ and $0 < \gamma_W(\vartheta) \leq \gamma_J$ such that Thm. B and the clauses below hold. Throughout, $0 < g \leq \gamma_J$, $\ell \in \mathfrak{L}(g)$, and (K, β) is a first-passage datum. Apart from dependences that are displayed, the constants do not vary with K, β, ℓ or with positions. The ceilings $\gamma_{U'}, \gamma_U, \gamma_J$ depend only on the constants fixed before them, among which is ϱ, and $\gamma_W(\vartheta)$ depends only on these and on ϑ. Each constant, threshold and function introduced by a clause of the two theorems may in addition depend on g and on the quantities displayed with it.

The frame is adapted to the tools. When the side is $\ell = 2L^m$ with $m \in \mathbb{N}$, each axis carries an even number $2L^{m+K}$ of sites. Each mirror pair $\{y_\mu = c\} \cup \{y_\mu = c + \ell/2\}$ therefore cuts the torus into two halves, and the chessboard cells come in pairs §§ 5.20 and 5.22. Because L is odd, the mirrors that bisect bonds at successive cutoffs are nested: $a_K(\mathbb{Z} + \frac{1}{2}) \subset a_{K+1}(\mathbb{Z} + \frac{1}{2})$. Because barycentres are used, the identity $\mathcal{O}(f) \circ \mathsf{r}^* = \mathcal{O}(\mathsf{r} f)$ is exact for each lattice isometry r, where r^* denotes its action on configurations. If the support of f has distance greater than Ca_K from the mirror, every contributing plaquette and all its bonds stay on that same side. A barycentre alone does not guarantee this for a support touching the mirror; the continuum reflection-positivity passage uses fixed positive support gaps. In the Gaussian curvature model of Prop. 3.21, let $V_{\mathrm{lat}} = (\ell/a_K)^4$ be the number of sites. Its exact two-cochain space has dimension $3(V_{\mathrm{lat}} - 1)$ per colour: the kernel of the one-cochain coboundary consists of the $V_{\mathrm{lat}} - 1$ gradients and four harmonic one-cochains. Translation and hypercubic symmetry make the diagonal of its orthogonal projector constant on the $6V_{\mathrm{lat}}$ plaquettes. Thus the quadratic observable has expectation

$$\langle \mathcal{O}_{\mathrm{quad}}(f) \rangle_{\mathrm{G}} = \frac{N^2 - 1}{4\beta} \left(1 - \frac{1}{V_{\mathrm{lat}}}\right) \sum_p f(x(p)).$$

For fixed ℓ and smooth f, its leading Riemann-sum term is $\frac{3(N^2-1)}{2\beta} a_K^{-4} \int f$. Along the weak-coupling sequence $\beta \asymp K$, this term diverges when $\int f \neq 0$. This is a calculation in the Gaussian model; the interacting continuum construction uses the exact lattice expectation for centering. Moreover $|x - y|^{-8}$ is not locally integrable. For these reasons only $n \geq 2$ and only separated tuples are considered, and positivity is stated for the centred σ_S. The axioms of Osterwalder and Schrader require nothing more, because their test functions vanish to infinite order wherever points coincide. By a mirror Σ of $\mathbb{R}^4$ we mean a hyperplane $\{u \cdot x = c\}$ with either $u = e_\mu$, the unit vector of the μ-th coordinate (coordinate), or $u = (e_\mu \pm e_\nu)/\sqrt{2}$ for some $1 \leq \mu < \nu \leq 4$ (diagonal). Its reflection is θ_Σ and its open side is $\mathbb{E}_+(\Sigma)$. A torus has only the coordinate pairs as mirrors, and there the open side is a slab.

Theorem A (Continuum correlations)**.** Assume the uniform background, interaction, history, flow and ordinary-source estimates of § 2.4, with their stated domains and normalization. For the short-distance clauses assume the interacting comparison and running-normalization estimates there; for the matched-cutoff and Ward clauses assume their additional estimates. Then the following conclusions hold. **(a) Existence.** Each run started from $\beta \geq g^{-2} + B_\sharp$ reaches first passage. For

such a run, $c(\beta - g^{-2}) - C \le K(\beta, g) \le C(\beta - g^{-2}) + C$, and since $b_k \le B_\sharp$ also $g^{-2} < x_K(\beta) \le g^{-2} + B_\sharp$. Hence $K(\beta, g) \to \infty$ as $\beta \to \infty$, and so $\mathcal{W}_K(g) \neq \varnothing$ for infinitely many K. The values $x_k(\beta)$ are the same whatever torus the steps are carried out on, and $\beta/\log(1/a_K) \to \frac{11N^2}{12\pi^2}$ uniformly on $\mathcal{W}_K(g)$. (i) Let $g \le \gamma_U$. Then for each K there is a tuned $\beta_K^\natural$, that is, one with $x_K^\natural(\beta_K^\natural) = g^{-2}$, and it satisfies $\frac{1}{2}c_0 K - c_5 \le \beta_K^\natural - g^{-2} \le \frac{3}{2}c_0 K + c_5$. Moreover $S^T_{n;K,\ell,\beta_K^\natural} \to S_n^{\natural,\ell}$ as $K \to \infty$ along the whole sequence. This convergence holds on each torus of the family and on tuples of Lipschitz functions whose supports are pairwise disjoint. (ii) On a fixed torus, from every sequence of first-passage data with $K_j \to \infty$ one can extract a subsequence that converges on $\mathfrak{S}(T_\ell)$. (iii) The same holds on $\mathfrak{S}(\mathbb{R}^4)$ when in addition $\ell_j \to \infty$. The limits obtained in this way along tori, with defining sequence (K_j, ℓ_j, β_j), are what the phrase "a limit of (a)(iii)" means. The same also holds for $S_n^T[\nu_j]$ with $\nu_j \in \mathcal{G}^{\mathrm{tor}}_{K_j,\beta_j}$, so volume-first limits exist.

(b) Symmetry, positivity and growth. Each continuum limit has the following properties. (i) It is invariant under W_4 and under the translations of $\mathbb{E}$. (ii) It is reflection positive at each coordinate mirror: $\sum_{i,j} \bar{c}_i c_j \, \sigma_S(\theta_\Sigma X_i \cdot X_j) \ge 0$ whenever $X_i \in \mathfrak{S}(\mathbb{E}_+(\Sigma))$. (iii) It is symmetric. (iv) It is regular: there is a unique distribution of locally finite order on $\mathbb{E}^n_{\neq}$ of which S_n is the restriction. On C^1 functions, and with the same constants, it satisfies (c)(1) on T_ℓ, and it satisfies both bounds (c)(2) when it is a limit of (a)(ii)–(iii). (v) On $\mathbb{R}^4$ it satisfies the growth condition

$$|\mathsf{S}_n^{\sigma_S}(\varphi)| \le c_{\mathrm{E}} C_{\mathrm{E}}^n (n!)^{\varkappa} |\varphi|_{k_{\mathrm{E}} n}$$

on $\mathcal{S}_{\neq}(\mathbb{R}^{4n})$. Take the form $\langle F, G\rangle = \sigma_S(\theta \bar{F} \cdot G)$ on $\mathbb{C}\mathfrak{S}(\{x_4 > 0\})$. The separable space $\mathcal{H}(S)$ then carries three structures:

- $\mathcal{T}_t[F] = [\tau_{te_4} F]$, $\mathcal{T}_t = e^{-tH}$, which form a strongly continuous semigroup of self-adjoint contractions, where $H \ge 0$ and $H\Omega = 0$;
- a strongly continuous unitary representation $e^{iv\cdot P}$ of $\mathbb{R}^3$ that leaves Ω fixed, the P_j commuting strongly with H;
- a unitary representation of W_3 that leaves Ω fixed and commutes with H.

Already for $g \le \gamma_J$, each volume-first limit is a limit of (a)(iii) and is, in addition, reflection positive at each diagonal mirror.

(c) Correlation bounds and nontriviality. Let $n \ge 2$, let the f_i be Lipschitz with supports pairwise at distance $\ge \mathsf{d} > 0$, and in (2) let the supports also lie in balls of radius R. Then

$$(1)\ |S_n^T| \le C_n(\mathsf{d})\, e^{n c_V \ell^4} \prod_i \|f_i\|_\sharp;$$

$$(2)\ |S_n^T| \le C_n^\infty(\mathsf{d}; R) \prod_i \|f_i\|_\sharp \ (\ell \ge Cn(R+1)),$$

$$|S_n^T| \le A(\mathsf{d}; R) B(R)^n (n!)^{\varkappa_\star} \prod_i \|f_i\|_\sharp \ (\ell \ge \ell_G);$$

Here $C_n^\infty(\mathsf{d}; R)$ does not increase as d grows. The bounds (2) also hold, with no condition on a volume, for $S_n^T[\nu]$, where ν is an arbitrary periodic Gibbs state on $\mathbb{L}_K$ of Wilson's weight at β, and where (K, β) is a first-passage datum.

(3) The class $\mathfrak{T}_{\mathbb{E}}(\mathsf{d}; \vartheta)$ consists of the pairs of Lipschitz functions $f, h \ge 0$, neither of which is identically zero, that satisfy the following conditions. Each is supported in a ball of radius d, and $\mathsf{d} \le \mathrm{dist}(\mathrm{supp}\, f, \mathrm{supp}\, h) \le 6\mathsf{d}$. In addition, $\int f \ge \vartheta \|f\|_\infty \mathsf{d}^4$ and $\mathrm{Lip}\, f \le \|f\|_\infty/(\vartheta \mathsf{d})$, and the same two conditions hold for h. Assume $g \le \gamma_W(\vartheta)$, $\mathsf{d} \le \mathsf{d}_0$ and $(f, h) \in \mathfrak{T}_{T_\ell}(\mathsf{d}; \vartheta)$. Assume also $K - s(\mathsf{d}) \ge n_0$, so that at least n_0 steps lie between the scale d and the cutoff. Then

$$\langle \mathcal{O}(f); \mathcal{O}(h) \rangle_{K,\ell,\beta} = \zeta_K(\mathsf{d})^2 \, \tfrac{3(N^2-1)}{\pi^4} \, g(\mathsf{d})^4 \, \mathcal{K}_{\mathrm{free}}(f,h) \, (1+\varepsilon),$$
$$|\varepsilon| \le \min\{\tfrac{1}{2}, \bar{\varepsilon}_\ell(\mathsf{d})\}.$$

In this formula $g(\mathsf{d}) = g_{K-s(\mathsf{d})}(\beta)$, where $L^{-s(\mathsf{d})} \approx \mathsf{d}$ up to logarithmic factors. Also $\underline{x}_s \le g(\mathsf{d})^{-2} \le \bar{x}_s$, and both bounds are affine in $s = s(\mathsf{d})$. The factor $\zeta_K(\mathsf{d}) = \zeta'_{K-s(\mathsf{d})}$ is the running normalisation, that is, it measures how $x_{K-s(\mathsf{d})}$ responds when β is shifted by a constant §5.20.1.2. One has $|\zeta_K(\mathsf{d}) - 1| \le \bar{\eta}(\mathsf{d})$ and $|\frac{11N^2}{12\pi^2} g(\mathsf{d})^2 \log \frac{1}{\mathsf{d}} - 1| \le \bar{\eta}(\mathsf{d})$. Here $\mathsf{d}_0 \in (0,1)$, and the two functions $\bar{\eta} : (0, \mathsf{d}_0] \to [0, \frac{1}{3}]$ and $\bar{\varepsilon}_\ell : (0, \mathsf{d}_0] \to [0, \frac{1}{2}]$ are non-decreasing; moreover $\bar{\eta}, \bar{\varepsilon}_\ell \to 0$ as $\mathsf{d} \to 0$. Hence, on each torus, $\varepsilon \to 0$ uniformly with respect to the cutoff, to the bare coupling as it ranges over its window, to the pair, and to where the pair is placed. For periodic Gibbs states the identity remains true, but only with $|\varepsilon| \le \frac{1}{2}$.

(4) Consequently the limits of (a)(ii)–(iii) obey the law stated at the opening of the text, for those pairs in $\mathfrak{T}_{\mathbb{E}}(\mathsf{d}; \vartheta)$ in which f, h are of class C^1; the tuned $S^{\natural,\ell}$ are not included. The error satisfies $(1-\bar{\varepsilon})(1-\bar{\eta})^4 \le 1 + \eta \le (1+\bar{\varepsilon})(1+\bar{\eta})^4$, with $\bar{\varepsilon} = \bar{\varepsilon}_\ell(\mathsf{d})$ on T_ℓ and $\bar{\varepsilon} = \frac{1}{2}$ on $\mathbb{R}^4$, where in addition $\dim \mathcal{H}(S) \ge 2$.

For clause (5), assume in addition the comparison eq. 6.ccxxxiii for the actual normalized history/block-field law, with $x = g(\mathsf{d})^{-2}$ and $\zeta = \zeta_K(\mathsf{d})$. On the whole prescribed four-test class, its remainder must satisfy

$$|\mathcal{R}_4(\underline{f})| \le \epsilon_{4,\ell}(\mathsf{d}) \, g(\mathsf{d})^8 \prod_i \|f_i\|_\infty, \qquad \epsilon_{4,\ell}(\mathsf{d}) \longrightarrow 0 \quad (\mathsf{d} \downarrow 0),$$

for each fixed admissible torus, uniformly in the permitted cutoff, bare coupling and support positions. The comparison retains the actual constraint, gauge-normalization and closed-mode identifications accompanying eq. 6.ccxxix, the coarse-complement estimate eq. 6.ccxxx, and the weighted lineage-age estimate of Prop. 5.71 at a rate strictly greater than 16, or a stronger direct estimate for these four insertions. All the nonquadratic, source, boundary and excluded-history terms listed after eq. 6.ccxxxiii belong in $\mathcal{R}_4$. This additional input has the torus scope of clause (5).

(5) The class $\mathfrak{T}^{(4)}_{\mathbb{E}}(\mathsf{d}; \vartheta)$ consists of the quadruples whose pairs all belong to $\mathfrak{T}_{\mathbb{E}}(\mathsf{d}; \vartheta)$ and for which $\operatorname{supp} f_i \subset B(c_i, \mathsf{d}/16)$, the four centres c_i lying on one line. On the tori there exists $\vartheta_\square \in (0,1]$ with the following property. Let $\vartheta \le \vartheta_\square$ and $g \le \gamma_W(\vartheta)$. Then there are constants $0 < c_\square \le C_\square$, which may depend on g and ϑ, such that the bound below holds whenever $K - s(\mathsf{d}) \ge n_4$, where $n_4 \ge n_0$ is an integer, d is smaller than a threshold, which may depend on ℓ, and the quadruple belongs to $\mathfrak{T}^{(4)}_{T_\ell}(\mathsf{d}; \vartheta)$:

$$c_\square (N^2-1) \, g(\mathsf{d})^8 \prod_i \|f_i\|_\infty \le S^T_{4;K,\ell,\beta}(f_1, \dots, f_4) \le C_\square (N^2-1) \, g(\mathsf{d})^8 \prod_i \|f_i\|_\infty :$$

on these quadruples the connected four-point function is therefore strictly positive. On rescaled quadruples it decreases as the fourth power of the reciprocal of the logarithm of the scale.

(d) Fixed-torus uniqueness. Assume $g \le \gamma_U$. Take $(\beta^\natural_K)$ and $S^{\natural,\ell}$ as in (a)(i). (1) Let ϱ be large and $g \le \gamma_{U'}$. Then the first-passage windows lie close to the tuned couplings: $\mathcal{W}_K(g) \subset [\beta^\natural_K - \frac{1}{4}\varrho, \ \beta^\natural_K + \frac{1}{4}\varrho]$ for each K. (2) For $|\beta - \beta^\natural_K| \le \frac{1}{4}\varrho$ the reference runs of length K are well defined, and $\beta \mapsto x^\natural_K(\beta)$ is bi-Lipschitz uniformly in K. As $K \to \infty$, the functions $t \mapsto x^\natural_K(\beta^\natural_K - t)$ converge uniformly on $|t| \le \frac{1}{4}\varrho$. The limit function has a compact interval I as its range, and this interval contains $[g^{-2} - c'\varrho, g^{-2} + c'\varrho]$. (3) For each torus of the family, one has a family $(S^{(\ell,x)})_{x \in I}$. Each of its members is a family of connected functions, defined on tuples of Lipschitz functions whose supports are pairwise disjoint. It satisfies $S^{(\ell,g^{-2})} = S^{\natural,\ell}$, and $x \mapsto S^{(\ell,x)}_n$ is continuous on

I. Moreover, whenever $K_j \to \infty$, $|\beta_j - \beta^\natural_{K_j}| \le \frac{1}{4}\varrho$ and $x^\natural_{K_j}(\beta_j) \to x$, it follows that $x \in I$ and $S^T_{n;K_j,\ell,\beta_j} \to S^{(\ell,x)}_n$, with no passage to a subsequence.

Consequently, take two sequences of bare data close to the tuned couplings whose renormalised couplings converge to the same value. They have the same limit on T_ℓ. Under the conditions of (1) this applies to every sequence of first-passage data, and every limit of (a)(ii) is equal to some $S^{(\ell,x)}$. On each torus, the renormalised coupling by itself determines the limit theory.

(e) Rotations. Let $\omega \in \mathfrak{so}(4)$, and let χ be a cutoff whose support lies in $(-\ell/2 + 2a_K, \ell/2 - 2a_K)^4$. Consider the rotational Ward identity satisfied by $\mu_{K,\ell,\beta}$ with respect to the deformation field $\chi(y)\,\omega y$. The shell flux is the boundary term of this identity:

$$\mathfrak{B}_{\omega,\chi} = \beta \sum_p a_p\,(\nabla^{\mathrm{s}}_\omega \chi)(x(p)) - \beta \sum_p \mathfrak{h}_{\omega,\chi}(p) - \tfrac{3}{2} \sum_p a_p \sum_{\rho \in \{\mu,\nu\}} (\omega x(p))_\rho\,(\nabla^{\mathrm{c}}_\rho \chi)(x(p)),$$

where $\mu < \nu$ are the two directions spanning p and $\nabla^{\mathrm{s}}_\omega, \nabla^{\mathrm{c}}_\rho$ are lattice differences, and where

$$\mathfrak{h}_{\omega,\chi}(p) = a_K^{-1} \sum_{b \subset \partial p} \sum_\rho [\chi(x_b) - \chi(x(p))]\,(\omega x_b)_\rho\,\mathfrak{d}_{b,p,\rho}$$

, the $\mathfrak{d}_{b,p,\rho}$ being bounded, gauge-invariant local densities. Each term contains a difference of χ. For $\mathfrak{B}_{\omega,\mathcal{R}} := \mathfrak{B}_{\omega,\chi_\mathcal{R}}$, only terms whose plaquette anchors lie in $\{\mathcal{R} - a \le |x(p)| \le 2\mathcal{R} + a\}$ can contribute, where $a = a_K$. The local densities also read neighboring plaquettes. Their full field dependence lies in the enlarged shell $\{\mathcal{R} - 3a \le |x| \le 2\mathcal{R} + 3a\}$, as in eq. 6.cccxciii. These shells surround the transition region $\mathcal{R} \le |y| \le 2\mathcal{R}$, where $\chi_\mathcal{R}$ falls from 1 to 0. A limit of (a)(iii) is O(4)-invariant if and only if the following holds for one $\omega \neq 0$ (equivalently, for all ω), for all $n \ge 2$ and for all separated tuples with smooth entries:

$$\liminf_{\mathcal{R}\to\infty} \limsup_{j\to\infty} \left|\langle \mathfrak{B}_{\omega,\mathcal{R}}; \mathcal{O}(f_1); \dots; \mathcal{O}(f_n)\rangle_{K_j,\ell_j,\beta_j}\right| = 0.$$

In that case $\mathcal{H}(S)$ carries a strongly continuous unitary representation of O(3). This representation leaves Ω fixed, commutes with H, and extends the representation of W_3. This equivalence singles out the one infrared input, and for volume-first limits Thm. B settles it. ■□

What the equivalence uses. When $\chi = 1$ near the supports, the identity takes the following form (the exact lattice Ward hypothesis in eq. A.lxxxi):

$$\sum_{i=1}^n \langle \mathcal{O}(f_1); \dots; \mathcal{O}(\nabla^{\mathrm{s}}_\omega f_i); \dots; \mathcal{O}(f_n)\rangle_{K,\ell,\beta} = \mathfrak{U}_{\omega,\chi}(f_1, \dots, f_n)$$
$$+ \langle \mathfrak{B}_{\omega,\chi}; \mathcal{O}(f_1); \dots; \mathcal{O}(f_n)\rangle_{K,\ell,\beta}\,:$$

besides the flux, it contains a bulk term $\mathfrak{U}_{\omega,\chi}$. This term is the correlation between the $\mathcal{O}(f_i)$ and lattice artefacts of dimension six, distributed over $\operatorname{supp}\chi$. Once $\mathfrak{U}_{\omega,\chi_\mathcal{R}} \to 0$ along every defining sequence, the rotation defect of S, namely the derivative $\frac{d}{dt} S_n(e^{t\omega} f_1, \dots, e^{t\omega} f_n)|_{t=0}$, equals minus the limit of the correlation between the flux and the $\mathcal{O}(f_i)$, and clause (e) follows.

This vanishing requires the typed first-order insertion estimates, the joint-insertion moment bound, and the volume-transfer estimate in the Ward hypotheses. The first-order estimates are needed on fixed tori and slowly growing volumes; the joint-insertion bound and volume transfer are needed for arbitrary sequences with $\ell_j \to \infty$. On this route the anisotropy estimate also requires the exponent stated next.

One marginal operator remains in $\mathfrak{U}$: a traceless diagonal anisotropy of Wilson's weight. Its coefficient is of the size $g_0^{-1} \approx K^{1/2}$, and it disappears only through its own decay K^{-c_1} along the flow. What is needed is $c_1 > \frac{1}{2}$.

This number is expressed through one-loop data. Put the weight $1 + \mathsf{e}_{\pi(p)}$ on each a_p, where $\pi(p)$ is the coordinate plane of p. Differentiating the one-loop coefficient of step l plane by plane at $\mathsf{e} = 0$ gives a derivative that commutes with W_4. Let $\mathsf{m}(l)$ denote the eigenvalue of this derivative on the traceless diagonal weights $\mathsf{e}_{\{\mu,\nu\}} = \mathsf{e}_\mu + \mathsf{e}_\nu$, $\sum_\mu \mathsf{e}_\mu = 0$. Then $c_1 \in (\frac{1}{2}, 1]$ is an exponent such that $\sum_{i<l\le j} \mathsf{m}(l) \ge c_1 c_0 (j-i) - C$. The one-loop law in this channel, $|\sum_{l\le k} \mathsf{m}(l) - c_0 k| \le C$, gives $c_1 = 1$.

The law comes from a telescoping sum. By the law of total covariance, the sum of the one-loop responses of the steps $l \le k$ is a single trace on the bare lattice. The logarithmic part of this trace is $\int_1^{L^{2k}} d\sigma/\sigma = 2k \log L$, in proper time σ, multiplied by the heat coefficient on a constant abelian background. It equals kc_0, with the same c_0 as the coupling itself. In the continuum, an anisotropy of the weight amounts, to first order, to a change of coordinates, and it does not run (see the Ward comparison hypotheses). Rotation invariance in Thm. B (1) follows from Prop. 6.26, whose proof uses no Ward identity and does not depend on c_1.

Theorem B (Canonical components)**.** Assume the background, interaction, history and flow inputs of § 2.4, the ordinary-source hypothesis D1 in its stated rooted-domain geometry, and the interacting two-point and running-normalization inputs F2–F3 there. The latter inputs are required uniformly over the periodic Gibbs states used to realize the limit and its components, on the full test class specified in Prop. 6.25, including $\vartheta_* = 1/12000$. Let $g \le \min\{\gamma_W(\vartheta), \gamma_W(\vartheta_0)\}$, and let S be a volume-first limit with defining sequence (K_j, β_j, ν_j). (1) Every ν_j is a periodic Gibbs state and is invariant under all translations of the lattice; moreover S is a limit of (a)(iii). In addition to (b) and (c)(4), it satisfies $H \ge |P_j|$ for $j = 1, 2, 3$, is O(4)-invariant, and is reflection positive at the diagonal mirrors. (2) Its canonical decomposition exists and is unique up to isomorphism. Here an isomorphism is a homeomorphism of the spaces X that carries λ and the σ_ξ along with it. Let P_0 be the projection onto $\ker H$. The map $P_0[F] \mapsto (\xi \mapsto \sigma_\xi(F))$ extends to a unitary map $\ker H \to L^2(\mathsf{X}, \lambda)$ with $\Omega \mapsto 1$, by the zero-energy representation theorem of § 7.8. If X has exactly $m < \infty$ points, then $\dim \ker H = m$; if X is infinite, then $\ker H$ has countably infinite Hilbert dimension. This does not identify the set-theoretic cardinality of an infinite compact phase space with its Hilbert dimension. The components are permuted, and λ is preserved, by the isometries that leave S invariant (translations, W_4, rotations). (3) Each σ_ξ has the following properties. (i) It has the same invariances and positivity properties, and it is symmetric and regular. (ii) Its one-point function is $S_1^{\sigma_\xi}(f) = \mathfrak{c}_\xi \int f$, where $\mathfrak{c}_\xi$ is real and continuous in ξ and $\int \mathfrak{c}_\xi \, \lambda(d\xi) = 0$. With the same constants, it satisfies the growth condition and the bounds (c)(2); it also satisfies the law (c)(4) in its form on $\mathbb{R}^4$. (iii) On $\mathcal{H}(\sigma_\xi)$ it has the operators of (b)(v) and a unique vacuum, $\ker H_{\sigma_\xi} = \mathbb{C}\Omega_{\sigma_\xi}$. Its joint spectrum lies in the closed forward cone $\{E \ge |q|\}$. It also has a strongly continuous unitary representation of O(3) that leaves Ω_{σ_ξ} fixed and commutes with H_{σ_ξ}. (iv) It has the cluster property:

$$|\sigma_\xi(X \cdot \tau_v Y) - \sigma_\xi(X)\,\sigma_\xi(Y)| \le C(X,Y)\,|v|^{-2}$$
$$(|v| \ge r(X,Y)),$$

where $C(X,Y)$ and $r(X,Y)$ are the same for all ξ and for all volume-first limits at g. (4) Consequently every Osterwalder–Schrader axiom holds for σ_ξ: growth, invariance under $\mathbb{R}^4 \rtimes \mathrm{O}(4)$, reflection positivity, symmetry and clustering. Its Schwinger functions coincide with the Schwinger functions of a Wightman theory. This theory has a single Hermitian scalar field on a separable Hilbert space and a unique vacuum. It is covariant under the proper orthochronous Poincaré group, its spectrum lies in the closed forward cone, and it is local. ■□

2.4. **Technical lemmas and proof dependencies.**

2.4.1. *Lemmas and dependencies of the proof outline.* This catalogue gives the technical statements and dependencies of the author's proof outline. It fixes the full domains, quantifiers and uniform constants of each lemma invoked in the argument. The accompanying sections expand some proofs; other technical statements are quoted here without their detailed proofs. A reference to one of these statements always retains its complete hypotheses and only the conclusions stated below. The catalogue identifies where the principal multiscale estimates enter. Those estimates require proofs beyond the finite-dimensional and reference calculations given here.

Different routes use different groups of hypotheses. On an existing sequence of arbitrarily fine admissible data, the scalar route uses D1 with its actual rooted geometry, G1, and the ultraviolet inputs F2–F3. The bridge sections derive compactness, D2, H1, compact Hilbert evolution and G2 from those data. The joint induction outlined in A–C and the flow section is responsible for constructing these data with the stated uniformity. Weighted and matched-run comparisons and typed Ward estimates remain requirements for the stronger statements that invoke them; the scalar route requires only its ordinary D1 and ultraviolet premises, together with the consequences derived from them.

Here are conventions shared by the packages. For numerical coefficients written in terms of N, the group is $\mathrm{SU}(N)$ and here $N = 2$. Fix an odd integer $L > 1$, a compact simple matrix group G, and dimension four. The principal example is $G = \mathrm{SU}(2)$. The lattice spacing is $a_K = L^{-K}$, and a finite torus has physical side ℓ. There is one group variable U_b per positively oriented bond, $U_{b^{-1}} = U_b^{-1}$, and normalized product Haar measure dU. Write

$$a_p(U) = 1 - \tfrac{1}{2}\,\mathrm{Re}\,\mathrm{tr}\,U_p,$$
$$A(w,U) = \sum_p w(x(p))a_p(U),$$
$$Z_{K,\ell}(w) = \int e^{-\beta A(1,U)+A(w,U)}dU.$$

The trace convention in this display is for SU(2); another group requires its own normalization. Let $\mathcal{O}_K(f) = A(f,U)$. The connected functions are the mixed derivatives at zero of $\log Z_{K,\ell}(\sum_i z_i f_i)$. Test functions used together have pairwise disjoint compact supports, separation at least $d > 0$, and individual supports in balls of radius R. Set $\|f\|_\sharp = \max(\|f\|_\infty, c_M\|\nabla f\|_\infty)$, with c_M fixed. All uniform constants below must be independent of K, the torus, the history, the positions of the tests, and the relevant Gibbs state. Dependence on g, n, d, R must be displayed. A lower bound on admissible ℓ may depend on g and on constants fixed earlier. Replacing this uniformity by a bound at one fixed cutoff does not satisfy an input.

A. Background fields and propagators: four inputs. **Technical statement A1: the constrained critical orbit.** For every allowed nested family of small-field regions and every regular coarse datum V, there must exist a regular critical orbit $[U(V)]$ for the Wilson action with the prescribed block averages. It is unique among regular critical orbits in a specified larger neighborhood. A chosen gauge gives a representative which is Borel in all real data and holomorphic in a complex neighborhood of each regular real datum. Both neighborhoods have stated radii on the local scale; their radii and constants are uniform in the number of scales. Existence of an unrestricted global minimizer is insufficient: the needed assertion concerns the constrained regular orbit and its gauge representative. Compatibility with restriction to subregions, with seam constraints, and with changing the torus must be part of the statement. This is the background-orbit input behind the local assertions numbered Prop. 3.25, Prop. 3.27 and the background theorems. For the pointed window deduction, the actual restrictions and substitutions must remain in their prescribed pair cores. These cores contain the usable Taylor chart ball and obey the curvature and own tent-action

bounds on the whole admitted core, including the finitely many young ages. § 3.3 proves a local chart for the actual one-step average near a pure-gauge double block, including the pivot derivative, exact straightening and measure factors. Its explicit chart radius and nonwrapping premise do not imply existence, uniformity or all-substitution room for the many-level critical orbit.

2.4.1.1. The regular proper background. §§ 3.7 and 3.8 realize the first physical blocking step at fixed L, with arbitrary admitted real flat holonomies. For the separated determining sets eq. 3.cc-cvi, which retain interior and outward rows and omit inward rows, Prop. 3.124 proves existence and uniqueness among all regular critical orbits. Its proof uses the actual proper strong inverse, forced trial correction, datum descent, and a reset of curvature and current after every ascent. Lem. 3.122 places arbitrary regular competitors in one actual Landau chart; Lem. 3.121 obtains the required strong norm from their actual currents. Cor. 3.125 then supplies a fixed physical holomorphic continuation ball at every such real datum, uniformly in depth and volume. The exact comb construction in § 3.11 selects its Borel real representative. The larger history input A1 also specifies its actual restriction, substitution and core requirements; those clauses retain their separate hypotheses and proofs.

Technical statement A2: coercivity on a fluctuation fiber. Let Q be the derivative of the chosen block average, and let $\mathcal{E}$ be the gauge-fixed Hessian on the fluctuation variables at a regular background. The chosen coordinates must remove all residual gauge directions. On each conditioning set and with its specified boundary conditions require

$$\mathrm{Re}\langle B, \mathcal{E}B\rangle \geq c\|B\|_2^2,$$
$$QB = 0,$$

with the norm in the units of that fluctuation scale. The same estimate, with $c/2$, must hold throughout the claimed complex neighborhoods. Zero modes, torus holonomies, and node constraints must either be absent from this space or treated separately. A mass for this constrained operator is not a mass gap for the physical continuum Hamiltonian. This is the quantitative content required by the conditioning and covariance assertions numbered 1c.6 and related claims. For the actual unweighted classical flat reference, §§ 3.4 and 3.5 prove $c(L)I \leq \mathsf{A}_k^{\mathrm{flat}} \leq CL^8 I$, uniformly in the number of previous classical blocking steps and in compatible tori, including real flat holonomies. They use the actual plain constraint and the soft internal-contour gauge. The curl-energy comparison is $\|\mathrm{d}a\|^2 \leq E_k(a) \leq 256\|\mathrm{d}a\|^2$. These are the flat classical estimates used in the nonflat comparisons below; their statements retain that reference-case scope.

2.4.1.2. The physical first step and a specified current extension. The nonflat first-step precision theorem supplies positivity for the actual Wilson action with its soft gauge term on the curved constraint fibre, at an admitted real block-axial trial background. Its radius and current ceilings are retained. § 3.10 then defines one full relative auxiliary-current extension, identifies its physical action at a critical physical pair, and proves the complete first-step half-disc estimate with the gauge part included. This chosen definition must be used consistently when invoking that result. Neither zero coarse readout nor a Ward identity identifies a separately unspecified completion. For the canonical proper precision eq. 5.cclxxviii, Prop. 5.45 proves uniform real coercivity and holomorphic invertibility on a common weighted C^1 complex background tube and independent-current ball. The estimate includes the outer second-jet correction and relative gauge, is uniform in the proper inner hierarchy and conditioning set, and also covers the stated strict tree-zero subspace with the gauge term omitted. The local inverse, logarithm and normalized Gaussian families are constructed in § 5.13. Invoking these results requires the actual precision, readouts and conditioning coordinates to be those specified there, with their stated regular-pair ceilings. Signed profiles, counterterm-modified precisions and interacting Hessians require their own comparisons on the joint history cores.

2.4.1.3. Layered site and projected-form reductions. § 3.13 proves the site intertwining, site inverse/Green/Gram and projected physical form/readout reductions within its separated geometry and regular-pair class, with field-row/Feynman and depth-uniform density-coefficient comparisons. Verifying that every actual background and history substitution lies in this class remains necessary. The fine Landau coercivity and its complex moving-slice continuation are proved in Props. 3.70 and 3.77; the specified current completion is identified in Prop. 3.90. The named propagator and decoupled families are supplied by Props. 3.112 and 3.171 and Lem. 3.172. Each result retains its own geometry, complete-read and regular-pair hypotheses. The six-propagator normalizations are recorded in § 3.12.

Technical statement A3: local inverse and response bounds. The inverses and response operators actually used, including conditional covariances and derivatives of $U(V)$, must obey their declared pointwise and source-norm bounds with exponential decay in scale units. The shorthand $Ce^{-c\,\mathrm{dist}(x,y)}$ applies after the local source and output normalizations have been specified. In § 3.12 the kernels use counting measure: the fine Green source estimates retain the factors $[\xi_y^2, \xi_y, \xi_y, 1]$, the inverse site Gram entries retain ξ_y^{-4}, and the inverse coarse field-row Schur entries retain ξ_c^{-2}. The stated short-distance, first-difference and Hölder factors must also be kept. For a fine-to-fine Green map, its density against physical fine volume is η^{-4} times its counting kernel; a counting-entry bound is not the same density bound. Coarse row operators instead use their own row weights and rescalings, as in eq. 3.miv. Weighted cell bounds in norms such as eq. 3.mclxxxiii are operator estimates, not pointwise density estimates. All required bounds must hold throughout the full complex datum polydisc, not only at the identity or at real data. For the pointed window this is the product bond-log domain eq. 4.xxv, with the scale-weighted potential, gradient and current response in eq. 4.xxvi–eq. 4.xxvii. For a region with several local scales, use a precisely defined weighted path distance and the corresponding powers of the local spacings. Holomorphic derivatives in each decoupling parameter must satisfy Cauchy bounds on a fixed enlarged complex disc. A derivative joining distant sets must retain the decay needed by the polymer norm. The mesh-uniform scalar estimate and its Dirichlet compressions are proved in the block-resolvent section. On the admitted separated regular-pair domains, Props. 3.171, 3.174 and 3.175 and Lem. 3.172 prove the non-Abelian decoupled response, its screened field and current bounds, holomorphy, and wall decomposition. The all-one physical identification and coupled response are proved in Props. 3.176 and 3.177; Cor. 3.179 identifies the prescribed response maps. This supplies the assertion numbered 1c.10 on those domains. Each application must still verify that its actual history data, complete determining reads and substitution lie in the stated domains with the required radius margins. § 3.6 proves exponential kernels for the actual unweighted classical flat precision and its constrained covariance, uniformly in depth and compatible volume. It derives the exact alias symbol, cancels its apparent gauge denominator on the full complex zero cone, proves a uniform strip, and then inverts using the flat gap. Periodization and unitary flat holonomies preserve the bounds. This establishes the stated flat reference kernels, not the nonlinear response or decoupling bounds required on the full interacting domains. The finite-box affine comparison in eq. 4.xxxvii prescribes the affine test field's exact averages on the same determining set, including the seam rows. The weighted first response controls the effect of discarding its remote rows.

2.4.1.4. Primitive inversion versus nonlinear response. § 3.14 gives the exact coupled field–multiplier inverse, with the true datum differential, weighted transposes and constrained Hessian. It proves the response and complex-ball deductions from stated two-sided primitive inverse bounds. Boundary forcing is kept in its own norm. § 3.15 proves mesh-uniform local scalar estimates and their flat-unitary covariant version. Applying them to a nonlinear response requires the actual connection, forcing and covariant Laplacian point bounds recorded there. The nonlinear application uses those primitive equations and bounds for the actual response on every allowed core. Once they hold, the Hölder conclusion follows from the displayed argument; no further Hölder lemma is invoked.

Technical statement A4: averaging schemes and locality. Any transfer from one averaging scheme to another must provide a uniform intertwining map, including its coarse gauge factor. On fluctuation fibers the transferred Hessians, inverses and constraints must obey A1–A3 with the same allowed losses, for every number of blocking steps. Restrictions to a region must depend only on an explicitly bounded enlargement of that region. Equality of two linearized averages only at the identity is insufficient. A proof must bound the accumulation of their differences at nonflat backgrounds and must state the gauge in which the comparison is made.

2.4.1.5. Exact restriction with its boundary price. The finite factorization in § 3.11 shows how a new constrained variation fixes the old data and why restriction preserves criticality. Cutting the plaquette action can change its boundary current. The changed bonds are in the new bare boundary layer, where the local scale is η; the at-most-six-plaquette estimate pays a fixed current constant. That constant and the datum/seam losses are included in the actual uniqueness-input ceiling. Under this admission and regular critical uniqueness, the restriction identity is a deduction. More general changes of averaging scheme still need the stated physical and complex-domain intertwining estimates; the restriction proof alone does not supply such a comparison.

B. Cluster expansion and power counting: four requirements. **Requirement B1: a conditional polymer majorant.** Let polymers be finite connected sets of scale cubes, with incompatibility meaning intersecting supports. A specified positive size $a(X)$ and activities $z(X)$ must satisfy, uniformly in all external data,

$$\sum_{Y:Y\not\sim X} |z(Y)|e^{a(Y)} \le a(X).$$

The same inequality, with strict room, must hold for complex sources and decoupling parameters on the domains used for differentiation. Require the absolutely convergent connected-cluster formula for the logarithm, including termwise differentiation and a uniform majorant for each derivative used later. The finite-volume identity must be exact before taking limits. This is the content needed from the convergence statement numbered 1d.4.1; a formal graph expansion is not sufficient. The unmarked polymer part of § 4.5 derives the local unmarked activity and union-filed logarithm bounds from its actual enlarged Gaussian matrix/core hypotheses, sharp-cutoff structure and local potential budgets. The Mayer-parameter discs are established at the Gaussian integral, before zero-freeness is inferred. Gaussian volume costs, failed bonds, actual neighbor-layer closures and the spare potential slot are all paid for in the rate allocation. This also supplies eq. 4.xciii under those primitive hypotheses. Their verification for the actual complex interacting matrices and all allowed cores remains necessary; convergence of an unrelated model gas would not supply it.

Requirement B2: conditional pointed marginal extraction. §§ 4.2 and 4.3 prove the following implication for an actual regular member with no stored color spectators. Its pointed total and differentiated sums must converge normally; it is locally gauge invariant, and the individual member's pointed totals are covariant under unit translations and the full hypercubic group. Use the actual free response, with gauge covariance and affine constant-curvature reproduction modulo gauge, with zero linear current. The usable pair core, localized response and entropy gap must give the absolute Hessian moments in eq. 4.v. Then eq. 4.xix defines its coefficient and eq. 4.xxiv proves cancellation by that same member's own midpoint tent action. Different members may be chosen at different sites; their coefficients cannot be interchanged.

On physical radius a, the readout retains $|b(E)| + \|T[E]\| \le Ca^{-2}\|E\|$. § 4.23 supplies its stated near-zero inclusion and normalization. For the nonlinear remainder also require A1–A3 throughout the complex datum domain, the actual core inclusions, spatial Hölder regularity, compatible boundary equations and the whole-core bound on the own tent action. Put $\sigma = L^{-(n-j)}$,

$\rho = \max(1, a_{\mathrm{out}}/a)$ and $0 < \alpha_H \le 1$. Under the window domain conditions the near-domain sum at one base point, after its vacuum and own counterterm subtraction, has bound

$$C\|E\| \left[\rho^2\sigma^{4+\alpha_H} + \rho^3\sigma^6 + (1+\rho^2\sigma^4)e^{-c/\sigma}\right].$$

The final exponential term includes remote domains without a nonwrapping chart. No factor proportional to the actual curvature is asserted for that tail. Under the ordinary age bound $\rho^2 \le C(1+n-j)$, the finite young-age core fallback and the $O(\sigma^{-4})$ site count give the summable weight $C\|E\|(1+n-j)^{3/2}L^{-\alpha_H(n-j)}$.

These are conditional deductions, not verification that all actual RG formed members have the required hypotheses. They do not establish arbitrary torus-sensitive or field-sensitive tails, source derivatives of the formation map, or the fluctuation disintegration laws in F2. Stronger assertions in 1e.1.13, 1e.1.15 and 1e.1.16 require separate estimates.

Technical statement B3: the one-loop law with a summable lattice correction and controlled nonlinear errors. For the chosen normalization let $c_0 = 11N^2 \log L/(12\pi^2)$. The Gaussian contribution b_j^0 must be independent of the bare coupling and obey $|b_j^0 - c_0| \le CL^{-\sigma j}$, or a stated summable substitute. The full increment must have a decomposition

$$b_j = b_j^0 + f_j + q_j,$$
$$|f_j| \le C x_{j-1}^{-1/2} (\log x_{j-1})^p,$$
$$|q_j| \le C x_{j-1}^{-(\kappa_0-4)/2},$$
$$\kappa_0 > 4.$$

If a later deduction needs a stronger error, that stronger estimate must be proved separately. The coefficient c_0 requires an actual lattice trace calculation with the stated zero-mode convention. A continuum perturbative coefficient quoted without this comparison does not prove this input.

Technical statement B4: the ordinary step and its finer derivatives. The ordinary source box allows a separate Euclidean regular member at each base point, its own scalar counterterm, a variable Wilson weight, and scale-small noncovariant defects. The step must be holomorphic on this product box with a majorant independent of the number of labels. It is not necessary that the whole spatial array be translation invariant. The ordinary regular-output estimate does not by itself prove every marked or large-field derivative.

For the stronger comparisons actually invoked, require the potential derivative bound in eq. 4.dxciii and the one-zone complex-mass bound in eq. 4.dxciv, on the domains stated in that section, with constants independent of the levels and source positions. The regular irrelevance weight, squared-radius weights for defects, and large-field survival weights have different roles. In particular the survival factor belongs in the bound on a zone's output; it does not enlarge its input radius by its reciprocal. Joint marked derivatives and typed tensor counter-insertions must satisfy their corresponding estimates. For the stronger routes these finer conditions are stated technical lemmas; entire dependence of the bare partition function alone does not imply them. They are required for the retained stronger comparison and Ward routes. The ordinary-source insertion and angular proofs below do not obtain their operator estimates by assuming these typed Ward derivatives. § 4.20 proves ordinary old-level summations, scalar action-load and reserve implications. The source-insertion and renewed-pointing parts of § 4.5 derive the local first response under their local Gaussian and bond-split hypotheses; its unmarked polymer part derives the needed majorant from the stronger primitive matrix/core and potential package. Its window-formation part derives the ordinary formation bound using one near window member at

each old base point before its bracket is applied. The linear bootstrap retains the source norm and gradient gain under these inputs, the constant-source slopes and the old-remainder bounds. Actual nonlinear background/core inclusions and history formation remain to be verified; these implications do not supply them.

C. Large-field histories and closed induction: four inputs. **Technical statement C1: exact measurable operations.** Every move must be a specified Borel kernel, change of variables, or partition of unity on an explicitly defined space. The tests are total, including at configurations where logarithms or minimizers fail to exist. Every stored variable is integrated exactly once or retained exactly once. For every bounded gauge-invariant insertion F, the sourced construction must preserve the total integral of $Fe^{-\beta A}$. An operation preserving only the integral without F cannot be used to transport that observable. For real inputs every summand used as a probability weight must be nonnegative.

Technical statement C2: geometric margins and determination. The allowed histories must have a constructive definition. At level j, tests, local backgrounds and retained terms depend on at most a stated enlargement of the determining regions. Every enlargement lies inside the margin supplied by the next region. Healing, restriction, joining and continuation must preserve these properties, including near holes, seams, and waiting windows. On an admissible torus each cell, each box on which the operation acts, and its prescribed bounded neighborhood admit a common lift. Use the companion identities on non-wrapping domains in matching step units. Other carriers enter the torus estimates with their winding retained. The number of histories with a specified size must have a proved entropy bound, with the same size function used in the rarity estimate.

Technical statement C3: rarity with entropy and insertions paid for. For each created large-field component X at level j, require a mass bound $\mathfrak{M}_j(X) \le \exp[-cp_0(g_j) - \kappa|X|_j]$ with the stated supremum over external complex data inside its internal integral when component majorants are multiplied. Here $p_0(g) = (\log g^{-2})^p$, and κ exceeds the entropy rate of C2. The bound must include the Wilson factor actually available to pay for that component, all stored Jacobians and gauge factors, and the designated insertion weights. A failure of existence of a background, as opposed to a quantitative large-field inequality, must also be covered. Drop-outs without their own Wilson factor need a separate bound after attachment to their carrying term.

Technical statement C4: invariance of the inductive class. There must be one nonempty class $\mathfrak{C}_j$ of complete presentations, with the same constants at every level, containing the bare measure. Under the increment and tube conditions, the exact step maps $\mathfrak{C}_j$ into $\mathfrak{C}_{j+1}$. Its conclusions include the analytic polymer bounds, C1–C3, boundary bounds, covariance, and the required stability floor. All constants must admit one simultaneous order of choice, without a parameter needing to be both smaller and larger than quantities chosen later. The step assertion 2.11 requires all these properties; each must be proved.

D. Sources and local correlation bounds: four requirements. **Technical statement D1: the ordinary localized source bound and stability.** Require the precise torus hypotheses in eq. 5.cdxxxv–eq. 5.cdxxxvi of § 5.22: holomorphic point counterterms and localized source energies, a strict entropy gap, source dependence only on the specified regions, and independence of the representation of a source function by a list of tests. On the ordinary source ball, require the normalized upper stability bound and unsourced partition-function floor there, with constants uniform in cutoff and allowed torus. The source class must include the global mirror-periodized Lipschitz profiles used in the chessboard construction. Fixed-cutoff bounds for point counterterms may depend on the cutoff but must be uniform in the torus.

For the graded deduction, this input also specifies the actual domain indexing of § 5.23. Take $M = L^{m_0}$ with fixed integer $m_0 \ge 0$, and the cofinal compatible tori $\ell = 2L^m$, $m \ge m_0$. At scale $a_s = L^{-s}$ the localization cubes have side Ma_s; their counts in every direction are even integers. Every fixed power-of-L chessboard tiles all sufficiently large members of this family. All actual

scales $0 \le s \le K$ are retained. A domain X is indexed by its union of these cubes, with $m(X)$ the minimum number of edges of a finite connected cubical edge tree meeting every cube. Its source dependence is contained in a fixed number of neighboring cube layers. The source-energy bound uses $e^{-\kappa m(X)}$, with κ above the rooted entropy rate for this actual indexing. If extra domain types are present, their multiplicity must be included in that stated entropy gap.

The closed-walk count in eq. 5.cdxlvi, the ball-root count in eq. 5.cdxlvii, and the global weighted count in eq. 5.cdxlviii are then proved geometric consequences. In particular, the sharp local count is $C(1+u/a_s)^4 e^{-ct}$, and the global count is $C\ell^4 a_s^{-4}$. The weaker abstract estimate in eq. 5.cdxxxvi alone does not imply these sharper bounds and is insufficient for the graded conclusion below. Checking that the localized RG energies use this specified geometry is part of D1, not supplied by writing an abstract domain sum.

These are raw partition-function bounds. A zero-free logarithm on the whole global source ball is not assumed. The fixed-volume normalized zero-free lemma gives a suitable neighborhood when needed; the all-state transfer theorem instead constructs common holomorphic cell normalizers and obtains the derivatives at zero directly. The elementary transfer does not prove the ordinary RG source estimates in this input. § 5.21 proves explicit sufficient criteria for the upper bound and floor from the normalized positive label/history representation: total-variation bounds with a weighted label sum, and a regular all-small-field label with its own action bound. Those criteria, including the reserve and allocation of Wilson factors, remain to be verified for the construction. A pointwise polymer logarithm cannot replace that history representation without an exact common integral formula.

2.4.1.6. The actual history norm and the remaining local checks. § 4.18 proves the weighted genealogy count, reserve arithmetic, gauge-normalizer half-disc bound, strong-mass induction and loaded label sum from their explicit finite-operation hypotheses. Its norm integrates the supremum over all admitted reads; a bound at each fixed read is insufficient. To apply the result one must identify the literal stored-coordinate operation and its fixed reference measure, admit every later read to the same core, prove the complete quadratic domination and localized energy envelope, and construct owned witnesses for the failed tests. The original inner Wilson weight is retained. The source extension has two proved routes: an actual pointwise excess bound, or an ordinary kernel holomorphic and bounded in its Banach norm on a complex source ball over a fixed reference measure, together with a real estimate with a sufficiently large prepaid mass-weight coefficient on a full real source ball and one common actual field/read core for both estimates. Both routes retain their specified formation and domain premises. The lower partition floor also needs its admitted positive regular label and common normalization; an upper history-mass estimate does not prove that floor.

Requirement D2: graded all-state bounds derived from D1 and G1. Prop. 5.76 uses D1 in its actual rooted setting above and the proved chessboard domination from G1. It yields one fixed finite integer k and $B(R) = C(R+1)^4$ such that, for periodic Gibbs states ρ, ν at the same datum,

$$\left| \rho \prod_{i=1}^{n} [\mathcal{O}_K(f_i) - \nu(\mathcal{O}_K(f_i))] \right| \le B(R)^n (n!)^k \max\{1, d^{-5n}\} \prod_i \|f_i\|_\sharp .$$

For $n \ge 2$ the cumulants under ρ satisfy the same estimate with $[2B(R)]^n$ in place of $B(R)^n$. Each support lies in its own radius-R ball, placed anywhere, and different supports have distance at least d. The first-order case uses the one-point difference bound. All constants are uniform in cutoff, states and support positions.

The proof gives a polynomial cell-normalizer loss $Q_i \le Cn^p$ and $k = \lceil p \rceil + 5$. It uses a genuine product source polydisc from separate chessboard factors and common univariate normalizers. The separation singularity is explicitly d^{-5n}, not a single d^{-5} prefactor independent of n. D2 is therefore a conditional deduction of the ordinary analytic input D1 with its specified geometry and G1; it is

not an additional graded-source hypothesis. D1's analytic estimates and actual RG realization are not proved by this deduction.

Technical statement D3: age-resolved uniform rarity. The probabilities or positive weights of live regions persisting from a given level to a later level must have a summable bound uniform in volume and in the location of a test. Witness selection, replication by reflections, and pattern counting must preserve the insertion and source weights. State the resulting tail function $r(m)$ with $\sum_m r(m) < \infty$, together with every additional moment in m used later. A rarity estimate for one newly created component is insufficient for this persistence assertion. This input represents the age and survival arguments wherever actual history persistence or weighted comparisons are used. The ordinary graded all-state estimate D2 is obtained by its GS route above and does not require this separate history-persistence hypothesis.

For deductions from a fixed-bump Riemann sum, the cutoff is required to be sufficiently fine.

Requirement D4: one-point transfer derived from D1. Prop. 5.75 proves, under D1, that periodic Gibbs states ν, ρ at the same datum satisfy

$$|\nu(\mathcal{O}_K(f)) - \rho(\mathcal{O}_K(f))| \le C_1(R)\|f\|_\sharp.$$

If both states are invariant under all plaquette isometries, the bound implies $|\nu(a_p) - \rho(a_p)| \le Ca_K^4$ by testing a fixed nonnegative bump of nonzero integral. The uniform bound on differences follows from a common holomorphic normalizer; neither individual uncentered mean is required to remain bounded. This is essential when a pure component is centered with respect to a mixture.
E. Flow, tuning and comparison of cutoffs: four inputs. **Technical statement E1: a consistent flow.** The recursion $x_j = \beta - \sum_{i\le j} b_i$ must be defined up to first passage, with $b_i \le B_\sharp$ and $\lambda(j-i) - C \le x_i - x_j \le B_\sharp(j-i)$, $\lambda > 0$. Its increments must be independent of the admissible torus and of the unused finer cutoff. These are hypotheses for the elementary first-passage argument; they cannot be deduced from a recursion whose next step is itself undefined outside the invariant tube specified by the flow lemmas. Together with B3 they imply the leading logarithmic relation between β and the cutoff.

Technical statement E2: a frozen calibration and tuning map. For auxiliary choices fixed independently of β, the terminal map $\beta \mapsto x_K^\natural(\beta)$ must be holomorphic on a stated complex neighborhood of a real interval. On that interval require $0 < c \le \partial_\beta x_K^\natural \le C$, and endpoint values bracketing the prescribed renormalized inverse coupling. All intermediate values must remain in the allowed tubes. This supplies existence and local uniqueness of a tuned bare coupling by elementary analysis. The holomorphy assertion is not valid merely because the original finite-lattice partition function is entire. The flow section proves the slope implication both from the stronger independent coupling polydiscs and from the weaker marked bare-disc route. In the latter, the marked forcing is of size $C\epsilon_i'/\varrho$, not $C\epsilon_i'/x_{i-1}$, and is retained in the discrete Gronwall estimate. Its summability needs the stated exponent restriction. Canonical tuning uses the admitted real interval; broader presentation gluing additionally needs an admitted real overlap. Overlapping geometric complex discs alone do not establish that admission.

Technical statement E3: a summable matched-cutoff comparison. At matched terminal coupling, require for each fixed torus and separated tuple

$$|S^T_{n;K+1}(X) - S^T_{n;K}(X)| \le C(n,d,g,\ell)\epsilon_K \prod_i \|f_i\|_\sharp,$$

$$\sum_K \epsilon_K < \infty.$$

The floor in K may depend on the fixed torus. To compare two nearby terminal couplings, add a uniform Lipschitz term proportional to their difference. Neither assertion implies infinite-volume uniqueness. This is the actual analytic input behind the matched-run claims numbered 8a and the tuned Cauchy sequence; a bounded difference at each cutoff does not suffice.

Technical statement E4: compatibility of calibrations. When moving between a self-calibrated first-passage run and a frozen run, the maps must represent the same bare integral and satisfy a stated uniform bound on their coupling discrepancy. That discrepancy must be small enough for every comparison domain and source radius used above. Exact dilation identifies the same finite lattice in two units, but supplies no estimate on this calibration discrepancy. Uniqueness statements must state which terminal coupling and which calibration they use.

F. Short-distance normalization and nontriviality: four requirements. **Requirement F1: the proved free-kernel comparison.** The exact continuum coefficient is proved in appendix A.3. For the remaining lattice comparison, let $a = \ell/n$, with integer n, and use plain coordinate inner products on site, bond and positively oriented plaquette cochains of the periodic lattice. Let d_1 be its unscaled circulation matrix and P_{ex} the orthogonal projection onto $\operatorname{ran}\mathrm{d}_1$. A standard Gaussian on that range has covariance P_{ex}. Its physical curvature kernel is the 6×6 matrix of components

$$K_{a,\ell;P,Q}(p,q) = a^{-4} P_{\mathrm{ex}}(p_P, q_Q),$$

with each component sampled at its own plaquette barycentre. Appendix A.4 proves the following comparison with the continuum matrix K, with $\gamma = 1/2$:

$$\begin{gathered} |K_{a,\ell;P,Q}(p,q) - K_{P,Q}(x(p) - x(q))| \le C r^{-4}\big[(a/r)^{\gamma} + (r/\ell)^4\big], \\ a \le r/10, \\ r \le \ell/10, \\ r = |x(p) - x(q)|, \end{gathered}$$

for some fixed $\gamma > 0$, uniformly in a, ℓ, plaquette positions and orientations. Periodic differences are represented by the short displacement in this range. The same section proves separated smearing convergence and the resulting quadratic-density coefficient. This closes the free exact-cochain Gaussian requirement; the interacting extraction F2 remains an independent input.

The projection convention in this input is distinct from physical weighted block means. When passing to unit physical blocks use the adjoints and physical difference d_η established in the block-normalization section. Under plain fine and coarse inner products an arithmetic block mean does not have an isometric adjoint; no projection identity may silently interchange these conventions. Neither normalization proves the interacting extraction F2.

Technical statement F2: extraction of the leading two-point term. For the prescribed short-distance test pairs require the finite-cutoff identity

$$S^T_{2;K,\ell}(f,h) = C_G \zeta_K(d)^2 g_K(d)^4 \mathcal{K}(f,h)(1 + r_{K,\ell}(f,h)),$$

where $C_G > 0$, the real-data error satisfies $|r| \le 1/2$, and all lower cutoff requirements are explicit. For the angular deduction this input must cover the full class $\mathfrak{T}(d;\vartheta_*)$ in eq. 6.cccxxvi–eq. 6.cccxxx of § 6.12, with $\vartheta_* = 1/12000$, or a broader class. These are nonnegative C^1 tests in radius-d balls, with support distance between d and $6d$, the stated lower integral and upper Lipschitz bounds, and arbitrary positions. A law proved only for a narrower shape class is insufficient without a further inclusion argument.

The same bound is required for $S_2^T[\rho]$ in every periodic Gibbs state used to approximate the limit or any component. At fixed d its eventual cutoff threshold and constants must be uniform in those states and support positions. This quantifier is part of the stated F2 lemma, not a consequence of a torus-only law. On each fixed torus any asserted $r \to 0$ needs a separate uniform estimate; it must not be silently promoted to a statement uniform in volume. This is the substantive Gaussian-extraction input behind the short-distance law, including all interaction and large-field remainders. The finite source insertion and renewed-pointing proofs retain the $\alpha^2 s$ potential norm under the actual unmarked-majorant, leg-path and complex-domain hypotheses. The window formation and linear bootstrap propagate it under their explicit ordinary inputs; the resulting near-field estimate requires the complete field to have size δ, not merely a δ-sized increment on an arbitrary α-background. Remote and holonomy tails retain their separate bounds. These deductions do not verify the background and history inputs for the interacting construction.

The actual clean-history normal form must still control every old activity's localized Hessian, the conditional exterior force and pointwise deletion with the same exterior field and correct flag mass. That route also requires the nonlinear averaging-fibre comparison; gauge fixing the actual run provides a route that avoids it. The corresponding normal-form estimates are invoked in F2. An arbitrary resolved coupling supplies neither law. § 6.2 proves the covariance arithmetic and common-normalizer transfer once their inputs hold. The old-activity part of § 4.5 derives the localized Hessian from the actual all-substitution window room, window-first value bounds and holomorphy on a Gaussian-coordinate ball of radius $c\alpha/g$. The resulting scale-small bound has factor $(g/\alpha)^2$. Establishing that room, and the conditional exterior-force and pointwise clean-class laws, remains necessary. The local one-step chart or a value bound without a complex domain does not supply those conditions.

The transfer of a Gaussian reference law has two different scopes. D1's common cell normalizer compares any two periodic infinite-volume states; an infinite reference obtained with a Gaussian estimate uniform along arbitrarily large tori therefore needs no finite-volume vacuum comparison. A law proved only on one prescribed finite reference torus instead requires a comparison with those states. Compatible local counterterms, the floor and vacuum-density comparison give one sufficient route. The local companion criterion in eq. 6.vii–eq. 6.ix proves that vacuum comparison from explicit nonwrapping and normalization data; it is not required in the infinite-reference route. Per-torus estimates whose distance thresholds decrease with the volume do not establish the latter reference law.

2.4.1.7. The conditional law cannot be replaced by a formal Gaussian. § 6.3 gives the actual coarea/conditional-density bookkeeping and the exact Stein identities, including cutoff boundary fluxes. It retains the exterior force, the conditional mean, the third and fourth cumulants, and the change of conditional means when clean and bad classes are mixed. A small Hessian for old activities bounds none of these other quantities by itself. The remaining comparison must identify one actual positive conditional measure and its normalizer, and bound these terms uniformly on the specified exterior fields before applying the covariance arithmetic. The localization of both the observable and its deletion must be the one in that identity. The test transfer additionally uses a uniform scaled C^1 shape bound and the stated lattice-to-support ratio, so a positive continuum mass cannot disappear at every sampling point. These are explicit remaining law and boundary estimates for the F2 route.

2.4.1.8. The Gaussian cutoff reference. § 6.6 proves uniform normalized boundary-flux and quadratic Wick-error estimates for centered Gaussian laws with the stated convex physical cutoffs, including dependent blocks. The actual flat first-step elimination is proved at $x = \theta$, with curvature covariance $P_{\mathrm{d}_1 \ker P_L}$. Comparison with the full P_{ex} reference also requires its coarse complement. The interacting conditional law, complete Hessian, exterior force, normalized force/boundary cumulants and common-reference means remain model inputs.

Technical statement F3: the running normalization at the witness scale. The witness depth must be defined without reference to a desired conclusion, and its lattice separation must lie within the permitted comparison range. Require

$$g_K(d)^{-2} = c_* \log(1/d)(1 + o(1)),$$
$$\zeta_K(d) = 1 + o(1),$$
$$c_* > 0,$$

with the precise uniformity needed by F2. A derivative of a running coupling with respect to a constant source must be shown to equal this normalization; it is not an independent choice of field renormalization. F2–F3 give a nonzero two-point limit by a closed lower bound. Appendix A.8 proves summability of the normalization slopes from the actual increment estimates on coupling-sized independent complex polydiscs and control of the large-field remainder loss. The flow section preserves the alternative with an actual marked remainder on a fixed bare-coupling disc and its separate summable forcing. A sharp $O(g \log^p g^{-2})$ slope rate on this weaker route needs $p_R \geq 3/2$; summability alone needs $p_R > 1$. Analyticity on an ordinary source disc alone does not provide the required marked size and history bounds.

Here is their sufficient ultraviolet consequence, with its size estimate included. Use

$$\mathcal{K}(f, h) = \iint f(x)h(y)|x - y|^{-8}\, dx\, dy.$$

If the nonnegative supports lie in radius-d balls at distance at least d, and v_4 is the volume of the unit ball in $\mathbb{R}^4$, then

$$0 \leq \mathcal{K}(f, h) \leq d^{-8}\|f\|_{L^1}\|h\|_{L^1} \leq v_4^2\|f\|_\infty\|h\|_\infty.$$

The uniform F3 bounds imply $|\zeta_K(d)| \leq Z$ and $g_K(d)^4 \leq C[\log(1/d)]^{-2}$ for small d and all permitted sufficiently fine cutoffs. Thus F2 gives

$$0 \leq S_2^T[\rho](f, h) \leq C'[\log(1/d)]^{-2}\|f\|_\infty\|h\|_\infty.$$

The lower inequality uses $1 + r \geq 1/2$; the upper inequality uses $1 + r \leq 3/2$. At each fixed pair these closed inequalities pass to every limit and to the all-state phase realizations. Taking $u(d) = C'[\log(1/d)]^{-2}$ proves precisely eq. 6.cccxxvii, with $u(d) \to 0$. This deduction does not verify the state-uniform extraction or running normalization required in F2–F3.

2.4.1.9. Flow bookkeeping and its actual coefficients. § 5.2 proves the arithmetic first-passage, forced-slope and tuning implications under the stated coefficient, source-disc and history-error bounds. The reference frame, initial physical weight and vacuum normalization are kept fixed in each comparison. Tensor reduction uses the period average where only periodic covariance has been established; a pointwise own counterterm requires its full pointed covariance. What remains for the interacting flow is to identify and estimate the literal formed coefficients and their admitted overlap domains. An alternative auxiliary pointing or current convention cannot supply those coefficient identities without its own comparison.

Technical statement F4: interpretation of the observable sector. The conclusions of F1–F3 concern the scalar $\mathrm{tr}(F^2)$ sector. To identify a reconstructed theory as the full Yang–Mills theory, specify a sufficient gauge-invariant observable family, its consistency relations, renormalization, and its relation to this scalar sector. Supply the needed continuum gauge identities or equivalent identification. A nonzero scalar Wightman field alone does not provide this identification. If no

such input is verified, the conclusion must be stated as existence of the conditional scalar observable theory, with full gauge-theory identification left open.

2.4.1.10. A complete cutoff family and a precise extension problem. §§ 7.10 and 7.11 construct the full cutoff invariant algebra. Finite Wilson trace words separate every finite SU(2) gauge orbit, including degenerate ranks, and their polynomials are uniformly dense in the invariant continuous functions. § 7.12 exhibits configurations with arbitrarily small plaquette curvature and identical action data but distinct Wilson traces. Its example states are not asserted to be Wilson Gibbs or continuum states. The conclusion is the precise information distinction between the two algebras. § 7.13 proves the mixed positivity, relation, consistency, support, graph-domain and representation consequences of specified joint readouts. The remaining F4 task is to construct a sufficient family of such readouts from this same lattice theory, prove its compatible joint continuum estimates and reconstruction, and justify sufficiency for the intended gauge theory. Cutoff density alone is not a uniform continuum approximation theorem.

G. Symmetries, rotations and phases: four requirements. **Requirement G1: proved finite-lattice symmetries and positivity.** appendix A.5 proves link-reflection invariance and the common period $2\mathbb{Z}^4$ for every periodic SU(2) Wilson DLR state at fixed $\beta > 0$. Appendix A.6 then proves invariance and reflection positivity at every coordinate site, coordinate link, and diagonal lattice mirror, on the full bounded Borel half-space bond algebra. No restriction to torus-selected states is made. The compositions give all unit translations and signed permutations. At $\beta = 0$ the unique product Haar state has the same properties. Adapted split tori are used for diagonal mirrors; an invalid diagonal split of an ordinary cubic torus is not assumed.

Requirement G2: scalar rotations derived from ordinary sources and the ultraviolet law. Consider limits through periodic Gibbs states, including the canonical components with their all-state realizations. G1 and the compactness inheritance argument provide their coordinate and diagonal reflection positivity; § 6.16 provides the exact coordinate cube cone. A component with mean $c \int f$ is first centered at its own mean. Its self-centered cutoff moments converge to this centered functional by the finite subset expansion and the convergent one-point differences; the same expansion restores the invariant mean after the proof. Under D1 in its actual rooted geometry, Prop. 6.23 proves a Hilbert insertion bound uniform in the number of surrounding fields. This operator estimate does not follow from D2 alone.

Prop. 6.24 converts that bound to an analytic L^1 plate density, with the explicit loss of five powers of the time margin. § 6.11 constructs the holomorphic product kernels and vectors, glues their frames, and proves the finite angular band and continued Gram positivity. Prop. 6.25 uses eq. 6.cccxxxv to remove every nonconstant two-point harmonic, including the critical frequency. Its diagonal measure and cone support are constructed in the proof. The shape bound eq. 6.cccxxvii gives the required limit. Alternatively § 6.12.6 deduces it from the ordinary source estimates at the running stops, with their stated logarithmic dependence on the inverse coupling. Prop. 6.26 proves polygon divisibility, integer convexity, removal of exceptional distributional support by common cuts, and full O(4) covariance. QF transfers this covariance to the diagonal-flat Schwartz domain. For the canonical components, the symmetry of the decomposition also transfers covariance once it has been established for the mixture. The separate component two-point law uses the state-uniform estimates on their realizing states.

This proves G2 conditionally for this state class, using either supplier of eq. 6.cccxxxv. The ordinary-source route uses the quantitative stopped estimates. Typed Ward counter-insertions and distant-shell flux belong to the separate route below. The density comparison also applies the route, with the same hypotheses, to limits of first-passage sequences above the cutoff-dependent side threshold. For a general growing cubic-torus limit one must establish the mirror and cone interface separately.

The stronger Ward route requires the following: an exact lattice identity must pass to $\delta_\omega S_n(X) = -\lim_{R\to\infty}\lim_j \langle \mathfrak{B}_{\omega,R}; X\rangle_j$, with every bulk and discretization error controlled and the claimed boundary limit existing and vanishing. The order of those limits and the typed estimates needed for them remain assumptions wherever that route is invoked. The angular proof does not establish those separate comparison estimates.

Requirement G3: the proved finite-spacing plateau law. For a spacing $a > 0$, let $\Omega_a = \mathrm{SU}(2)^{\mathcal{B}_a}$, where $\mathcal{B}_a$ is the countable set of positively oriented bonds of $a\mathbb{Z}^4$. Give this space its product topology. Let $\mathcal{G}_{a,\beta}$ be the translation-invariant probability measures satisfying the Wilson DLR equations at inverse coupling β. The finite-bond conditional kernel integrates the bonds in W against the normalized density $\exp[-\beta\sum_{p:p\cap W\neq\varnothing} a_p]$ and holds the other bonds fixed. These kernels take continuous local functions to continuous local functions. Thus $\mathcal{G}_{a,\beta}$ is a compact convex set. Its reflection invariance and reflection positivity are proved under G1.

Let $\mathcal{I}$ be the completed σ-field of events invariant, modulo the measure, under all translations in $a\mathbb{Z}^4$. For bounded local functions A, B define

$$\mathrm{Pl}_\nu(A,B) = \nu(\overline{E_\nu[A \mid \mathcal{I}]}E_\nu[B \mid \mathcal{I}]).$$

Prop. A.12 proves the following law, with one numerical constant C independent of $a, \beta, \nu, r, n, A, B$. If $r \geq 1$ is an integer, A, B depend only on bonds with both endpoints in $a[-r,r]^4$, and $y \in a\mathbb{Z}^4$ has $n = |y|_\infty/a - 2r \geq 1$, then

$$|\nu(\overline{A}\,\tau_y B) - \mathrm{Pl}_\nu(A,B)| \leq C\left[(r/n)^2 + (r/n)^3\right]\mathcal{N}_{\nu,r}(A)^{1/2}\mathcal{N}_{\nu,r}(B)^{1/2},$$

where

$$\mathcal{N}_{\nu,r}(A) = \max_{\mu=1,\dots,4;\,\gamma\in\Gamma_{16}} \nu(\overline{\theta_\mu\gamma A}\tau_{2rae_\mu}\gamma A) \leq \|A\|_\infty^2.$$

Here θ_μ reflects x_μ to $-x_\mu$, and Γ_{16} is the group of coordinate sign changes. Nonnegativity of these reflection sizes follows from G1. The law holds for every $\nu \in \mathcal{G}_{a,\beta}$, including mixtures. It is a statement before any continuum component is constructed.

Prop. 7.7 constructs the required conditional probabilities on this compact metric space, including Borel versions and simultaneous probability-valued uniqueness. Applied to $\mathcal{I}$, this theorem, the DLR equations, and the law above yield a unique decomposition into ergodic DLR states. The argument and the required closedness of the pure state set are proved in the phase-interface section. Compactness of that pure set and existence of continuum components are conclusions, not assumptions.

Requirement G4: all-state moments derived from ordinary sources. Choose $a_j = L^{-K_j} \downarrow 0$, couplings β_j, and centering states $\nu_j \in \mathcal{G}_{a_j,\beta_j}$. Write $\mathcal{O}_j(f) = \sum_p f(x(p))a_p$. Under the precise ordinary source hypothesis D1, Prop. 5.75 proves for every $\rho \in \mathcal{G}_{a_j,\beta_j}$ that

$$|\rho(\mathcal{O}_j(f)) - \nu_j(\mathcal{O}_j(f))| \leq C_1(R)\|f\|_\sharp,$$

$$|\kappa_n^\rho(\mathcal{O}_j(f_1),\dots,\mathcal{O}_j(f_n))| \leq C_n(d;R)\prod_i \|f_i\|_\sharp$$

$$(n \geq 2).$$

The tests are real C^1 functions; each support is contained in a ball of radius R, and different supports have distance at least $d > 0$ in the second bound. Here $\|f\|_\sharp = \max(\|f\|_\infty, c_M\|\nabla f\|_\infty)$. The constants are independent of j, ρ and support positions. They also apply to the separated reflected copies used in G3. For the chosen sequence, assume that the moments centered at ν_j

converge on every separated tuple; alternatively obtain such a sequence from the preceding compactness theorem. The per-order transfer alone would not establish factorial growth. In the actual rooted setting of D1, Prop. 5.76 also provides D2, and Prop. 5.78 gives H1. The bounds displayed here and G3 suffice for the canonical decomposition constructed below. They do not assume that decomposition or clustering of its future components.

H. Test spaces and reconstruction: four requirements. **Requirement H1: quantitative diagonal-flat extension derived from D2.** Let $\mathcal{S}_{\neq}(\mathbb{R}^{4n})$ be the Schwartz functions flat, to all orders, whenever two arguments coincide. Under the D2 moment bound, passed to a separated-tuple limit, Prop. 5.78 constructs its unique continuous extension to this space and proves

$$|\mathsf{S}_n(\varphi)| \le C_{\mathrm{E}}^n (n!)^{\kappa_{\mathrm{E}}} \sup_{|\alpha| \le k_{\mathrm{E}} n, x} (1+|x|^2)^{k_{\mathrm{E}} n/2} |\partial^\alpha \varphi(x)|,$$

$$k_{\mathrm{E}} = 20,$$

$$\kappa_{\mathrm{E}} = k + 32.$$

The constants are independent of n. The same uniform statement applies to component limits obtained from the all-state bounds. Only the position-uniform radius-one moment bound is used; a unit partition already gives an effective $B(R) \le CB(1)(1+R)^4$. The explicit dyadic/product-box proof includes tensor-relation independence, all diagonal cutoffs, infinity cutoffs, and the positive-time boundary. Its constrained tensor density transfers reflection positivity to finite positive-time Schwartz sequences. Thus H1 follows from D1 in its GS geometry and from G1.

A distribution only on the complement of the diagonals with unspecified constants would not establish this result. Diagonal-flat functions are not dense in the full Schwartz space; an extension across diagonals or contact-term identities still need a separate renormalization statement.

Requirement H2: positivity and continuous Euclidean evolution. § 6.16 proves the compact-tuple Hilbert construction from invariant separated moments, full reflection positivity and position-independent per-ball bounds. It proves strong continuity, time contraction and the cube spectral cone for the stated lattice approximation. For the full positive-time test sequences in the precise reconstruction theorem, the required finite quadratic inequalities are $\sum_{p,q} \mathsf{S}_{p+q}(\Theta\overline{\varphi}_p \otimes \varphi_q) \ge 0$. All tensors in this expression must belong to the declared domain. Under H1 and the constrained tensor-density lemma, those full sequence inequalities and the same Hilbert evolution follow from the compact-tuple construction. The proof bounds all translated matrix elements before iterating Cauchy–Schwarz. Its position-independent per-ball hypotheses are supplied by D1 for the ordinary phase moment bounds. The compact argument does not by itself give quantitative Schwartz growth; that additional conclusion follows from the GS/QF estimates in H1.

Requirement H3: the checked reconstruction theorem import. § 7.3 states the corrected Osterwalder–Schrader theorem in its diagonal-flat domain and verifies its quantitative hypotheses. The norm comparison tracks the dimension-dependent constants as the field number grows, so both derivative order and factorial coefficient growth have the required form. H1–H2 supply their stated flat test continuity and positive ordered form. G2 supplies full Euclidean covariance and permutation symmetry on the declared ordinary-source and ultraviolet route. Clustering is used for the unique-vacuum component; the cluster-free version retains the stated possibly nonunique vacuum.

The energy-band and test-space sections derive the actual fields, positive unrestricted tempered moments and joint boundary values from the damped insertions, and derive Lorentz covariance from G2. Their identification with the imported realization is proved before locality is transferred. The resulting field is on $\mathcal{K}_{\mathrm{ord}}$. Equality with the whole Euclidean Hilbert space is not required.

The representation and phase sections give the remaining domain and scalar direct-integral identifications.

The corrected theorem applies by the hypothesis checks above. We cite its continuation and locality conclusions; the model estimates A–F require their own proofs. Contact terms invisible to diagonal-flat Euclidean data are not assigned arbitrary values. Actual D1, F2–F3 and the existence of the admissible data supplying these hypotheses remain the model requirements.

2.4.1.11. What is reconstructed directly. The energy-band construction gives the actual fields and their common invariant energy domain. The test-space estimates supply full non-tensor Schwartz extensions, joint boundary limits and the needed graph approximations. The representation section identifies their canonical closures and generators. § 7.9 constructs the measurable direct integral of the ordered component sectors and proves that its mixed cyclic range is onto that integral. The remaining named reconstruction import supplies locality and its stated stronger output order after the verified hypothesis matching. Its proof is an identified functional-analysis import, not an additional unknown model estimate.

Technical statement H4: scope of the final conditional assertion. The conditional existence statement may use only verified deductions on its declared route. For periodic-state limits the ordinary D1 hypothesis in its actual geometry, the ultraviolet F2–F3 hypotheses, and the proved bridges give the scalar conditions on a sequence of admissible data; H3 is supplied by the checked theorem import just stated. Actual verification of D1 and of the interacting short-distance law is not supplied here. The additional weighted, matched-cutoff and Ward conclusions require their stated hypotheses. Full gauge-theory identification additionally needs F4. A mass-gap conclusion would require a new estimate, for example a bound yielding spectrum outside zero contained in $[m, \infty)$ for some $m > 0$. None of the packages above supplies that estimate. A finite lattice measure, a subsequential separated-point limit, an axiomatic scalar theory, and its Yang–Mills identification are successive claims, each requiring its own proof.

2.4.1.12. The exact spectral question left open. The scalar direct-integral theorem identifies the mixed zero-energy space with $L^2(X, \lambda)$. It also proves that the gap above that entire space is the essential infimum of the component gaps. Positivity of a component gap at each phase does not imply a positive uniform lower bound. An equivalent sufficient target is a common positive exponential decay rate for the positive heat-semigroup matrix elements on a dense core, after subtracting the full zero-energy projection. No such rate is proved here. Enlarging the observable family requires the corresponding joint spectral and vacuum assertions on the larger Hilbert space, rather than only on its scalar subspace.

2.5. **Domains and dependencies of the analytic construction.** The inverse, background and integration results use different analytic domains. We specify their order here, including the two changes of domain which enter the regular trajectory. This also fixes the meaning of the physical identifications used below. All constants are uniform in depth and compatible volume after the displayed choices have been made. They need not be uniform as an exponent approaches an endpoint or as the blocking integer is changed.

2.5.1. *The reference for the inverse.* An admitted proper geometry specifies the field and site rows, their assigned scales, bare components and complete determining collars. It is given before an inverse is constructed. Choose a real current-regular reference U_* in that geometry. A nearby pair is

$$U = e^{i\eta E} U_*, \qquad \|E\|_{\mathcal{A}_\alpha} < r_*, \qquad \|J\|_{\infty,3} < \gamma_*. \tag{2.xxxi}$$

Here r_*, γ_* are the smaller strong-family radii chosen after $\alpha, p_{\mathrm{ell}}, \kappa_+$ and the final separation and reblocking parameters. The admitted geometry includes these separation choices. The energy current ceiling alone does not give these strong families. The frames and norms are fixed at U_*. The present field U, its restoration and its actual constraint are allowed to vary. The current J is an independent parameter. It is not defined by differentiating the action of U.

The order of the operators is consequential. Positive local Dirichlet columns first give the field and site primitives. Positive coarse inversion then gives the projected zero-current inverse. The first current correction is performed before its row Schur inverse and first lift are formed. That lift supplies the multiplier readout used in the second current correction. In the notation of Prop. 3.112, this order is

$$G_0, \quad G, \quad H, \quad \omega_* = H^\sharp J, \quad G_1, \quad H_1. \tag{2.xxxii}$$

The second lift is not substituted for H in the definition of ω_*. The physical transposes include the row lengths and fine counting densities before any supremum norm is estimated.

The fourth-order construction in Prop. 3.160 provides a new coefficient family for the site restoration. It supplies two Hölder derivatives of the gauge parameter. The strong current construction in Prop. 3.163 then provides the full field–multiplier saddle in the required finite-p force classes. These are estimates on coefficients and their complete carriers. An endpoint decay bound for the completed operator would not suffice for this step.

There is a second distinction in the norm. For joint Taylor expansions of local base data the required positive majorant is

$$\sup_y \sum_X e^{\kappa_+ \sigma_c(X)} \sup_{P_X \in \mathfrak{D}_X^+} \|K_y[X](P_X)\|. \tag{2.xxxiii}$$

The supremum over each local coefficient domain precedes the carrier sum. A bound with one global supremum outside that sum does not imply this bound. Lem. 3.164 proves the stronger order of operations. In a coarse short-power stage it uses the uniform entry bound and the full endpoint count, giving $C(1+B_m)^4(q')^m$. The exponential contraction pays that polynomial after the fixed construction parameters are enlarged.

2.5.2. *The nonlinear germ and its physical restriction.* The auxiliary scalar action is specified explicitly in eq. 3.mcxlviii. Its current convention is part of its definition. The nonlinear equation is solved on the domain eq. 2.xxxi with a smaller strong radius. At zero reduced datum its auxiliary potential is zero. Put $C(B) = \Pi_U(A(b_U(B)))$ for the completed field before the final literal node gauge. The derivatives are

$$D_b A(0) = H_1, \qquad D_b \Pi_U(A(b))\big|_{b=0} = SH_1, \qquad D_B C(0) = SH_1 D b_U(0). \tag{2.xxxiv}$$

The last expression includes the actual literal-to-reduced datum map. A further literal node gauge contributes its specified fine gauge vector to the literal field derivative.

The remainders are formed before they are assigned to carriers. In particular, $QS = Q$ is used to write the constraint remainder as $Q\Xi + N_q(\Pi)$, so each of its terms has quadratic field degree. The current and multiplier remainders are rewritten in their actual point-force classes before restoration adjoints are applied. Thus the tree series has no linear term that must cancel between different carriers. Props. 3.167 and 3.169 prove convergence over every datum degree and every local base degree. The base variables in that statement are supported strong Banach slots, with bounded-overlap reconstruction. They are not independent discs for every raw fine link.

The physical restriction is an exact scalar identity. At

$$J = j_U = Q^\sharp \omega_{\mathrm{phys}}, \tag{2.xxxv}$$

the selected auxiliary action equals the physical action on the finite gauge completion, with its constraint multiplier and explicit penalties. The gauge tests remove the gauge penalty. The artificial row mass is constant on the prescribed constraint and is removed from the physical multiplier by the shift $\nu_{\mathrm{phys}} = \nu - a_f b$. Uniqueness then identifies the solution with the physical constrained orbit. This is the content of Prop. 3.150. The off-current construction remains the selected convention just defined; its existence does not identify any other prescribed auxiliary action.

2.5.3. *Producing the homogeneous reference.* The reference in eq. 2.xxxi is an input for a proper geometry. In the homogeneous case it can instead be constructed from coarse curvature alone. For a real coarse field V with sufficiently small plaquettes, Prop. 3.193 constructs a smooth quaternionic bundle connection whose original coarse-edge transports are exactly those of V. Its fine samples have physical curvature and Wilson current $O(\kappa)$. Their actual hierarchical means differ from V by $O(\kappa)$, uniformly in the number of means.

The current estimate pairs opposite plaquettes before division by the third power of the fine spacing. The mean estimate uses the full plain-mean row majorant. These two operations prevent,

respectively, a loss of one inverse fine spacing and a factor growing exponentially with the number of blocking steps. The forced trial equation retains the trial current as a source and corrects both defects. Prop. 3.194 therefore produces the physical homogeneous orbit without assuming a global gauge close to a flat connection.

The bundle construction also supplies the comparison of nearby real references. Its Kato map aligns the connections before fine edges are sampled. A change of a coarse datum then gives a relative fine potential of size $O(\|B\|)$, rather than a frame jump divided by the fine spacing. The resulting strong comparison, with the larger uniqueness margin, identifies complex germs on overlaps. There is no need to assume that an arbitrary complex overlap contains a real point.

For constant diagonal plaquette weights, Prop. 3.199 uses the same smooth trial. Its principal perturbation is estimated from $W^{2,p}$ to L^p. The full joint inverse is first proved in that stronger field norm. It is not inferred from a $C^{1,\alpha}$ output estimate. The weighted current of the corrected physical orbit is small because it is the actual row transpose of the bounded physical multiplier. No point bound for its unweighted current is inserted into this argument.

These statements produce homogeneous references, including large holonomies and nontrivial bundle topology. The definition and construction of mixed-scale proper histories still use their stated geometry and admission hypotheses.

2.5.4. *The physical Gaussian and the integral domain.* At a physical critical pair the mass-added second inverse has a positive energy gap. Its effective coarse action Hessian is

$$D^2S = (QG_1Q^\sharp)^{-1} - a_f. \tag{2.xxxvi}$$

The artificial row mass is subtracted. The actual outer precision also contains the first action gradient paired with the second derivative of the outer chart:

$$K_\tau = \tau\{\mathsf{C}_V^\sharp(D^2S)\mathsf{C}_V + \langle\omega, \Phi''(0)\rangle\} + K_G. \tag{2.xxxvii}$$

Here $\mathsf{C}_V = D\Phi_V(0)$ is the linear outer chart map. The lower bound for this matrix is proved by flux transfer and the geometric curl–gauge estimate. It does not follow merely from positivity of the mass-added coarse Schur matrix. Props. 3.201 and 5.41 prove the real physical gaps, and Prop. 5.42 constructs the local Gaussian families with their sector and normalization bounds on its declared unweighted canonical domain near a physical pair with small unweighted current. The weighted physical continuation has the sector proved in Prop. 3.202. That sector statement does not by itself supply independent weighted Gaussian cube families.

For the regular trajectory the old interaction is defined on a fixed raw field ball of radius r. It must be evaluated there throughout the integration. Let $R > r$ be the larger output radius. The literal intermediate field and the outer graph satisfy the two separate bounds

$$\|\log \mathsf{p}_j(W)\|_\infty \le C_pR/L < r/64, \qquad \|\log Z_V(\gamma B) - \log V\|_\infty \le C_{\mathrm{dom}}(L)|\gamma|b < r/64. \tag{2.xxxviii}$$

Thus an output argument on the larger ball is sent well inside the old ball before the fluctuation is added. The complete old functions are evaluated there. Gauge identities on admitted overlaps are used after that inclusion has been proved.

Here is a useful explicit order for these choices. First fix $0 < \alpha < 1$ and $p_{\mathrm{ell}} > 4/(1-\alpha)$ for the strong estimates. Fix the desired transport shrink t, final spatial and period rates, and a larger intrinsic rate. Choose the odd blocking integer L from eq. 4.cccxc; the literal amplitude constant in that choice is uniform in L. Choose the Gaussian and carrier localization parameters for those fixed rates. Choose R within the resulting common analytic radii and put $r = tR$. The constants $C_{\mathrm{dom}}(L)$ and the positive Gaussian margins are now fixed. Finally enlarge the coupling floor until eq. 2.xxxviii holds at the physical $\gamma = \theta^{-1/2}$ with $b = A_1(\log\theta)^{p_{\mathrm{cut}}}$, where $p_{\mathrm{cut}} > 1/2$. The last choice is possible since $\theta^{-1/2}(\log\theta)^{p_{\mathrm{cut}}}$ tends to zero. It changes no previous geometric parameter.

The finite exponent used in the elliptic estimates is a different parameter, fixed before the strong inverse constants and the blocking choice. The logarithmic exponent p_{cut} belongs to the real

fluctuation cutoff. Keeping these roles distinct prevents a false endpoint conclusion for the elliptic estimates.

2.5.5. *Formation, tuning and differentiated cutoffs.* For a fixed profile ceiling the formation bounds give

$$\|\mathbf{F}_j\| + \|D_h\mathbf{F}_j\| \le C_H\epsilon(\theta_j), \qquad \|\partial_x\mathbf{F}_j\| \le C_H\epsilon(\theta_j)/\theta_j, \qquad \epsilon(t) = (\log t)^m/t. \tag{2.xxxix}$$

The reference θ_j, its cutoff and the Gaussian coordinate scaling are frozen. Differentiation in $x = \theta_j\tau$ means $\theta_j^{-1}\partial_\tau$. The common-radius transport has an exact semigroup and exponential age decay. Its adapted norm gives a one-step contraction. These are the inputs for the opposite-end conditions $h_0 = 0$, $x_N = X$.

The scale sums needed for tuning have different sizes:

$$\sum_{j<N} \epsilon(a_j) \le C\{1 + (\log a_0)^{m+1}\}, \qquad \sum_{j<N} \frac{\epsilon(a_j)}{a_j} \le C(\log X)^m/X, \qquad a_j \asymp X + N - j. \tag{2.xl}$$

The first sum need not be small. It is a sublinear correction to the bare coupling. The second sum controls the contraction and can be made small independently of N. Prop. 5.51 uses these two sums separately. Props. 5.52 and 5.53 allow a bounded irrelevant initial profile and estimate its effect after retuning to the same endpoint.

Changing a plaquette weight is a different derivative. The moving weighted background changes the centre of the free colour balls. For its first weight derivative, Prop. 4.54 compares it with the fixed isotropic kernel on the same Haar-disintegrated fibre. The difference is a normalized rooted sphere functional with bound

$$C_H\theta^{1/2}(1+b)^K e^{-cb^2}. \tag{2.xli}$$

This is smaller than every fixed inverse power of θ. Its six curvature readouts vanish. It must nevertheless be included in the profile forcing before the diagonal stress recurrence is estimated. Prop. 5.54 uses this actual fixed-kernel first jet. It makes no claim about a uniform fixed-centre complex weight disc.

2.5.6. *The interface with the continuum statements.* The analytic constructions above give the specified inverses, physical homogeneous backgrounds, regular integration maps and tuned regular trajectories. Their identities retain their reference domains and the complete functions to which pointings were assigned. They provide concrete inputs to the multiscale source argument.

The main continuum statements also require the stated estimates for complementary histories, exterior changes, source normalizers and the short-distance comparison. The regular trajectory does not replace those operations by a bound for a single positive quadratic form. Nor does a classical or Gaussian descent identity identify quantum partition functions on different volumes. The hypotheses in Thms. A to C retain those specified model estimates. Each use below refers to the corresponding quantitative statement, with its original source and geometry class.

3. Background fields and constrained inverses

The renormalization step integrates fluctuations around a constrained background field. We construct the averaging maps and their coordinate charts, compare the flat and background-dependent quadratic forms, and state the uniform inverse estimates on the required current spaces. The nonlinear response estimates then control differentiation of the background and of its propagator. These are the inputs to the local integration in §4.

3.1. **Block averages and gauge fixing.**

3.1.1. *Block averages, gauge fixing, and the renormalisation group of this construction.* A block average must turn a fine gauge field into a coarse one while preserving gauge covariance and the coarse-lattice symmetries. The associated change of variables must preserve the integral and provide local fluctuation coordinates. We first specify the averaging map and its gauge choices, which are the geometric ingredients of the renormalisation step.

Setting and objects. *The numbers.* Each statement of this part bears a number belonging to one of three groups. The group 1a.1 concerns the block average of a gauge field; the group 1a.2 concerns the renormalisation transformation, namely its exact identities, its invariant form and the anatomy of a single step; the group 1a.3 concerns gauge fixing and regular configurations. A label "Theorem, Proposition, Lemma 1a.n.m" denotes statement m in group 1a.n, while "1a.n" standing alone denotes the group itself. *Requirements on an average.* We work in level-k units, with L odd and centred blocks $B(y) = \{x : |x - y|_\infty \le \frac{1}{2}(L-1)\}$. We put $\varpi(W) = \sup_p |\partial W(p) - \mathbf{1}|$, and ϖ_c denotes the same supremum taken over the double block $B(c_-) \cup B(c_+)$. For kernels we use the norms $\|K\|_{\mathrm{row}} = \sup_c \sum_b |K(c,b)|$ and $\|K\|_{\mathrm{col}} = \sup_b \sum_c |K(c,b)|$. Elements of the group cannot be added, and transports joining different pairs of points cannot even be compared. A block average $\mathcal{M} : \mathcal{V}_k \to \mathcal{V}_{k+1}$ is required to have the following properties: gauge covariance; locality; linearity at first order; analyticity near flat fields, on G^c as well; symmetry under the isometries of the coarse lattice; and Borel measurability on the whole of $\mathcal{V}_k$, because $\mathbf{T}$ integrates over all configurations. For the mean of group elements Bałaban gives axioms (109 (1987), (0.5)–(0.9)). Such a mean is any analytic G^c-valued function M on families of small diameter that satisfies

$$M(\{\mathbf{U}_j^{-1}\}) = M(\{\mathbf{U}_j\})^{-1},$$
$$M(\{u\mathbf{U}_j v\}) = u\, M(\{\mathbf{U}_j\})\, v,$$
$$M(\pi\{\mathbf{U}_j\}) = M(\{\mathbf{U}_j\}),$$

$$\tfrac{1}{i}\log M(\{e^{iA_j}\}) = \tfrac{1}{n}\sum_j A_j + (\text{higher orders}),$$
$$\mathbf{U}_j \in G \text{ for all } j \;\Rightarrow\; M(\{\mathbf{U}_j\}) \in G.$$

According to Bałaban, the results of his 1987 paper and of the earlier papers hold for every mean of this kind. For the map $\mathcal{M}$, the second of the two symmetric block averages that he introduces, he states that every result of the paper on averaging operations (Comm. Math. Phys. 98) holds, with proofs that are for the most part unchanged. This statement concerns that single paper; the broader sentence, which refers to "this, and previous papers", is the one about means. Of the two symmetric averages together he states that they are equally good, and that many other averages can also be used. He also states that the block average admits an axiomatisation as well. Already in 1985 he states that the analysis of the paper on averaging operations, together with its propositions, extends easily to other averages that satisfy the two requirements set out in its introduction, namely gauge covariance and agreement with the linear block average at first order. No proof accompanies any of these statements. For the theorems of 1984–85 on averaging, gauge fixing, propagators and backgrounds, the proofs are carried out for an average that is not symmetric. Prop. 3.12 states which properties of an average the proofs use, and it compares the linear parts (1a.1).

The mean, the contours, the map. The *mean* $\mathrm{av}(V_\bullet)$ (Federbush) is the solution, close to the family, of $\sum_i \log(V_i V^{-1}) = 0$. By $\mathcal{G}(y,x)$ we denote the family of shortest paths from y to $x \in B(y)$ that complete the displacement in one direction before passing to the next. There is one such path for each ordering of the directions, so the family has at most 4! members and does not contain every shortest path. The *comb* $\Gamma_{y,x}$ is the member with the order $4,3,2,1$. The averaged contour

variable is $U(y,x) := \mathrm{av}(U(\Gamma))_{\Gamma\in\mathcal{G}(y,x)}$, and we set $U(x,y) = U(y,x)^{-1}$ and $U(y,y) = \mathbf{1}$. With $x' = x + (c_+ - c_-)$, one defines

$$W_x = U(c_-,x)\,U([x,x'])\,U(x',c_+)\,U[c]^{-1},$$
$$\mathcal{M}(U)(c) = \exp\Big(L^{-4}\sum_{x\in B(c_-)}\log W_x\Big)U[c]$$
$$\text{on } \mathrm{Dom}(c) = \{\varpi_c < C^{-1}L^{-2}\}:$$

the W_x are closed transports based at c_- and lying near $\mathbf{1}$, so their logarithms can be added. Where $U(y,x) = \mathbf{1}$, only straight segments are left, so the form is adapted to the block axial gauge. Off $\mathrm{Dom}(c)$ the map is given by two cruder rules, both covariant. When none of the elements $Y_{x,\Gamma,\Gamma'} = U(\Gamma)U([x,x'])U(\Gamma')^{-1}U[c]^{-1}$ equals $-\mathbf{1}$, one replaces $\log W_x$ by the arithmetic mean, over (Γ,Γ'), of the intrinsic logarithms of the $Y_{x,\Gamma,\Gamma'}$; this is Bałaban's first symmetrised average. In the remaining case one sets $\mathcal{M}(U)(c) = U[c]$. This third rule is required because Bałaban defines his average on all configurations by means of the spectral logarithm, which satisfies $\log(-\mathbf{1}) = i\pi\mathbf{1} \notin i\mathfrak{g}$ and so leads out of SU(2) (1a.1). By $\mathcal{M}^k$ we mean the iterate only, and not a mean taken in a single stroke over B^k. In Bałaban's paper of 1987 the lattices consist of centres of cubes and have coordinates in $a_j(\mathbb{Z}+\frac12)$. The single translation $x \mapsto x+\frac12 L^m\sum_\mu e_\mu$ of T_ℓ, $\ell = 2L^m$, maps them onto the $\Lambda_{j,\ell}$ at every level simultaneously, since $\frac12 L^m = \frac12 L^{m+j}a_j$ and L^{m+j} is odd. This is the second place where the oddness of L is used, the first being the centring of the blocks (1a.1). Bałaban also remarks that all the results were obtained first for the two-dimensional chiral models, in which the fields sit on the sites and the action is $\sum_b[1-\frac12\,\mathrm{Re}\,\mathrm{tr}\,U(b_-)U(b_+)^{-1}]$. In those models block averages are means of group elements, and neither contours nor a gauge group enter.

Linear averages of bond functions a, which enter in the form $e^{i\mathsf{a}}W$ without any length factor, are defined as follows, where $\bar{\mathsf{a}}(y,x)$ denotes the arithmetic mean of $\mathsf{a}(\Gamma)$ over $\mathcal{G}(y,x)$:

$$(\mathsf{Q}^{\mathrm{s}}\mathsf{a})(c) = L^{-4}\sum_{x\in B(c_-)}\mathsf{a}([x,x']),$$
$$\sigma(y) = L^{-4}\sum_{x\in B(y)}\bar{\mathsf{a}}(y,x),$$
$$(\mathsf{Q}^{\mathrm{pl}}\mathsf{a})(c) = \sigma(c_-) + (\mathsf{Q}^{\mathrm{s}}\mathsf{a})(c) - \sigma(c_+),$$
$$(q\lambda)(y) = L^{-4}\sum_{x\in B(y)}\lambda(x);$$

here Q^{pl} is the derivative of $\mathcal{M}$ at $\mathbf{1}$. The operator $\mathsf{S}(W_0)$ is Q^{s} formed with parallel transport to c_-, namely

$$(\mathsf{S}(W_0)\mathsf{a})(c) = L^{-4}\sum_{x\in B(c_-)}\sum_{b\in[x,x']}\mathrm{Ad}\,(W_0(c_-,x)W_0([x,b_-]))\mathsf{a}(b)$$

.

The straightened average of $\mathbf{W} = e^{i\mathsf{a}}W_0$ relative to W_0 and its *block factor* u are given by

$$\mathsf{u}(y) = \exp\Big(L^{-4}\sum_{x\in B(y)}\log\,[\mathbf{W}(y,x)W_0(y,x)^{-1}]\Big),$$
$$e^{i\mathcal{Q}^1(W_0,\mathsf{a})(c)}\mathcal{M}(W_0)(c) = \mathsf{u}(c_-)^{-1}\mathcal{M}(\mathbf{W})(c)\,\mathsf{u}(c_+).$$

The right-hand side equals $\mathcal{M}(\mathbf{W}^v)$, where v is the gauge transformation with $\mathbf{W}^v(y,x) = W_0(y,x)$ (the block axial gauge relative to W_0) and with trivial average $\bar{R}_{W_0} v = \mathbf{1}$; here $\bar{R}_W$ is the averaging of gauge transformations that is defined below under *Gauge transformations*. Together these two conditions imply $v = \mathsf{u}^{-1}$ at the coarse sites. Bałaban gives two reasons for the straightening. First, the variational problems of § 3.11 involve composing the average with the passage from the axial gauge to the Landau gauge. Second, only the straight linear average admits the explicit representations of the propagators § 3.12.1; this average is compatible with composition, has an explicit Fourier symbol and does not change under $q\lambda = 0$. The change of gauge has to preserve this form, and the non-linear counterpart of $q\lambda = 0$ is $\bar{R}_{W_0} v = \mathbf{1}$. A third reason appears in the proof of Prop. 3.6.

Order k; the maps denoted by Q. Along the sequence $W_{0,n} = \mathcal{M}^n U_0$ we set $\mathsf{a}_0 = \eta_k A$, $\mathsf{a}_{n+1} = \mathcal{Q}^1(W_{0,n}, \mathsf{a}_n)$, $v_0 = \mathbf{1}$, $v_{n+1} = v_n\, \mathsf{u}(W_{0,n}, \mathsf{a}_n)$, and define

$$\mathcal{Q}_k^\sharp(U_0; A) := \mathsf{a}_k = Q_k^\sharp(U_0) A + C_k(U_0, A),$$

$$\mathcal{Q}_k(U_0; A) = \tfrac{1}{i} \log \left[\mathcal{M}^k(e^{i\eta_k A} U_0) \mathcal{M}^k(U_0)^{-1}\right] = Q_k(U_0) A + C_k^{\mathrm{pl}}(U_0, A).$$

A sharp indicates the straightened objects, which are the ones that enter the propagators; Bałaban's $Q_k(U_0, \eta A)$ is the same object built with combs. Without the sharp, $\mathcal{Q}_k$ and Q_k refer to the plain average, whose remainder is denoted C_k^{pl}, while C_k denotes the remainder of the straightened average. The product $v_k = v_k[A]$ of the k block factors is the *node factor*, and $\dot{v}_k$ denotes the linear part of $\frac{1}{i} \log v_k$. The letter Q is used for maps of four kinds (1a.1). (1) The non-linear constraint map $\mathcal{Q}_k$ of the plain iterate $\mathcal{M}^k$, and next to it its straightened form $\mathcal{Q}_k^\sharp$. (2) $Q_k(U) = \partial_A \mathcal{Q}_k(U; A)|_{A=0}$, together with $Q = Q_1(\mathbf{1})$ and $Q_V = Q_1(V)$; this is the operator in the delta function of a step. (3) $Q_k^\sharp(U)$, the operator that enters the propagators and the Landau gauge. Its leading term is the *straight* average with parallel transport, $Q_k^{\mathrm{st}}(U) = \eta_k \mathsf{S}(W_{0,k-1}) \cdots \mathsf{S}(W_{0,0})$. The two differ by $O(\alpha_0)$ in row norm, and they are equal at $U = \mathbf{1}$. There, after the translation of Prop. 3.12, each of them is Bałaban's Q_k of 1984. (4) $Q'_k(U)$, which averages site functions. In a background, the linear average in Bałaban's papers (99 (1985) 389, (3.15)) is $Q_j^{\mathrm{B}}(U) := Q(\bar{U}^{j-1}) \cdots Q(\bar{U}) Q(U)$. It is the linear part of his gauge-corrected average built with combs, and each of its factors equals the straight covariant average up to $O(L^2 \alpha_0)$. Props. 3.6 and 3.12 provide two comparisons, that of (2) with (3) and that of Q_k^{B} with $Q_k^\sharp$, and § 3.12.1 relies on both.

Gauge transformations are averaged by means of the same contours,

$$(\bar{R}_W v)(y) = v(y) \exp\Big(L^{-4} \sum_{x \in B(y)} \log\left[v(y)^{-1} \operatorname{Ad}(W(y,x)) v(x)\right]\Big),$$

and the iterates of this map give $\bar{R}_U^{(j)}$. The linear part, $Q'_j(U)\lambda$, is the mean over $B^j(y)$ of λ after transport to y.

Isometries on 1-forms. An isometry r acts by $(\mathsf{r}U)(b) = U(\mathsf{r}^{-1} b)$. Bond functions are specified on the positively oriented bonds, whereas a reflection reverses orientation. Since $(e^{i\mathsf{a}} W_0)(\bar{b}) = \exp\big(-i \operatorname{Ad}(W_0(b)^{-1}) \mathsf{a}(b)\big) W_0(\bar{b})$, the action relative to W_0 must include a twist:

$$(\mathsf{r}_{W_0} \mathsf{a})(b') = \mathsf{a}(b) \ \text{ if } \mathsf{r}^{-1} b' = b,$$

$$(\mathsf{r}_{W_0} \mathsf{a})(b') = -\operatorname{Ad}\left(W_0(b)^{-1}\right) \mathsf{a}(b) \ \text{ if } \mathsf{r}^{-1} b' = \bar{b};$$

on pairs the action is $\mathsf{r}(\mathbf{U}, \mathbf{J}) = (\mathsf{r}\mathbf{U}, \mathsf{r}_{\mathbf{U}} \mathbf{J})$ (1a.1).

Lift, regions, determining sets. The *lift* is defined by $(Q_k^{*} V)(b) = V(c)$ when $b_\pm \in B^k(c_\pm)$; on every bond contained in a single block of order k its value is $\mathbf{1}$. For a bond function B on $\mathbb{T}^{(k)}$,

its linear lift is the 1-form that takes the value $\eta_k^{-1}B(c)$ on these crossing bonds and the value 0 on bonds lying within a block. The value $\mathcal{M}^q(W)(c)$, and also which rule applies, depend on W only in $B^q(c_-)\cup B^q(c_+)$. Averages are therefore defined for a field given on part of a lattice; they remain covariant and obey the semigroup law $\mathcal{M}^{q+1}W(c')=\mathcal{M}(\mathcal{M}^qW)(c')$. Understood in this way, $M_{\mathbf{B}}(U):=(\mathcal{M}^jU|_{\Gamma_j})_j$ is defined on configurations given on a region, and the problems that define the localised backgrounds $U_{k,\square}$ are set up near a cube without reference to the torus (1a.1).

The transformation. Here δ denotes the Dirac distribution at $\mathbf{1}\in G$ with respect to Haar measure. It is a class function, and it is the limit $\mathfrak{a}\to\infty$ of the normalised weights $\propto e^{-\mathfrak{a}(1-\frac{1}{2}\operatorname{Re}\operatorname{tr}W)}$. The transformation sends a complex Borel measure ν to its image $\mathbf{T}\nu=\mathcal{M}_*\nu$, which is written with the kernel $\delta(\mathcal{M}(U)V^{-1})$. Thus a coarse configuration receives the total weight of the fine configurations whose average it is. Wilson and Kadanoff introduced the block-spin transformations $(\mathbf{T}_t\rho)(V)=\int dU\,t(V,U)\rho(U)$, with $t\ge0$, $\int dV\,t(V,U)=1$ and $t(V^{u|\mathrm{coarse}},U^u)=t(V,U)$; the transformation here is the member of this family with a hard constraint. Decompositions of unity and the factor $\mathfrak{G}_k$ are inserted into the integral. They are built with the auxiliary choices $\varepsilon_k,\delta_k,\alpha_{i,k},\check{R}_k$ and with the weight of $\mathfrak{G}_k$. All of these depend on a single number $\mathtt{t}$, which is x_k in the run and θ_k in a reference run. Only $\check{R}_k$ is formed with the minimum of these numbers taken over all levels $i\le k$, which makes it non-increasing in k. A history h records outcomes, and these yield the term τ_h, or the term $\tau_h^{\mathfrak{w}}$ when ρ_0 is multiplied by a bounded complex weight $\mathfrak{w}(U)$. In addition to χ_k and $\chi^{(k)}$ there is the approximate fluctuation test $\chi'_k(\square)=\mathbf{1}\{|V_k(V_{k,\square}^{\mathrm{bg}})^{-1}-\mathbf{1}|<2\delta_k \text{ near } \square\}$, which is built with the local averaged background $V_{k,\square}^{\mathrm{bg}}=\mathcal{M}^kU_{k+1,\square}$. Braces denote a difference between backgrounds: $\{F\}:=F(U_k(V_k))-F(U_{k+1})$.

The block algebra. The block field of depth s, $V^{(s)}:=\mathcal{M}^{K-s}U$, is defined on $\Lambda_{s,\ell}$, a lattice that does not depend on the cutoff $K\ge s$. The *block algebra* $\mathfrak{A}$ is the set of gauge-invariant functions F, bounded and continuous, that depend on only finitely many block variables $V^{(s)}(b)$. The composite $F\circ\mathcal{M}^{K-s}$ is defined for every $K\ge s$, so these observables exist at all cutoffs simultaneously (1a.2). The block algebra is a notion separate from Thms. A and B, whose observables are the smeared curvature evaluated at the bare scale; neither theorem refers to $\mathfrak{A}$.

Two operations (1a.2). Let $\Delta=\mathsf{C}^{\mathsf{T}}\Delta^{(k)}\mathsf{C}$, let $z^{(k)}$ be a product of Jacobians, and let $\chi(S_{k+1})$ denote the tests on $\Omega_{k+1}\setminus\Lambda_{k+1}$. To obtain $\zeta(\Omega_{k+1}^c)$, form for each outcome that determines this same Ω_{k+1} the product of the tests and gauge-fixing factors localised in $\Omega_k\setminus\Omega_{k+1}$, and add these products over all such outcomes. The one-step operation collects everything that step $k+1$ does not carry out:

$$\mathbf{T}^{(k)}(Z_{k+1})F=\int dV_k|_{\Omega_{k+1}^c}\,\delta(\mathcal{M}(V_k)V_{k+1}^{-1})\,\zeta(\Omega_{k+1}^c)\;z^{(k)}\int d\mathcal{A}_k^{\mathrm{s}}|_{\Omega_{k+1}\setminus\Lambda_{k+1}}\chi(S_{k+1})\,e^{-\frac{1}{2}\langle\mathcal{A}_k^{\mathrm{s}},[\Delta-\Delta C^{(k)}(\Lambda_{k+1})\Delta]\mathcal{A}_k^{\mathrm{s}}\rangle}F,$$

where, more precisely, the Gaussian exponent of the operation is a part of this quadratic form, namely a part that couples no two components of $\Omega_{k+1}\setminus\Lambda_{k+1}$; the remainder of the form is assigned to the boundary terms $B^{(k+1)}$ §4.17.1.3. As long as $\mathbf{R}$ does not intervene, $\mathbf{T}'_{k+1}=\mathbf{T}^{(k)}(Z_{k+1})\mathbf{T}'_k$. For $x\in\mathbb{C}$ and a function S of the bare fields, we define the pure small-field integral and then the regular part of step $k+1$ by

$$(\mathbf{T}_k^{\mathrm{sf}}[\mathtt{t}]F)(W)=\int dV\,\delta(\mathcal{M}(V)W^{-1})\,\mathfrak{G}_k(V)\,\chi^{(k)}(T_\ell)\,F(V),$$

$$\mathfrak{E}_{k+1}[\mathtt{t};x;S](W)=\log\big(\mathbf{T}_k^{\mathrm{sf}}[\mathtt{t}]\,e^{-xA(U_k(\cdot))+S(U_k(\cdot))}\big)(W)+xA(U_{k+1}(W))-S(U_{k+1}(W)).$$

Regular configurations. We consider sequences $\Omega_0\supset\cdots\supset\Omega_k$, with $\Omega_{k+1}=\emptyset$, in which each Ω_j is a union of M_1-cubes of level j and $\operatorname{dist}(\Omega_j^c,\Omega_{j+1})\ge CM_1L^j\eta_k$. The small-field case is the constant sequence $\Omega_j=T_\ell$. Layer j is the set $\Omega_j\setminus\Omega_{j+1}$. It has the local scale $\xi_j=L^j\eta_k$ and the

tops $\mathbb{Y}_j = \Lambda_j(\mathbf{B})$, which are its sites in $\mathbb{T}^{(j)}$. Its pillars are the $B^j(y)$, $y \in \mathbb{Y}_j$, and over all $j \le k$ the pillars partition the bare sites of Ω_0. We define

$$\mathfrak{U}_k(\Omega_\bullet, \alpha) = \{U : |\partial U - \mathbf{1}| < \alpha\, \eta_k^2 \xi_j^{-2},\ |J(U)| < \alpha\, \xi_j^{-3} \text{ on layer } j\},$$
$$|f|_{(-s)} = \sup_j \sup_{\text{layer } j} \xi_j^s |f|,$$

together with

$$\|A\|_1 = \max\{|A|_{(-1)}, |\nabla_{U_0} A|_{(-2)}\}$$

and

$$\|\lambda\|_0 = \max\{\sup|\lambda|, |D_{U_0}\lambda|_{(-1)}\}$$

. Both conditions are invariant under gauge transformations. Combined with the Bianchi identity, the second condition is an elliptic system for the field strength F_U, and all bounds on derivatives come from this system; minimisers satisfy the second condition. The complex neighbourhood of radius α_1 is the set of $\mathbf{U} = e^{i\eta_k A'} U$ with U real and regular and $\|A'\|_1 < \alpha_1$. The norm $\|A'\|_1$ controls only first differences, whereas the current of $\mathbf{U}$ is a second difference. Thus the current enters the domains $U_j^c(X, \alpha_0, \alpha_1)$ as an independent variable $\mathbf{J}$ with $|\mathbf{J}| < \alpha_0$. The real centre U is required to have small curvature and small local potentials, but not a small current. The backgrounds of the averages of $\mathbf{U}$ are required to satisfy what the condition on the current provided, and U_j^c is the set of all such pairs. This set is not saturated with respect to the G^c-valued u, which act by

$$(\mathbf{U}, \mathbf{J}) \to (\mathbf{U}^u, \mathrm{Ad}(u)\mathbf{J})$$

. The extent to which a term is invariant under these transformations is given in Prop. 3.28 and in § 4.5.

Gauges. Because G is compact, the gauge is not fixed in order to obtain finiteness. The reason for fixing it is that the integrand of $\mathbf{T}$ does not change under the block group $\mathcal{G}_{\mathrm{bl}} = \{u : u = \mathbf{1} \text{ on } \mathbb{T}^{(k+1)}\}$. Consequently, in each block there are $3(L^4 - 1)$ directions $D_V\lambda$ along which the Hessian at the minimum vanishes, and there is then no Gaussian measure, no covariance and no decay. Similarly, the residual group $\mathcal{G}^{\mathrm{res}}$ leaves the constraints $\mathcal{M}^j U = V_j$ on Γ_j unchanged. This group consists of the bare u that equal $\mathbf{1}$ at the *nodes*, which are the end points of the bonds of $\mathbf{B}[\Omega_\bullet]$. Hence a background is an orbit and not a point. No gauge has all of the following properties at once: locality (on a torus, no global gauge turns small curvature into a small potential), compatibility with the averages, covariance under the remaining gauge group, symmetry under the hypercubic group W_4, and regularity uniform in k. Axial gauges are algebraic and strictly local and have Jacobian one; they appear in the integrals and serve to select representatives. *Box axial:* the condition $V = \mathbf{1}$ on the tree of combs that issues from the base point y_P of a box. *Block axial:* the condition $V(y, x) = \mathbf{1}$ on the averaged contour variables. It is imposed softly on a set P'' of blocks, at those pairs (y, x) for which the mean $V(y, x)$ is defined (no factor is inserted at the other pairs), by means of

$$\mathfrak{G}_k(V; P'') = \prod_{y \in P''} \prod_{x \in B(y) \setminus y} z_{\mathfrak{G}}^{-1}\, \mathbf{1}\{|V(y,x) - \mathbf{1}| < \varepsilon_k\}\, e^{-x_k(1 - \frac{1}{2}\operatorname{Re}\operatorname{tr} V(y,x))},$$
$$\mathrm{GF}_k(V) = \sum_{y,x} [1 - \tfrac{1}{2}\operatorname{Re}\operatorname{tr} V(y,x)] \ge 0.$$

Tower axial relative to U_0, written $\mathrm{Ax}(\Omega_\bullet, U_0)$: in every pillar and at every level $n < j$, the contour variables of $\mathcal{M}^n U$ coincide with those of $\mathcal{M}^n U_0$. When the tops are the only nodes, solving this condition from the top down selects one representative in each orbit of $\mathcal{G}^{\mathrm{res}}$. An example, for $U_0 = \mathbf{1}$, is the representative of the orbit $U_k(\mathbf{V})$ of the regular critical configurations of § 3.11. Suppose that an inward bond of layer $j-1$, that is, a bond of $\mathbb{T}^{(j-1)}$ joining a point of layer $j-1$ to a point of Ω_j, is retained as an additional constraint (see § 3.11, *Inward bonds*; by the Notation, §4, the determining set contains no such bond). Its end point then lies inside a pillar of layer j. That end point is a node but not a top, and it is called a *junction node*; in § 3.11 it is the seam node. The transport from the top to a junction node is invariant under $\mathcal{G}^{\mathrm{res}}$, so the condition cannot be achieved there. Leaving out these conditions gives the gauge $\mathrm{Ax}^\circ(\Omega_\bullet, U_0)$, which meets in exactly one point every orbit where the contour variables are defined. Representatives are covariant. Given a gauge transformation v on the nodes, its lift is the bare transformation $\tilde{v}$ whose value at a bare site is the value of v at the first node reached when one ascends from that site through the centres of its blocks. The map $W \mapsto W^{\tilde{v}}$ then sends the constraint set of $\mathbf{V}$ onto the constraint set of $\mathbf{V}^v$; it also sends orbits to orbits and maps $\mathrm{Ax}^\circ(\Omega_\bullet, \mathbf{1})$ onto itself. Hence, for the representative taken at the reference $U_0 = \mathbf{1}$, $U_k(\mathbf{V}^v) = U_k(\mathbf{V})^{\tilde{v}}$. For nests of boxes whose lattices are of different levels §4.17.1.3, the tree consists of shell trees, connected by one entrance bond in each box. Trees depend on the choice of a frame in W_4, and averaging over the $2^4\,4!$ frames restores the symmetry (1a.3).

The estimates are carried out in the elliptic Landau gauge, and this gauge comes with a determinant. We put $Q^\sharp = (Q_j^\sharp|_{\Gamma_j})_j$, with each component normalised to total weight $1 + O(\alpha_0)$, so that $\mathcal{Q}_j^\sharp(U_0; A) = \xi_j Q_j^\sharp A + C_j(A)$. Further, $Q' = (Q'_j|_{\mathbb{Y}_j})_j$, and its null space is denoted $N(Q')$. On layer j we set $\xi = \xi_j$ and $a = \xi_j^{-2}$. We also put $G' = (\Delta_{U_0} + Q'^* a Q')^{-1}$, and R is the orthogonal projection onto $\Delta_{U_0} N(Q')$. Relative to U_0, a *Landau pair* (A, u) of U is a pair satisfying

$$U^{u^{-1}} = e^{i\eta_k A} U_0,$$

$$R\, D^*_{U_0} A = 0,$$

$$\bar{R}^{(j)}_{U_0} u = \mathbf{1} \ \text{ on } \mathbb{Y}_j,$$

in which conditions on averages take the place of the condition $u = \mathbf{1}$ at the nodes, since that condition cannot be handled analytically. This has a cost. Transformations u of this kind do not form a group: $\bar{R}u_1 = \bar{R}u_2 = \mathbf{1}$ does not imply $\bar{R}(u_1 u_2) = \mathbf{1}$. The word "orbit" therefore has no meaning, and the set that such transformations generate depends on its base point. For this reason the operations come in a fixed order. First, the tower axial gauge Ax° selects a base point in each orbit of $\mathcal{G}^{\mathrm{res}}$. Next, the set is generated from that base point. Finally, the set is intersected with the slice. The average that belongs to this gauge is the *reduced average*

$$\mathcal{M}_{\mathrm{red}}(W; U_0) = \mathcal{M}(W)^{\mathsf{n}_W^{-1}} \mathcal{M}(U_0)^{-1} = e^{i\mathcal{Q}^1(U_0, \mathsf{a})}$$

; here n_W stands for the block factor $\mathsf{u}(U_0, \mathsf{a})$ taken at $W = e^{i\mathsf{a}} U_0$. The reduced average is the straightened average, under the name it bears in the theory of gauges. The contour variable is required to be the same in all four objects $\mathcal{M}$, n_W, $\bar{R}$ and Ax: it must be the mean in each of them, or the comb in each of them.

Statements.

Lemma 3.1 (the mean)**.** Consider families $V_\bullet = (V_1, \dots, V_n)$ in G^c of small diameter $\operatorname{diam} V_\bullet := \max_{i,i'} |V_i V_{i'}^{-1} - \mathbf{1}|$, where the radii do not depend on n. For such families the mean near the family is unique. It is holomorphic, with bounds independent of n (by the contraction principle), and it is symmetric. On families in G it takes values in G, and there it is the only mean lying in G. Here

a mean of $V_\bullet$ is an element V with $\max_i |V_i V^{-1} - \mathbf{1}| < 1$ and $\sum_i \log(V_i V^{-1}) = 0$; the logarithm is the series logarithm, which has a meaning because of the first condition. Next, $\mathrm{av}(TV_\bullet T') = T\,\mathrm{av}(V_\bullet)T'$ holds for $T, T' \in G$. It also holds for $T \in G^c$ as long as $\mathrm{cn}(T)\,\mathrm{diam}\, V_\bullet$ remains below the radius, where $\mathrm{cn}(T) := |T|\,|T^{-1}|$ is the condition number. The identity $\mathrm{av}(V_\bullet^{-1}) = \mathrm{av}(V_\bullet)^{-1}$ holds in G. It holds in G^c when $\mathrm{diam}\, V_\bullet$ is below half the radius and $\mathrm{cn}(V_i) \le 2$ for all i. Finally, $\frac{1}{i}\log \mathrm{av}(e^{iA_\bullet}) = \frac{1}{n}\sum_j A_j + O(\max_j |A_j|^2)$. ■

Lemma 3.2 (small curvature: nearby transports, comb gauge)**.** Consider a box that contains at most s sites along each direction and has plaquette size ϖ. Suppose the m steps of a path are rearranged so that the rearranged paths stay inside the box. Then the transport along the path changes by at most $(1+\varpi)^{m(m-1)/2} - 1$. Moreover, with $h(x) = W(\Gamma_{y,x})$,

$$|W^h(b) - \mathbf{1}| \le |b_- - y|_1\, \varpi,$$
$$W^h = e^{i\mathsf{a}^0},$$
$$|\mathsf{a}^0| \le Cs\varpi.$$

Consequently the contour families on $\mathrm{Dom}(c)$ are of diameter $\le CL^2\varpi_c$, and one has $\mathcal{M}(W)(c) = e^{iY} W[c]$ where $|Y| \le CL^2\varpi_c$. ■

Proposition 3.3 (the averaging map)**.** Let U, u be arbitrary, and let r be any isometry that preserves $\mathbb{T}^{(k+1)}$ (translations, W_4, coordinate and diagonal reflections). Then

$$\mathcal{M}(U^u) = \mathcal{M}(U)^{u|_{\mathrm{coarse}}},$$
$$\mathcal{M}(\mathsf{r}U) = \mathsf{r}\,\mathcal{M}(U);$$

and $\mathcal{M}^n(U)(c)$ depends on U only in $B^n(c_-) \cup B^n(c_+)$. The averaging map has four further properties.

- It is Borel. Each of the three rules applies on a Borel set, and $\mathcal{M}$ is continuous on each of these sets but not across their boundaries. Outside $\mathrm{Dom}(c)$ no further regularity is required.
- It is holomorphic at $e^{i\mathsf{a}}W_0$ for $\varpi_c(W_0), |\mathsf{a}| < c_L$.
- It is onto: $\mathcal{M}^k(Q_k^{s*}V) = V$.
- On small fields of one colour it is linear: $\mathcal{M}(e^{ifT}) = e^{i(\mathsf{Q}^{\mathrm{pl}}f)T}$ whenever $T \in \mathfrak{g}$, $|T| = 1$, and f is real with $\sup|f| < c_L$.

For a G^c-valued g, covariance is obtained at the expense of room in the domain, and the amount of room lost is $\mathrm{cn}(g)$. Precisely, consider the graded domains $\mathrm{Dom}^c_\theta(c)$, $0 < \theta \le 1$, on which the contour families and the W_x lie within θ times the radii. If $\mathrm{cn}(g(c_\pm)) \le \varkappa$ and $\varkappa\theta \le 1$, then $\mathbf{W}^g \in \mathrm{Dom}^c_{\varkappa\theta}(c)$ and

$$\mathcal{M}(\mathbf{W}^g)(c) = g(c_-)\,\mathcal{M}(\mathbf{W})(c)\,g(c_+)^{-1}.$$ ■

Proposition 3.4 (one averaging multiplies curvature by L^2)**.**

$$|\partial\mathcal{M}(W)(p') - \mathbf{1}| \le L^2\varpi + C(L^2\varpi)^2;$$
$$|\partial U - \mathbf{1}| \le \alpha_0\eta_k^2,\ \alpha_0 \le c$$
$$\Rightarrow$$
$$\varpi(\mathcal{M}^n U) \le 2\alpha_0(L^n\eta_k)^2$$
$$(n \le k),$$

and $\mathcal{M}^n U(c)$ differs from the straight bare transport by at most $C\alpha_0(L^n\eta_k)^2$. Consequently the first rule is applicable on every level, and on $\{|\partial U - \mathbf{1}| < c\,\eta_k^2\}$ the map $\mathcal{M}^k$ is real-analytic. ∎

Proposition 3.5 (one step relative to a reference)**.** Let $\varpi = \varpi(W_0) \le c_L$, and consider complex $|\mathsf{a}| < c_L$. Then $\mathcal{Q}^1$ and $\frac{1}{i}\log \mathsf{u}$ depend holomorphically on a, are covariant and do not exceed $C|\mathsf{a}|$ in size; moreover

$$\mathcal{Q}^1(W_0, \mathsf{a}) = \mathsf{Q}(W_0)\mathsf{a} + C^1(W_0, \mathsf{a}),$$
$$\mathsf{Q}(\mathbf{1}) = \mathsf{Q}^{\mathrm{s}},$$
$$\|\mathsf{Q}(W_0) - \mathsf{S}(W_0)\|_{\mathrm{row,\,col}} \le C\varpi,$$

$$\|\mathsf{S}(W_0)\|_{\mathrm{row}} \le L,$$
$$\|\mathsf{S}(W_0)\|_{\mathrm{col}} \le L^{-3},$$
$$|C^1| \le C|\mathsf{a}|^2.$$ ∎

Proposition 3.6 (k steps, uniformly in k)**.** Assume $|\partial U_0 - \mathbf{1}| \le \alpha_0\eta_k^2$ with $\alpha_0 \le c$, and let A be complex with $\sup|A| < c$. Here c, C depend only on L. The following hold holomorphically in A and in the complex shifts $\mathbf{U} = e^{i\eta_k A'}U_0$ of U_0 with $\sup|A'| < \alpha_1 \le c$. The bounds are uniform in A'; in the bounds on the row norm and on the functional derivative, $\alpha_0 + \alpha_1$ then replaces α_0.

$$\mathcal{M}^n(e^{i\eta_k A}U_0) = \big(e^{i\mathsf{a}_n}\mathcal{M}^n U_0\big)^{v_n},$$
$$|\mathsf{a}_n| \le 2L^n\eta_k \sup|A|,$$
$$|v_n - \mathbf{1}| \le CL^n\eta_k \sup|A|,$$

$$Q_k^\sharp(U_0) = \eta_k\,\mathsf{Q}(W_{0,k-1})\cdots\mathsf{Q}(W_{0,0}),$$
$$\|Q_k^\sharp(U_0)\|_{\mathrm{row}} \le 1 + C\alpha_0,$$
$$|C_k| \le C\sup|A|^2,$$

$$Q_k(U_0)A = Q_k^\sharp(U_0)A - D_{\mathcal{M}^k U_0}\dot{v}_k(A),$$
$$|Q_k A| \le C\sup|A|,$$
$$|C_k^{\mathrm{pl}}| \le C\sup|A|^2 :$$

thus a coarse gradient separates the two linear parts, and this gradient does not become small as the curvature does. More generally, let h be G^c-valued with $\mathrm{cn}(h)\,\mathrm{cn}(v_n) \le 2$. Then $(e^{i\eta_k A}U_0)^h$ has well-defined averages, and $\mathcal{M}^n\big((e^{i\eta_k A}U_0)^h\big) = \big(e^{i\mathsf{a}_n}\mathcal{M}^n U_0\big)^{hv_n}$. This ball is much larger than the regular class, because the plaquettes of $e^{i\eta_k A}U_0$ are $O(\eta_k)$ rather than $O(\eta_k^2)$. Accordingly, the validity of the first rule on every level and the analyticity are consequences of the factorisation, not of Prop. 3.4. The remainder decomposes as $C_k = C_k^{(2)} + C_k^{(3)} + \cdots$, where

$$C_k^{(2)}(U_0, A) = \sum_{n<k} \mathsf{Q}(W_{0,k-1})\cdots\mathsf{Q}(W_{0,n+1})\,C^{1,(2)}(W_{0,n}, \mathsf{a}_n^{\mathrm{lin}}),$$

$$|n\text{-th term}| \le CL^{n-k} \sup |A|^2 :$$

the non-linearity consists of commutators and is concentrated at the coarsest of the k scales. The derivative $K_A(c,b) := \partial \mathcal{Q}_k^\sharp(c)/\partial A(b)$ satisfies $\|K_A\|_{\mathrm{col}} \le 2\eta_k^4$ and the Lipschitz bound $\|K_A - K_{A'}\|_{\mathrm{col}} \le C\eta_k^4 \sup|A - A'|$. Consequently $1 + C\alpha_0 + C|A|$ is a bound for the functional derivative $\eta_k^{-4} K_A$, the adjoint K_A^* is a bounded operator for the sup norm, and K_A acts boundedly from L^2 to ℓ^2. The Lagrange equations of § 3.11 involve K_A^*. Complex regular fields $\mathbf{U} = e^{i\eta_k A'} U_0$ with $\sup|A'| < \alpha_1 \le c$ have averages that are regular, each on its own scale:

$$|\partial \mathbf{U} - \mathbf{1}| \le \alpha_0' \eta_k^2, \quad \alpha_0' \le c$$

$$\implies \quad |\partial \mathcal{M}^n \mathbf{U} - \mathbf{1}| \le 2\alpha_0' (L^n \eta_k)^2.$$

Here the complex curvature bound is proved directly. Fix a level-n plaquette p_n and let Y be the union of the four complete backward blocks of its corners, with all bonds and plaquettes whose vertices lie there. If this read wraps, lift its literal averaging formulas to a periodic cover on which the read embeds. Put $\ell = L^n$, $t = \ell\eta_k$ and $r = \alpha_0' t^2$. The case $n = 0$ is the hypothesis. For $n \ge 1$, use the coordinate comb in this box. Its paths have at most $C\ell$ bare links. The real factors are unitary, and each complex increment and its inverse have norm at most $e^{\eta_k \alpha_1}$. The resulting gauge g therefore satisfies

$$\sup_x \mathrm{cn}(g(x)) \le K := e^{C\alpha_1 t}.$$

The strip between neighboring combs contains at most $C\ell$ plaquettes. Their conjugating paths have the same bound on their condition numbers. The product and logarithm estimates give

$$\mathbf{U}^g = e^{ia}, \qquad \|a\|_\infty \le C\ell\alpha_0' \eta_k^2 = Cr/\ell.$$

All constants here depend only on L; the fixed ceiling is decreased so that the products stay in their logarithm charts.

Extend a by zero outside Y only to use the flat supremum-ball Taylor estimate; its supremum does not increase, and the four output rows do not change. No curvature bound across this new boundary is asserted. Let $P_n(a) = i^{-1} \log \mathcal{M}^n(e^{ia})$ and let L_n be its linear part at zero. The flat recursion eq. 3.mccliii and its node factors give the uniform holomorphic ball of Lem. 5.26. Cauchy on a fixed larger ball therefore gives

$$\|P_n(a)\|_\infty \le Cr, \qquad \|P_n(a) - L_n a\|_\infty \le Cr^2.$$

Indeed its normalized input is ℓa, of size at most Cr, on a fixed larger ball. Let d_0 and d_n denote oriented sums around fine and level-n plaquettes, respectively. In the one-step linear formula the two contour terms at each corner cancel. Its curl is the average of the sums over the L^2 fine plaquettes filling the corresponding square. Iterating this exact identity gives a plaquette average with nonnegative weights and total weight ℓ^2. For the selected plaquette every fine plaquette in this identity lies in Y, so

$$|(\mathrm{d}_n L_n a)(p_n)| \le \ell^2 \sup_{p \subset Y} |(\mathrm{d}_0 a)(p)|.$$

On precisely this stock the finite plaquette product gives $\sup_{p\subset Y} |(\mathrm{d}_0 a)(p)| \le K\alpha_0' \eta_k^2 + C\|a\|_\infty^2$. Apply the same product estimate to the four coarse logarithms. Complex covariance then conjugates the result back by the gauge at the base point. This covariance is valid throughout the retained chart. The flat raw-angle recursion bounds the intermediate plain logarithms by CrL^{s-n}, so every one-step contour family has a fixed reserve. Conjugation by g or g^{-1} spends at most K of that reserve, and K is as close to one as required by decreasing c. This admission uses the flat recursion, independently of the complex curvature estimate being proved. Consequently

$$|\partial \mathcal{M}^n \mathbf{U} - 1| \le K^2 r + Cr^2 \le r(1 + C\alpha_1 t + Cr) \le 2r.$$

The choice is uniform because $0 < t \le 1$. The formulas commute with pullback, so the same bound descends from the cover. From $|\nabla_{U_0} A'| < \alpha_1$ one obtains only $\alpha_0' = \alpha_0 + C\alpha_1$. Thus the domains U_j^c require, as a separate condition, that the complex plaquettes be small; the estimate just proved preserves their prescribed curvature scale.

All of this holds on determining sets, layer by layer. At the bare bonds of layer j the local scale is $\xi(b) = \xi_j = L^j \eta_k$; it is the local scale of layer j in the sense of "Regular configurations". On determining sets the ceilings on α_0 and on $\sup_b \xi(b)|A(b)|$ are lowered by the factors L^{-2} and L^{-1}. At a bond of Γ_j that lies astride a seam, one factor is lost. Writing $K_A(c,b) = \partial \mathsf{a}_j(c)/\partial A(b)$ for $c \in \Gamma_j$, one has

$$|\partial \mathcal{M}^j U_0 - \mathbf{1}| \le 2L^2 \alpha_0,$$

$$|\mathsf{a}_j| \le 2L \sup_b \xi(b)|A(b)|,$$

$$\sup_c \sum_b \frac{|K_0(c,b)|}{\xi(b)} \le 2L,$$

$$\sum_j \sum_{c \in \Gamma_j} |K_A(c,b)| \le \frac{C\eta_k^4}{\xi(b)^3},$$

and this factor is lost once, without compounding; it cannot be removed (Prop. 3.13). The last bound is a sum over the levels at which a given bare bond enters. ∎

Proposition 3.7 (linear averages; gauge transformations)**.** The operator

$$Q_k^{\mathrm{st}} := Q_k^{\mathrm{st}}(\mathbf{1}) = Q_k^{\sharp}(\mathbf{1}) = \eta_k (\mathsf{Q}^{\mathrm{s}})^k$$

is the straight average taken over the blocks of order k, and

$$(Q_k^{\mathrm{st}} A)(c) = \eta_k^5 \sum_{x \in B^k(c_-)} A([x, x']),$$

$$u_k(p) = \prod_\mu \frac{\eta_k (e^{ip_\mu} - 1)}{e^{i\eta_k p_\mu} - 1},$$

$$c \le Q_k^{\mathrm{st}} Q_k^{\mathrm{st}*} \le 1,$$

where u_k coincides with the Fourier symbol of Q_k' up to a phase factor. The normalisation is as follows. Constants are mapped to the same constants, and $\|Q_k^{\mathrm{st}}\|_{\mathrm{row}} = 1$. Composing Q_k^{st} with the linear lift gives the identity, and $Q_k' Q_k'^* = 1$. The adjoint does not coincide with the lift. The operator $Q_k^{\mathrm{st}} Q_k^{\mathrm{st}*}$ is not a multiple of the identity: it is a convolution that couples each coarse bond to its two neighbours on the same line. This is why the display gives only a two-sided bound. In a background one has $|Q_k^{\sharp}(U_0)A| \le Q_k^{\mathrm{st}}|A| + C\alpha_0 Q_k''|A|$, where Q_k'' takes the mean of $|A|$ over every bond in the double block of order k. With gradients $(\mathrm{d}\lambda)(b) = \lambda(b_+) - \lambda(b_-)$, the two averages intertwine gradients in different ways:

$$\mathsf{Q}^{\mathrm{pl}} \mathrm{d}\lambda = \mathrm{d}(\lambda|_{\mathrm{coarse}}),$$

$$\mathsf{Q}^{\mathrm{s}} \mathrm{d}\lambda = \mathrm{d}(q\lambda),$$

$$Q_k^{\sharp}(U) D_U \lambda = D_{\mathcal{M}^k U} Q_k'(U) \lambda,$$

the last of these relations being exact and valid for the straightened average only. In a background the plain average satisfies, likewise exactly, $Q_k(U)D_U\lambda = D_{\mathcal{M}^k U}(\lambda|_{\mathbb{T}^{(k)}})$, where the restriction stands in place of Q'_k. For the main term $Q_k^{\mathrm{st}}(U)$, by contrast, the relation involving Q'_k is valid only up to $O(\alpha_0)$.

It follows that there are two residual invariances. The constraint $\mathcal{M}^k U = V$ is preserved by every transformation with $u = \mathbf{1}$ on $\mathbb{T}^{(k)}$. The straightened constraint is preserved by the w with $r_k = \mathbf{1}$, where r_k is defined below. In linearised form this condition is $Q'_k\lambda = 0$. When $A = 0$, and likewise at a field tower axial relative to U_0, these transformations are precisely the w whose averages are trivial. Of the two sets, only the first forms a group. The set generated by the second depends on its base point, and the tower axial gauge selects that base point in each orbit of the first. The two invariances correspond to each other through $v_k[A]$.

Now let A be real with $\sup|A| \le c$. Put $w = e^{i\lambda}$ and $e^{i\eta_k A^w}U_0 := (e^{i\eta_k A}U_0)^w$, and for a site function assume $\|\lambda\|_1 := \max\{\sup|\lambda|, \sup|D_{U_0}\lambda|\} \le c$. This norm is taken in level-k units, without local scales, and it differs from the norm $\|\cdot\|_1$ of 1-forms. It equals $\|\lambda\|_0$ for the constant sequence $\Omega_j = T_\ell$, whose only layer is k, with $\xi_k = 1$. The straightened averages change by r_n, where $r_0 = w$ and $r_{n+1} = \mathsf{u}(W_{0,n}, \mathsf{a}_n(A^w))^{-1}\, r_n\, \mathsf{u}(W_{0,n}, \mathsf{a}_n(A))$:

$$e^{i\mathsf{a}_n(A^w)}W_{0,n} = \big(e^{i\mathsf{a}_n(A)}W_{0,n}\big)^{r_n},$$
$$w|_{\mathbb{T}^{(n)}}\, v_n[A] = v_n[A^w]\, r_n,$$
$$r_n|_{A=0} = \bar{R}^{(n)}_{U_0} w,$$
$$\tfrac{1}{i}\log r_k = Q'_k(U_0)\lambda + O\big((\sup|A| + \|\lambda\|_1)\|\lambda\|_1\big).$$

We say that u is of class α when each $\bar{R}^{(j)}u$ is within α of $\mathbf{1}$ and its variation inside any block is less than $\alpha L^{j+1}\eta_k$. If u_1, u_2 are of class $\alpha \le c$, the averages are multiplicative up to second order,

$$\bar{R}^{(j)}(u_1u_2) = \bar{R}^{(j)}u_1\, \bar{R}^{(j)}u_2\, e^{i\mathsf{z}_j},$$
$$|\mathsf{z}_j| \le C(\alpha L^j\eta_k)^2,$$

and u_1u_2 is of class $2\alpha + C\alpha^2$. The averages of products depend holomorphically on complex λ. Precisely, let $u' = e^{i\lambda}$ with $\|\lambda\|_1 \le \alpha' \le c$, and let u_1 be of class α. Then the quotients $\tilde{u}^{(j)} := \bar{R}^{(j)}(u'u_1)(\bar{R}^{(j)}u_1)^{-1}$ have four properties: they are holomorphic in λ; they lie within $C\alpha'$ of $\mathbf{1}$; their covariant differences are $\le C\alpha' L^j\eta_k$; and $\frac{1}{i}\log\tilde{u}^{(k)} = Q'_k(U_0)\lambda + O((\alpha+\alpha')\alpha')$. 1a.3 uses this to show that the Landau gauge depends analytically on the fields. ■

Lemma 3.8 (rigidity of one step)**.** Suppose that W, W_0 have plaquette size $\le \varpi$, that their contour variables agree up to a defect δ, and that $|\mathcal{M}(W)\mathcal{M}(W_0)^{-1} - \mathbf{1}| \le \alpha_1$. Then

$$|W(b)W_0(b)^{-1} - \mathbf{1}| \le \alpha_1 + C\varpi + 2\delta$$

at every bond of the double block. Put differently, modulo the curvature, each bond variable is a function of the contour variables together with the average:

$$|W(b) - W(y, b_-)^{-1}W(y, b_+)| \le C\varpi,$$
$$|W(b') - W(c_-, b'_-)^{-1}\,\mathcal{M}(W)(c)\,W(c_+, b'_+)| \le C\varpi,$$

for b inside $B(y)$ with $y = c_\pm$, and for b' in the corridor of c, that is, among the bonds parallel to c joining $B(c_-)$ to $B(c_+)$. The defect has two sources: soft gauge fixing gives $|V(y,x) - \mathbf{1}| < \varepsilon_k$ instead of equality, and seams contribute the defect of Lem. 3.29. ■

Proposition 3.9 (the fibre is curved; the current enters)**.** Let $|\partial U - \mathbf{1}| \le \alpha_0 \eta_k^2$ with $\alpha_0 \le c$ (the range of Prop. 3.6). Let moreover $U \in \mathfrak{U}_k(\Omega_\bullet, \alpha_0)$ at the constant sequence $\Omega_j = T_\ell$; this membership brings in the further condition $|J(U)| < \alpha_0$. Suppose that M_1, $M\alpha_0$ and the number of sites of $\mathbb{T}^{(k)}$ satisfy the hypotheses of Lem. 3.24 [stated technical lemma; Group A], which provides G and H_k. Finally, let A be small. On $Q_k^\sharp(U)A + C_k(U,A) = 0$, in the Landau gauge, one has $A = A_1 - \mathsf{H}_k C_k^{(2)}(A_1) + \dots$ with $Q_k^\sharp(U)A_1 = 0$, and

$$A(e^{i\eta_k A}U) = A(U) + \langle J(U), A_1\rangle + \tfrac{1}{2}\langle A_1, \Delta_U^{\mathrm{W}} A_1\rangle - \langle \mathsf{H}_k C_k^{(2)}(A_1), J(U)\rangle + O(|A_1|^3).$$

In this expansion H_k denotes the right inverse $\mathsf{H} = GQ^*(QGQ^*)^{-1}$ of $Q = Q_k^\sharp(U)$, built from the G of § 3.12.1; with this choice the relation $RD^*GQ^* = 0$ is exact. For the derivative of $V \mapsto U_k(V)$ the corresponding objects are G_1, H_1. The term $O(|A_1|^3)$ collects all terms of order ≥ 3 in A_1. Indeed, the constraint is solved up to second order, and the solution is substituted into the Taylor expansion of the action. ∎

Proposition 3.10 (isometries and linearised objects)**.** Suppose that r preserves every lattice involved. Then $\mathsf{r}(e^{i\mathsf{a}}W_0) = e^{i\mathsf{r}W_0\,\mathsf{a}}\,\mathsf{r}W_0$, and

$$\mathcal{Q}^1(\mathsf{r}W_0, \mathsf{r}_{W_0}\mathsf{a}) = \mathsf{r}_{\mathcal{M}(W_0)}\mathcal{Q}^1(W_0,\mathsf{a}),$$
$$Q_k^\sharp(\mathsf{r}U)\,\mathsf{r}_U = \mathsf{r}_{\mathcal{M}^k U}\,Q_k^\sharp(U),$$
$$J(\mathsf{r}U) = \mathsf{r}_U J(U),$$
$$\Delta^{\mathrm{W}}_{\mathsf{r}U}\mathsf{r}_U = \mathsf{r}_U\Delta^{\mathrm{W}}_U,$$

and the corresponding relations hold for Q_k, Q_k', $\bar{R}$, u. For real W_0, the map r_{W_0} is an isometry both for the sup norm and for $\langle\cdot,\cdot\rangle$. These maps compose according to $(\mathsf{r}\mathsf{r}')_{W_0} = \mathsf{r}_{\mathsf{r}'W_0}\mathsf{r}'_{W_0}$. If the twisted action is replaced by the plain one (the action at $W_0 = \mathbf{1}$), these relations in general fail for a reflection reversing bonds. The plain and the twisted action are equal where $\mathrm{Ad}(W_0(b))$ acts as the identity on the reversed bonds b. Consequently, propagators, H_k, $\Delta^{(k)}$ and $C^{(k)}$ are covariant under all of W_4 only in the twisted sense, and § 3.12.1, § 4.5 and § 4.2 use the symmetry in this form. ∎

Proposition 3.11 (the fundamental equality; the transformation to the tower axial gauge)**.** Let U_0, A be as in Prop. 3.6. There exists exactly one u, defined on the bare sites, for which $(e^{i\eta_k A}U_0)^u$ is tower axial relative to U_0 and $\bar{R}_{U_0}^{(k)}u = \mathbf{1}$. Its averages are given by $\bar{R}_{U_0}^{(n)}u = u\,v_n$, so that $u = v_k^{-1}$ on $\mathbb{T}^{(k)}$, and

$$\mathcal{M}^k\big((e^{i\eta_k A}U_0)^u\big) = e^{i\mathcal{Q}_k^\sharp(U_0;A)}\,\mathcal{M}^k U_0\,:$$

once the gauge has been changed in this way, averaging of order k amounts to composing the straightened one-step averages k times. The transformation can be written explicitly. Let $x = x_0, \dots, x_k = y$ be the tower of block centres. Let $\mathsf{w}_j^{\mathrm{rel}}(z,x) = (e^{i\mathsf{a}_j}W_{0,j})(z,x)W_{0,j}(z,x)^{-1}$ be the relative contour variables of the straightened averages, let u_j be the block factors, and let T_{U_0} be the transport down the tower. Then

$$u(x) = \prod_{j=k-1}^{0} \mathrm{Ad}\left(\mathsf{T}_{U_0}(x_{j+1},x)\right)^{-1}\Big[\mathsf{u}_j(x_{j+1})^{-1}\,\mathsf{w}_j^{\mathrm{rel}}(x_{j+1},x_j)\Big],$$

$$|u - \mathbf{1}| \le C\sup|A|.$$

Consequently u depends locally and holomorphically on A and is of class $C\sup|A|$. At the bare scale, however, it fails to be regular: it jumps by $O(L^{j}\eta_{k}\sup|A|)$ between neighbouring bare sites belonging to different blocks of order j. ∎

Proposition 3.12 (two schemes; the linear parts compared; what carries over)**.** Bałaban's theorems of 1984–85 are proved for blocks that have their site at a corner and for single combs; this is scheme c. The map $\mathcal{M}$ uses centred blocks and means; this is scheme m. Since L is odd, one translation of his entire setting, by $\mathsf{e}_{j}=\frac{1}{2}(L^{j}-1)a_{K}(1,1,1,1)$ at level j, carries his blocks onto the centred blocks. Of the contour variable, the proofs of Lem. 3.2–Lem. 3.8 use only the following properties:

(i) there is one contour variable for each pair (y,x), and it is covariant;
(ii) its paths stay in the block and make fewer than L steps in each direction;
(iii) coarse translations carry the contour variables into one another;
(iv) it is G-valued on G;
(v) it is holomorphic near $\mathbf{1}$, with a mean of the $\mathsf{a}(\Gamma)$ as its linear part;
(vi) where the bond variables commute with one another, it is the exponential of that mean.

This list is one way of carrying out the axiomatisation that Bałaban mentions. The results of Lem. 3.2–Lem. 3.8 therefore hold in both schemes, with two exceptions. The first exception is covariance under isometries other than coarse translations. It fails for combs, since under an element of W_{4} a comb goes over into a comb of a different order, and a lowest corner into a different corner; this failure is precisely why the mean is used. The second exception is the three rules, which are formulated for $\mathcal{M}$ only. When the background is trivial, the two schemes have the same straightened linear part, $\mathsf{Q}_{\star}(\mathbf{1})=\mathsf{Q}^{\mathrm{s}}$, but different plain linear parts. In a background, let t denote a transport of U_{0} joining the two base sites of a block. Then

$$Q_{k}^{\sharp}(U_{0})=\mathrm{Ad}(t)\big(Q_{k}^{\mathrm{B}}(U_{0})+\mathsf{D}_{k}\big),$$
$$\|\mathsf{D}_{k}\|_{\mathrm{row}}\le C\alpha_{0},$$
$$\|\mathsf{D}_{k}\|_{\mathrm{col}}\le C\alpha_{0}\eta_{k}^{4},$$

and the same holds for Q_{k}'. Moreover, $\mathsf{D}_{k}(c,b)=0$ unless b lies under c. In each scheme, the linear part and the straight average of that scheme differ by a kernel of row norm $C\alpha_{0}$. In this leading part, a bare bond b parallel to c receives as its weight η_{k}^{5} multiplied by the count of segments $[x,x']$, $x\in B^{k}(c_{-})$, passing through b (a tent along the direction of c). Every such segment enters with the transport of U_{0} taken down a chain of contours and segments. The exact identity $Q_{k}=Q_{k}^{\sharp}-D\dot{v}_{k}$ is supplied in the present text. The identity involving D_{k} takes the place of the assertion of 1987 (109, p. 254) that the new average satisfies all the results of the paper on averaging operations. For real U_{0} the factor $\mathrm{Ad}(t)$ is orthogonal, so it cancels from $Q_{k}^{\sharp}(U_{0})^{*}\,a\,Q_{k}^{\sharp}(U_{0})$. Consequently, in the two schemes the forms defining G', R, G_{k}, H_{k} differ from each other by local forms whose relative size is $C\alpha_{0}$. Through this comparison, the operators built from $Q_{k}^{\mathrm{B}}(U_{0})$ are used in § 3.11. The operators are built afresh from $Q_{k}^{\sharp}(U_{0})$, and their bounds are derived from the case $U_{0}=\mathbf{1}$, in which, after the blocks have been aligned, the two linear parts are equal § 3.12.1. ∎

Proposition 3.13 (sharpness: fields of one colour)**.** Let $T\in\mathfrak{g}$ with $|T|=1$. For $U=e^{ifT}$, with f real and small (Prop. 3.3), everything is linear and explicitly computable. A constant curvature φ gives $\partial\mathcal{M}U(p')=e^{iL^{2}\varphi T}$, so the factor L^{2} of Prop. 3.4 is attained.

Now consider a seam. Let Ω_{1} be, locally, a slab $\{x_{1}\ge\mathrm{const}\}$. Let $z\in\mathbb{T}^{(1)}$ be the last coarse site outside it, and let p' be the coarse plaquette with corners $z,z+Le_{1},z+Le_{1}+Le_{2},z+Le_{2}$. Set $f(\langle x,x+e_{2}\rangle)=\mathsf{f}^{\Sigma}(x_{1})$ and $f=0$ on the other bonds, where $\mathsf{f}^{\Sigma}(t):=\sum_{t'<t}\mathsf{f}(t')$. Here $\mathsf{f}=\varphi$ on the $L-1$ bonds in direction 1 that lie in the block of z; on the $L-1$ bonds preceding them

the value is $-\varphi$, and everywhere else it is 0. The curvature has size at most φ and vanishes in Ω_1, while $\partial\mathcal{M}U(p') = e^{i\Theta T}$ with $\Theta = \frac{1}{2}L(L-1)\varphi$. Thus no bound $C\alpha_0$ with C independent of L can take the place of the bound $2L^2\alpha_0$ of Prop. 3.6.

At $U_0 = \mathbf{1}$, take a bond $c \in \Gamma_j$ astride a seam with outer end c_-. Such a bond has one end, its outer end, outside Ω_j; in § 3.11 it is called an outward bond. The weighted row sum equals $\sum_b \frac{|K_0(c,b)|}{\xi(b)} = \frac{1}{2}L(1-L^{-j}) + \frac{1}{2}(1+L^{-j})$, and its limit as $j \to \infty$ is $\frac{1}{2}(L+1)$. Indeed, along a segment $[x, x']$, a bare bond contained in $B^j(c_-)$ has $\xi(b) = L^{j-1}\eta_k$, while the remaining ones extend into $B^j(c_+)$, where the scale equals $L^j\eta_k$.

For a bond of Γ_j astride a seam, an additional block factor arises at its outer end. Moreover, the datum entering the straightened constraint (the reduced datum of § 3.11) is not the same as the plain datum. The factor is genuinely present. At $U_0 = \mathbf{1}$, take $\eta_k A = tT$ on the single bare bond $\langle z, z + e_\nu\rangle$, where z is the outer end of a bond of Γ_1, and $A = 0$ elsewhere. Then $\mathsf{u}(z) = \exp\left(it\frac{L^4-1}{8L^4}T\right) \neq \mathbf{1}$. Finally, $\|\mathsf{Q}^{\mathrm{pl}}\|_{\mathrm{row}} > 2L$. ■

Proposition 3.14 (the exact identities)**.** The transformation $\mathbf{T}$ preserves mass, positivity ($|\mathbf{T}\nu| \leq \mathbf{T}|\nu|$) and gauge invariance. It commutes with the isometries that map $\mathbb{T}^{(k+1)}$ onto itself, and

$$\mathbf{T}^n\nu = (\mathcal{M}^n)_*\nu,$$

$$\langle F(\mathcal{M}^k U)\rangle_{K,\ell,\beta} = \int F\, d(\mathbf{T}^k\rho_0) \Big/ \int d(\mathbf{T}^k\rho_0).$$

Consequently, whenever $F \in \mathfrak{A}$ has largest depth s, each of the numbers $\langle F \circ \mathcal{M}^{K-s}\rangle_{K,\ell,\beta}$, $K \geq s$, is the integral of one fixed function with respect to the normalised measures $\mathbf{T}^{K-s}\rho_0$, all on the same compact space $\mathcal{V}(\Lambda_{s,\ell})$. ■

Proof. The Borel property of the actual average follows from its three defining rules. Fix a coarse bond c, and put

$$\mathcal{N}_c = \bigcup_{x,\Gamma,\Gamma'} \{U : Y_{x,\Gamma,\Gamma'}(U) = -\mathbf{1}\},$$

with the finite index sets used in the definition of the average. Each holonomy is continuous, so $\mathcal{N}_c$ is closed. The small-curvature construction makes the first rule valid on the open set $\mathrm{Dom}(c)$. The other two rules apply respectively on

$$\mathrm{Dom}(c)^c \setminus \mathcal{N}_c, \qquad \mathrm{Dom}(c)^c \cap \mathcal{N}_c.$$

The first rule is analytic; the second is continuous on its domain because the intrinsic logarithm is continuous on $G \setminus \{-\mathbf{1}\}$; the last is the continuous straight-path transport $U[c]$. Thus the bond average is Borel on this finite partition. The configuration space has finitely many independent positive-bond coordinates, so $\mathcal{M}$ is a Borel map on the whole configuration space.

In particular $K(U, \cdot) = \delta_{\mathcal{M}(U)}$ is a probability kernel: $K(U, B) = \mathbf{1}_B(\mathcal{M}(U))$ is Borel for each Borel set B. Its defining identity is

$$\int F(V)\, K(U, \mathrm{d}V) = F(\mathcal{M}(U))$$

for every bounded Borel F. Integration against the input measure gives the asserted pushforward identity. Kernel normalization proves mass preservation, and positivity gives $|\mathbf{T}\nu| \leq \mathbf{T}|\nu|$. Iterating the same identity gives $\mathbf{T}^n\nu = (\mathcal{M}^n)_*\nu$. Gauge covariance gives gauge invariance of the pushforward, since every coarse gauge transformation extends to a fine one. The same argument with lattice isometries gives their commutation with $\mathbf{T}$. Apply the iterated identity to $\nu = \rho_0\, \mathrm{d}U$ and divide by its positive total mass to obtain the expectation formula. □

Proposition 3.15 (soft and hard constraints)**.** Each kernel t of the kind described above preserves mass, positivity and gauge invariance. In the case of linear site fields and of block means Q, the Gaussian kernels $t_{\mathfrak{a}} \propto e^{-\frac{\mathfrak{a}}{2}|\Psi - Q\Phi|^2}$, taken after the canonical rescaling by $L^{(d-2)/2}$, form a family that is closed under composition. In these kernels Φ, Ψ are site functions in dimension d, Q is the rescaled block mean, and Q_k is the mean over B^k, rescaled in the same way; the composition law reads

$$t_{\mathfrak{a}} * t_{\mathfrak{a}_k} = t_{\mathfrak{a}_{k+1}},$$
$$\mathfrak{a}_{k+1}^{-1} = \mathfrak{a}^{-1} + L^{-2}\mathfrak{a}_k^{-1},$$
$$\mathfrak{a}_k \to \mathfrak{a}(1 - L^{-2}),$$

and these kernels give rise to the propagators $(\Delta + \mathfrak{a}_k Q_k^* Q_k)^{-1}$, where $\Delta = D^*D$ acts on site functions. For the delta kernel the fibres are nested, and over regular data, up to gauge,

$$\{\mathcal{M}^{k+1}U = W\} = \bigsqcup_{\mathcal{M}(V)=W} \{\mathcal{M}^k U = V\}$$
$$\Rightarrow$$
$$U_k(V_k^{\mathrm{bg}}) = U_{k+1}(W),$$
$$V_k^{\mathrm{bg}} = \mathcal{M}^k U_{k+1}(W),$$
$$U_j(\mathcal{M}^j U_k(V)) = U_k(V) \ (j \le k) :$$

every background therefore coincides with the background of its own averages, and V_k^{bg}, with $\mathcal{M}^k U$ taken in the block axial gauge, is in that gauge the critical point of $V \mapsto A(U_k(V))$ on $\{\mathcal{M}(V) = W\}$. Suppose that $\Delta \ge 0$ is positive on $\ker Q$ and that Q is surjective. Then, under the constraint $QA = B$, the form $\frac{1}{2}\langle A, \Delta A\rangle$ attains its minimum at $\mathsf{H}B$, where $\mathsf{H} = \mathsf{G}Q^*(Q\mathsf{G}Q^*)^{-1}$ and $\mathsf{G} = (\Delta + aQ^*Q)^{-1}$. This holds for every $a > 0$. *Remark.* Let W be real and lie in a neighbourhood of $\mathbf{1}$; this neighbourhood may depend on k and on the torus. Then V_k^{bg} is, in that gauge, the unique point of minimum of $V \mapsto A(U_k(V))$ on $\{\mathcal{M}(V) = W\}$. ∎

Proposition 3.16 (the steps with their insertions are exact)**.** Each operation of **T** and of **R** consists of finitely many positive kernels, one for each outcome of the operation, whose sum is a probability kernel. These kernels depend on the auxiliary choices. Once the choices are fixed, the kernels depend neither on β nor on the density. When the run makes its own choices, the operations themselves vary with β. For a bounded, gauge-invariant, complex-valued $\mathfrak{w}$,

$$\tau_h^{\mathfrak{w}}(dV) = \int dU\, \mathfrak{w}(U)\rho_0(U)\, \mathsf{K}_h(U, dV),$$
$$\sum_h \mathsf{K}_h(U, \mathcal{V}_k) = 1.$$

Consequently $\tau_h \ge 0$ and $|\tau_h^{\mathfrak{w}}| \le \sup|\mathfrak{w}|\,\tau_h$. Moreover $\int \rho_k = Z_{K,\ell,\beta}$ and $\int \rho_k^w = Z(w)$ at every level, on a torus that is large compared with the cubes of side $M\check{R}_j$ of every level. This holds irrespective of the gauges and representatives chosen. It also holds for every real sequence of numbers t among those admitted in §4.17.1.45. These are the sequences whose terms are all $\ge \gamma^{-2}$, whose differences obey two-sided bounds of the same type as the flow inequalities of Prop. 3.18, and for which $\check{R}_j \le L\check{R}_{j+1}$. The sum over outcomes of the operations of **T** is $\mathcal{M}_*$. By contrast,

$\mathbf{R}$ preserves only those integrals of F that do not depend on the components on which it acts; in general, therefore, $\rho_k \neq \mathbf{T}^k\rho_0$. *Exact insertion:* for every gauge-invariant F,

$$\langle F(\mathcal{M}^k U)\rangle_{K,\ell,\beta} = \sum_h \int F^{(h)} d\tau_h \Big/ \sum_h \int d\tau_h,$$

$$|F^{(h)}| \leq \sup |F|,$$

where $F^{(h)}$ denotes the conditional expectation, under the joint law constructed from the kernels, of $F(\mathcal{M}^k U)$ given (h, V_k). If F depends only on fields away from those components, then $F^{(h)} = F$. *Covariance:* $\mathsf{r}_*\tau_h = \tau_{\mathsf{r}h}$ for every isometry that preserves all the partitions involved. An individual $E^{(j)}(X,\cdot)$ is covariant under the translations that preserve π_j. An individual $R^{(j)}(X,\cdot)$ is covariant under the translations that preserve the $M\check{R}_j$-cubes. Covariance under all isometries r of $\mathbb{T}^{(j)}$ holds only for the unrestricted pointed totals $\sum_{X\ni z} E^{(j)}(X, U_j, z)$. These totals are taken at $U_j = U_j(V)$, where V and $\mathsf{r}V$ both belong to a class of real block fields of level j lying near the regular ones § 4.5. Wherever the covariance of pointed totals is invoked below, it has this meaning. ■

Lemma 3.17 (units; the delta function resolved; regrouping)**.** When the plaquette variables are close to $\mathbf{1}$, $\xi^{d-4}a_p = \frac{1}{2}\xi^d\langle F_U, F_U\rangle(1 + O(\xi^4|F_U|^2))$. Hence, for $d = 4$, Wilson's action is a Riemann sum for $\frac{1}{2}\int|F|^2$ whatever the unit of length. A change of unit leaves A, ρ_k and x_k unchanged. On small fields, $\mathcal{M}(e^{i\mathcal{A}}V_k^{\mathrm{bg}})V_{k+1}^{-1} = \exp i\mathcal{Q}_1(L\mathcal{A})$ and $\mathcal{Q}_1(L\mathcal{A}) = LQ\mathcal{A} + C^{\mathrm{pl},(2)}(\mathcal{A}) + \dots$. Here $\mathcal{A}$ carries no factor of length. Up to the scaling of its argument by L, the map is $\mathcal{Q}_1(\cdot) = \mathcal{Q}_1(V_k^{\mathrm{bg}};\cdot)$, and this scaling accounts for the factor L in front of its linear part. The average here is the plain $Q = Q_{V_k^{\mathrm{bg}}}$, and $C^{\mathrm{pl},(2)}$ is the second-order part of the plain remainder $C_1^{\mathrm{pl}}(V_k^{\mathrm{bg}}, L\mathcal{A})$. The symbol $C_k^{(2)}$ is reserved for the straightened average.

An analytic substitution $\mathcal{A} = \psi^{\mathrm{lin}}(\mathcal{A}') = \mathcal{A}' - \mathsf{h}\tilde{D}(\mathcal{A}')$ changes only the variables on the pivot bonds. It turns the delta function into the linear one, $\delta(LQ\mathcal{A}')$, which is solved for a single pivot bond $b_0(c)$ for each coarse bond. The substitution comes from the implicit function theorem. In it, h inverts LQ on the pivot bonds, $LQ\mathsf{h} = 1$. The linearising correction $\tilde{D}$ is of second order and is written $\widetilde{\mathsf{D}}$ in § 4.5. It is the unique small solution of $\mathcal{Q}_1\big(L(\mathcal{A}' - \mathsf{h}\tilde{D}(\mathcal{A}'))\big) = LQ\mathcal{A}'$, obtained as the fixed point of a contraction. For F supported in this regular chart, and with the free integral restricted to its inverse image, the local coarea identity is

$$\int dV_k\, \delta(\mathcal{M}(V_k)V_{k+1}^{-1})F(V_k) = z^{(k)} \int \prod_{b\neq b_0(c)} d\mathcal{A}'(b)\; e^{\mathrm{Tr}\log(1-\mathsf{h}\,\partial\tilde{D}) + \sum_b \log\sigma_{\mathrm{H}}(\mathcal{A}(b))}\, F\big(e^{i\psi^{\mathrm{lin}}(\mathsf{C}\mathcal{A}')}V_k^{\mathrm{bg}}\big),$$

where σ_{H} is the density of Haar measure in exponential coordinates. Once this density is divided by its value $\sigma_{\mathrm{H}}(0)$ at $\mathbf{1}$, the Jacobians are $1 + O(\delta_k)$ for each bond. They are local and analytic, and they are included in $\mathbb{P}^{(k)}$. The factor $\sigma_{\mathrm{H}}(0)$, taken once for each non-pivot bond, is absorbed into the constant of the step. For every number b,

$$-x_k A + \sum_X E^{(k+1)}(X,\cdot) = -(x_k - b)A + \Big(\sum_X [E^{(k+1)}(X,\cdot) - E^{(k+1)}(X,\mathbf{1})] - bA\Big) + \sum_X E^{(k+1)}(X,\mathbf{1}),$$

and, summed over the levels, $-A(x_k(\cdot), U) - \sum_{j\leq k} b_j A(\varphi_j, U) = -\beta A(U)$. The constant of a step depends on the regions of that step. Let $|\Omega^{(k)*}|$ be the number of non-pivot bonds of $\mathbb{T}^{(k)}$ in Ω, and $\#_{k+1}(\Omega)$ the corresponding number of sites of $\mathbb{T}^{(k+1)}$. Let $z_{\mathfrak{G}} = \mathfrak{z}(x_k, \varepsilon_k)$ be the normaliser of $\mathfrak{G}_k$ for each block site (1a.3), and $\nu_{\mathfrak{g}} = \log\int_{\mathfrak{g}} e^{-|Y|^2/2}dY$. Then

$$\mathsf{E}^{(k)}(\Omega,\Lambda) = \big(\log\sigma_{\mathrm{H}}(0) - \tfrac{1}{2}(N^2-1)\log x_k\big)|\Omega^{(k)*}| - (L^4-1)\log z_{\mathfrak{G}}\,\#_{k+1}(\Omega) + \nu_{\mathfrak{g}}|\Lambda^{(k)*}| + \sum_{X\subset\Lambda}\big[E^{(k+1)} + R^{(k+1)}\big](X,\mathbf{1}),$$

together with $-\mathcal{E}_k = \sum_{j<k}\mathsf{E}^{(j)}(\Omega_{j+1},\Lambda_{j+1})$ and $E = \sum_{j<K}\mathsf{E}^{(j)}(T_\ell,T_\ell)$. Here $\mathcal{E}_k$ depends on the label, and at the all-small-field label the vacuum constant E equals $-\mathcal{E}_K$. ■

3.1.1.1. Primitive hypotheses for the joint step. Write $\mathcal{H}_{\mathrm{step}}$ for the following inputs on every actual determining region, stored-field fibre and allowed parameter domain. Retain the background and substitution admission in A1–A4 of § 2.4, and the actual matrix/core, potential and window estimates used in § 4.5. Their operations and local families must obey the declared covariance and common-lift compatibility rules.

For the history operations retain the common-core integrable envelope, kept Gaussian integral and owned failure-energy certificates in eq. 4.cdlxviii, eq. 4.dii and eq. 4.div of § 4.18. Use the stated label representation, common vacuum normalization and finite read ownership. Drop-out evaluations must preserve their failure certificates under the supremum inside the integral. In the sourced application also retain eq. 4.dxiii on the same fixed representation, or the ordinary complex/prepaid real extension hypotheses stated there that replace it.

The formation, geometric counting and integration arguments give their conditional successor bounds under these inputs. Any primitive estimate not yet verified for all actual histories remains a technical hypothesis of the closure assertions below. Class invariance C4 is their target, not an assumption used to prove them. Exact transport and mass preservation follow separately from the normalized measurable moves in C1. A homogeneous regular-sector construction alone does not verify the all-history premises in $\mathcal{H}_{\mathrm{step}}$.

Proposition 3.18 (the invariant form)**.** Assume $\mathcal{H}_{\mathrm{step}}$. Let $\mathfrak{F}_k$ denote the complete presentations in $\mathfrak{C}_k(\theta)$, written through their represented measures of the form below. Membership includes the specified domains, stored variables, measures, marks and reading rules. The step acts on this presentation; $\mathbf{RT}\mathfrak{F}_k$ below denotes its successor presentations. In it the $E^{(j)}$ are pointed families, the pointed totals of which are covariant with respect to every isometry of $\mathbb{T}^{(j)}$, and b_j is their coefficient § 4.2. A step does not preserve the form and the bounds alone §4.17.1.45. The measures of the class, with their bounds, are

$$\sum_{\mathcal{S}} \mathbf{T}'_k(\mathcal{S})\big[\chi_{k,\mathcal{S}}\, e^{A_{k,\mathcal{S}}(U_k(\mathbf{V}))}\big],$$

$$\|E^{(j)}\|_{j,\kappa} \le E_0,$$

$$\|R^{(j)}\|_{j,\kappa} \le g_j^{\kappa_0},$$

$$|B^{(j)}(X,\cdot)| \le \mathsf{B}\, e^{-\kappa d_j^\natural(\mathcal{S};X)},$$

$$\mathsf{M}(i,X) \le e^{-(2-c')\,p_0(g_i)},$$

where B is a constant chosen before γ (§ 4.17, §4.17.1.45), and where the last inequality, the *mass bound*, concerns those components X that $\mathbf{R}$ has acted on at some level $i \le k$. Such a component was healed, or left standing as an island, or else it dropped out at a failed test, either of a stage or of the main step of $\mathbf{R}$. No assumption is made on a drop-out: its bound follows from the bound for the islands of the lower levels, the Wilson weight of the carrying term over X being counted together with its operation. Let the constants be chosen in order, and let the torus be large compared with the $M\check{R}_j$-cubes at each level. If, in addition, $g_j \le \gamma$ and

$$\lambda_\sharp(j-i) - c_5 \le x_i - x_j \le B_\sharp(j-i)$$

$$(i \le j \le k+1),$$

hold, then $\rho_0 \in \mathfrak{F}_0$ and $\mathbf{RT}\mathfrak{F}_k \subset \mathfrak{F}_{k+1}$ *with the same constants.* No family of a level $j \le k$ is altered; only the background at which they are evaluated changes, $U_k \to U_{k+1}$. The new families come out of $\mathbf{T}$ with a surplus, and $\mathbf{R}$ uses it up: radii $(1+\beta_{\mathrm{s}})\alpha_{i,k} \ge \alpha_{i,k+1}$ and rate $(1+4\beta_{\mathrm{s}})\kappa$, where β_{s} is a fixed fraction. For given $(x_0,\dots,x_j)$, the activities $E^{(j)}(X,\cdot)$, $R^{(j)}(X,\cdot)$ do not depend on the label. When X does not wrap around the torus, they depend neither on the torus nor on the cutoff. Further, $x_{k+1} = x_k - b_{k+1}(x_0,\dots,x_k)$ with $|b_{k+1}| \le B_\sharp$. When the label has no large fields, $|\mathbf{E}_k(U_k)| + |\mathbf{R}_k(U_k)| \le C|\mathbb{T}^{(k)}|$. For a general label, every layer is measured in its own scale, and for each $j \le k$ one adds the sites of level j that lie in a rim around the large-field region Z_j (§ 4.2, § 5.2.1). Finally, stability holds if the flow inequalities hold for all $i \le j \le K$:

$$\chi_k\, e^{-x_k A(U_k) - E_- |\mathbb{T}^{(k)}|} \le \bar\rho_k,$$

$$\int \bar\rho_k \le e^{E_+ |\mathbb{T}^{(k)}|},$$

$$E_+ \le \tfrac{3}{2}(N^2-1)\log x_k + O(1).$$

The large-field factor (part §4.17.1.40). The operation $\mathbf{T}_k(Z)$ contains delta functions, tests and conditional Gaussian weights. Apart from the core factors of the islands in Z, it contains no Wilson weight. Hence, for a component produced by failed plaquette tests, $\mathbf{T}_k(Z)1$ carries no small factor. If no $\mathbf{R}$ has acted on Z, then under the tests of the term it obeys only the bound $\le \exp[C\sum_{t\le k} \#_t(Z_t \cap Z)]$. The small factor lies in three places. They depend on pairwise disjoint sets of plaquettes, factors and bonds, so no part of the small factor is used twice. The first is the Wilson weight: near a failed plaquette test of step j, $x_j A \ge c\, p_0(g_j)^2$. The second is the kept gauge-fixing exponents; together with the Wilson sum, they pay for a failed approximate fluctuation test. The third is the Gaussian forms of the fluctuation fields, which pay for a failed fluctuation test.

(1) Fix a history, and a component X of Z_k that has not been acted on by any $\mathbf{R}$. Let $(j_i, \mathfrak{c}_i)$ be the creation cells of the history in X, namely those cells of the creation set of step j_i, which are $M\check{R}_{j_i}$-cubes, that meet a failed test §4.17.1.40. Then, for all values of the exterior variables, and with the norm taken as the total variation of that part which the term of the history carries,

$$\big\|\mathbf{T}_k(X)\big[\chi_{k,\mathcal{S}}\, e^{-A(x_k(\cdot),U_k)}\big]\big\| \le \prod_i e^{-c\,p_0(g_{j_i})^2}\, \exp\Big[C\sum_{t\le k} \#_t(Z_t\cap X)\Big]:$$

there is one factor for each creation, taken at the coupling of its own step, and one constant for each site.

(2) Bounds of this kind do not multiply over the components, because the background couples the components to one another.

(3) What does multiply, piece by piece, is the pointwise majorant on which (1) rests. A piece (t, D) consists of a component D of the large-field region formed at step t, whose enlargement $D^\sim$ shares no cube with any component that $\mathbf{R}$ has acted on at a level in $[t,k]$, together with the stored variables $\xi_{t,D}$ belonging to it and the weight $\mathsf{w}_{t,D}$ of those variables. Throughout the support of the history,

$$A(x_k(\cdot),U_k) \ge A_{\mathrm{cr}},$$

$$e^{-A_{\mathrm{cr}}} \prod_{(t,D)} \mathsf{w}_{t,D} \le \prod_{\text{creations}} e^{-c\,p_0(g_t)^2} \prod_{(t,D)} \bar{\mathsf{w}}_{t,D}(\xi_{t,D}),$$

$$\int \bar{\mathsf{w}}_{t,D} \le e^{C\#_t(D)},$$

where A_{cr} denotes the Wilson sums near the creations in these pieces. Only those creations are counted on the right-hand side. Each $\bar{\mathsf{w}}_{t,D}$ is a function of the variables of its own piece only.

(4) After integration, take a whole label together with the list of those outermost components (i, X) that $\mathbf{R}$ has acted on and that still stand in the label. For some history having this label and this list, the bound carries one factor for each of its creation cells lying outside the components that $\mathbf{R}$ has acted on and that still stand in the label (islands and drop-outs; the creations inside such a component are spent in its mass), and one mass for each outermost one among these components:

$$\int \mathbf{T}'_k(\mathcal{S})\big[\chi_{k,\mathcal{S}}\, e^{-A(x_k(\cdot),U_k)}\big]dV_k \le \exp\Big[C\sum_j (1+\log x_j)\#_j(Z_j)\Big] \prod_{\text{creation cells } (t,\mathfrak{c})} e^{-c\,p_0(g_t)} \prod_{(i,X)} \mathsf{M}(i,X),$$

$$\mathsf{M}(i,X) = \frac{1}{|W_4|}\sum_{\omega} e^{c\,\mathsf{v}(\omega)} \int \sup_{\mathbf{p}} \big|e^{\Phi_\omega(\xi;\mathbf{p})}\big|\,\mu_\omega(d\xi),$$

where ω ranges over the local histories of X, each equipped with a hypercubic frame in W_4 of the gauge tree, and ξ denotes the stored variables. The variable $\mathbf{p} = (\mathbf{U}, \mathbf{J})$ ranges over the complex pairs on $X^\sim$ at which a term evaluates its factor e^{Φ_ω}. The exponent has the form $\Phi_\omega = \Phi^\circ_\omega(\xi) + \sum_f \Phi_{\omega,f}(\xi; \mathbf{p}|_{R_f})$ with $R_f \subset X^\sim$, and $\mathsf{v}(\omega)$ is a space-time volume. The supremum is taken inside the integral and the sum. This is the form of the mass for a healed component or an island. In the case of a drop-out, the Wilson weight of the carrying term over X appears inside the integral, and the supremum extends over the evaluations at ξ. These are the real configurations that are compatible with the stored variables and regular layer by layer, and at which every test listed by ω takes its recorded value, with the exception of the test whose failure made X a drop-out. They form a set fibred over ξ §4.17.1.40. The induction carries the mass bound at the coupling of level i of the action. In this bound the c of $2 - c$ is small, whatever the c in the weight $e^{c\,\mathsf{v}(\omega)}$. The mass evaluated at a later level does not exceed the mass at level i.

(5) The integral operation $\mathbf{T}'_k(X)$ on a component on which $\mathbf{R}$ acts contains, except in the case of a drop-out, a Wilson factor of its own, namely that of the core. When the component is healed or remains as an island, the total mass that is bounded is that of this operation, not that of $\mathbf{T}_k(Z)$:

$$\mathbf{T}'_k(X)\,1 \le \sup \exp\Big\{\sum_{j\le k} CM^4 \check{R}_j^5\, d'_j(Z_j)\Big\} \prod_{j\le k}\prod_i \exp\Big(-c\,p_0(g_j)^2\big(d'_j(Z_j^{(i)})+1\big) - 2p_0(g_j)\Big),$$

where the supremum extends over every admissible choice of the domains Z_j, $Z_j^{(i)}$ (Bałaban, Comm. Math. Phys. 122 (1989) 355, (1.79)), and the sums over the admissible sequences are counted among the costs. The inner product is taken over the regions $Z_j^{(i)}$ created at step j. For a component Z of Z_j which has been neither healed nor marked, the factor is written $\exp(-\kappa_j(Z) - 2p_0(g_{j(Z)}))$; here $j(Z)$ is the level at which the first creation in Z occurs. The *credit* satisfies $\kappa_j(Z) \ge \sum_{n=j+1}^{j+\mathsf{k}} CM^4 \check{R}_n^5\, d'_n(S^{n-j}Z)$, where the sum runs over the k further steps at which nothing is created. Here S denotes the hull in the next partition with a margin added. The number of $M\check{R}_n$-cubes that meet the region takes the place of the linear size d'_n, because a single cube has $d' = 0$ and still carries a cost. The credit covers the volume costs of every step until $\mathbf{R}$ acts on Z. Once no further step is owed, $\mathbf{T}'_k(X)1 \le e^{-(2-c)\,p_0(g_k)}$. Moreover, in the weighted sum over the labels, every component C of Z_k keeps a factor $\exp[-c\,p_0(g_k) - \kappa_1|C|_k]$, where $|C|_k$ is its number of cells. ∎

Proposition 3.19 (the small-field step as a map on actions)**.** Suppose that the tests and $\mathfrak{G}_k$ are formed at t, where t is large, and let $x \in \mathbb{C}$ with $|x - \mathsf{t}| \le c\,\mathsf{t}$. Suppose that the analyticity radii (α_0, α_1) of the levels $j \le k+1$ are small, with $CM\alpha_0 < \alpha_1$ and $\alpha_1^2 \le C\alpha_0$ at each level. Suppose also that they are comparable: the quotient of the radii of level $k+1$ by those of any level $j \le k$

lies between $(1+\beta_{\mathrm{s}})^{-1}$ and $(1+\beta_{\mathrm{s}})(k+2-j)^{1/2}$. These are the admissible systems of § 4.5. Let S be local, analytic and *renormalised* in the same way as $\mathbf{E}_k+\mathbf{R}_k$:

$$S=\sum_{j\le k}\Big[\sum_{z}\sum_{X\ni z}\big(G^{(j)}(X,\cdot,z)-G^{(j)}(X,\mathbf{1},z)\big)-e_jA\Big]+\sum_{j\in\mathcal{J}}\sum_{X}\big(H^{(j)}(X,\cdot)-H^{(j)}(X,\mathbf{1})\big),$$

$$N(S)=\sum_{j\le k}\omega_{k+1-j}\|G^{(j)}\|_{j,\kappa}+\sum_{j\in\mathcal{J}}\mathsf{q}_j^2\|H^{(j)}\|_{j,\kappa},$$

$$\omega_n\le Cn^CL^{-\alpha_{\mathrm{H}}n},$$

where the pointed totals of $G^{(j)}$ are covariant under all isometries of $\mathbb{T}^{(j)}$, and e_j is the coefficient § 4.2 of $G^{(j)}$. The totals of $H^{(j)}$ are invariant under the isometries of $\mathbb{T}^{(k+1)}$. Finally, q_j is the ratio of the analyticity radii of level $k+1$ to those of level j. Geometric weights occur only in the first sum. Both symmetries are part of the definition of "renormalised". The covariance of the pointed totals is what makes the bracket left after the subtraction of e_jA irrelevant § 4.2. Consider W in a class of real block fields, namely those at which every background formed in the step exists and yields pairs in the domains of the terms. Then, on the enlarged radii and uniformly in k,

$$\mathfrak{E}_{k+1}[\mathsf{t};x;S]=\log Z^{(k)}+\sum_{X\in\mathcal{D}_{k+1}}\mathsf{F}(X,U_{k+1})+\mathrm{const}$$

, where

$$|\mathsf{F}(X,\cdot)|\le C\big(|1-x/\mathsf{t}|+\delta(\mathsf{t})+\mathsf{s}\,N(S)+e^{-c\,\mathsf{t}\delta(\mathsf{t})^2}\big)\,e^{-(1+4\beta_{\mathrm{s}})\kappa d_{k+1}(X)},$$

with holomorphic dependence on x and on the parameters of S. The map $S\mapsto\mathsf{F}$ satisfies a Lipschitz bound with constant $C\mathsf{s}$; here $\mathsf{s}\ll1$ denotes the quotient of the fluctuation threshold by the analyticity radius. Everything above holds under the condition $\mathsf{s}\,(1+N(S))\le c$. Along the run, $G^{(j)}=E^{(j)}$ and $e_j=b_j$, while the $H^{(j)}$ are the aged $R^{(j)}$ of Prop. 3.20. ■

Proposition 3.20 (anatomy of step $k+1$)**.** The insertions are made in the following order. First, the plaquettes of the local backgrounds of V_{k+1} are tested. Next, on the blocks P'' that lie away from failures and from Z_k, where the $V(y,x)$ are defined, the factor $\mathfrak{G}_k(\cdot;P'')$ is inserted. Then the approximate fluctuation $V_k(V_{k,\square}^{\mathrm{bg}})^{-1}$ is tested, and this determines Ω_{k+1}. On that region V_k^{bg} is defined and $V_k=e^{i\mathcal{A}_k}V_k^{\mathrm{bg}}$ is set. Finally, $\mathcal{A}_k$ is tested, and this determines Λ_{k+1}. The insertions and tests just described, together with the regions that they determine, are those of Bałaban's form, whereas the sharper tests on collar and rim, together with their outcomes, are given in §4.17.1.1. As a formula,

$$(\mathbf{T}\rho_k)(V_{k+1})=\sum_{P,Q,R}\int dV_k\,\delta(\mathcal{M}(V_k)V_{k+1}^{-1})\;\chi_{k+1}\chi_{k+1}^{c}(P)\;\mathfrak{G}_k(V_k)\;\chi_k'\chi_k'^{c}(Q)\;\chi^{(k)}\chi^{(k)c}(R)\;\rho_k(V_k).$$

After Lem. 3.17 has been applied and the field has been scaled, $\mathcal{A}_k=g_kB$, a Taylor expansion about the critical point yields

$$x_k\big[A(U_k(V_k))+\mathrm{GF}_k(V_k)\big]=x_kA(U_{k+1})+\tfrac12\langle B,\Delta^{(k)}B\rangle+\sum_b O(g_k|B|^3).$$

Completing the square in $B|_{\Lambda_{k+1}}$ produces $C^{(k)}(\Lambda_{k+1})$, together with the conditional Gaussian that is kept in $\mathbf{T}^{(k)}(Z_{k+1})$:

$$(\mathbf{T}\rho_k)(V_{k+1}) = \sum_{\mathcal{S}'} \chi_{k+1}(\Omega_{k+1})\, \mathbf{T}^{(k)}(Z_{k+1})\mathbf{T}'_k(\mathcal{S})\Big[e^{A_{k,\mathcal{S}}(U_{k+1})+E_0^{(k)}(\Omega_{k+1})}\,\mathsf{I}\Big],$$

$$\mathsf{I} = Z^{(k)}(\Lambda_{k+1})\int d\mu_{C^{(k)}(\Lambda_{k+1})}(B)\,\chi^{(k)}(\Lambda_{k+1})\,e^{\mathbb{P}^{(k)}+\{A_{k,\mathcal{S}}\}'+\mathsf{W}^{(k)}},$$

where $E_0^{(k)}(\Omega)$ consists of the first two terms of $\mathsf{E}^{(k)}(\Omega,\Lambda)$. The measure $\mu_{C^{(k)}(\Lambda_{k+1})}$ is the Gaussian measure conditioned on the exterior fluctuation field, and its mean is linear in that field. The prime indicates that the quadratic part of $-x_k A$ has been absorbed into the measure. The term $\mathsf{W}^{(k)}$ is left over from a change of variables on the strip, that is, on the part of S_{k+1} lying along $\partial\Lambda_{k+1}$. Before any expansion, the logarithm is divided into three parts by interpolation:

$$\log\mathsf{I} = \int_0^1 dt_1\,\langle\{\mathbf{B}_k - A(x_k(\cdot)-x_k,\cdot)\}+\mathsf{W}^{(k)}\rangle_{t_1,1} + \int_0^1 dt_2\,\langle\{\mathbf{R}''_k\}\rangle_{0,t_2} + \log\mathsf{I}\big|_{t_1=t_2=0},$$

where $\mathbf{R}''_k$ contains the young $R^{(j)}$, namely those whose cubes are larger than a block. The logarithm is expanded § 4.5 and regrouped (Lem. 3.17, with b_{k+1}, φ_{k+1} and $\mathsf{E}^{(k)}(\Omega_{k+1},\Lambda_{k+1})$). This gives the form of level $k+1$:

$$\begin{aligned}(\mathbf{T}\rho_k)(V_{k+1}) &= \sum_{\mathcal{S}'}\chi_{k+1}\,\mathbf{T}'_{k+1}(\mathcal{S}')\exp\Big[A_{k,\mathcal{S}}(U_{k+1}) + \sum_{X\subset\Lambda_{k+1}}[E^{(k+1)}+R^{(k+1)}](X,U_{k+1})\\ &\quad + \sum_{X\cap Z^{\sim}_{k+1}\neq\emptyset} B^{(k+1)}(X;U_{k+1},\underline{\mathrm{f}}) + E_0^{(k)}(\Omega_{k+1}) + \nu_{\mathfrak{g}}|\Lambda^{(k)*}_{k+1}|\Big]\\ &= \sum_{\mathcal{S}'}\chi_{k+1}\,\mathbf{T}'_{k+1}(\mathcal{S}')\exp A_{k+1,\mathcal{S}'}(U_{k+1});\end{aligned}$$

after this, $\mathbf{R}$ acts. The terms with $X\subset\Lambda_{k+1}$ coincide with the terms of the pure small-field integral (among the $R^{(k+1)}$, here and in $\mathsf{E}^{(k)}$, a label keeps those whose X lies one cell inside Λ_{k+1}, and the others are counted among the $B^{(k+1)}$); this coincidence is the locality stated in Prop. 3.18. ■

Proposition 3.21 (a model case: the free field; the renormalisation group as nested orthogonal projections)**.** Let the *free curvature* F be the standard Gaussian vector in the Euclidean space $\Omega^2_{\mathrm{ex}} = \operatorname{ran}\mathrm{d}$ of exact 2-cochains on the bare lattice. Here d is the coboundary taking real 1-cochains to real 2-cochains on the bare lattice, and $\mathrm{d}_{(j)}$ is the coboundary of $\mathbb{T}^{(j)}$. This vector stands for one colour of the gauge field, taken in the quadratic approximation and up to closed forms. The plain linear average and the straight linear average induce the same average of curvatures, called the *plaquette average*:

$$\mathrm{d}_{(j)}(\mathsf{Q}^{\mathrm{pl}})^j = \mathrm{d}_{(j)}(\mathsf{Q}^{\mathrm{s}})^j = \mathsf{A}^{(j)}\mathrm{d},$$

$$(\mathsf{A}^{(j)}F)(P) = L^{-4j}\sum_{z\in B^j(y)}\ \sum_{p\in\mathrm{Sq}^{(j)}(z;P)} F(p),$$

where $\mathrm{Sq}^{(j)}(z;P)$ is the set of L^{2j} bare plaquettes which together cover the plaquette P of $\mathbb{T}^{(j)}$ with corner y, once it is translated to z. Put $\mathsf{W}_j := \Omega^2_{\mathrm{ex}} \ominus (\Omega^2_{\mathrm{ex}}\cap\ker\mathsf{A}^{(j)})$. These are subspaces of Ω^2_{ex} whose level is written as a subscript, and they are distinct from the term $\mathsf{W}^{(k)}$ of Prop. 3.20, whose level is written as a superscript. Let P_{W} denote the orthogonal projections. Then the spaces are nested, $\mathsf{W}_0\supset\mathsf{W}_1\supset\cdots\supset\mathsf{W}_K$. Given the block field of level k, the conditional expectation of

F is $P_{\mathsf{W}_k}F$. This is the curvature of the linear background, namely the exact cochain of smallest norm that has the prescribed plaquette averages. The covariances of the background and of the fluctuation are two complementary orthogonal projections, $\mathbb{E}\big[P_{\mathsf{W}_k}F(p)\,P_{\mathsf{W}_k}F(q)\big] = P_{\mathsf{W}_k}(p,q)$ and $P_{\mathrm{ex}} = P_{\mathsf{W}_k} + P_{\mathsf{W}_k^{\perp}}$, where P_{ex} is the projection onto Ω^2_{ex}. Finally,

$$F = P_{\mathsf{W}_K}F + \sum_{j=1}^{K} \mathcal{C}_{(j)}F,$$

$$\mathcal{C}_{(j)} = P_{\mathsf{W}_{j-1}} - P_{\mathsf{W}_j} = \mathcal{H}_{j-1}C_j^{\mathrm{tr}}\mathcal{H}_{j-1}^{*},$$

$$|\mathcal{C}_{(j)}(p,q)| \le C\eta_{j-1}^{4} e^{-\delta|x(p)-x(q)|/a_{K-j+1}},$$

where the summands are independent and the covariance of each summand is its own projection. Here, for a block field B of level $j-1$, $\mathcal{H}_{j-1}B$ denotes the curvature of its linear background, namely the exact 2-cochain on the bare lattice of smallest norm satisfying $\mathsf{A}^{(j-1)}\mathcal{H}_{j-1}B = \mathrm{d}_{(j-1)}B$; and C_j^{tr} is the fluctuation covariance, in a tree gauge, of step j. Thus step j integrates out precisely $\mathcal{C}_{(j)}F$, and the amplitude and range of each slice are those of its own scale. In this model the semigroup law is the nesting of the spaces, and the delta constraint is conditioning. The nesting of backgrounds takes the form $P_{\mathsf{W}_j}P_{\mathsf{W}_k} = P_{\mathsf{W}_k}$ $(j \le k)$. Three features of the full theory are absent from the model: the fibre is flat, no coupling runs, and no field is large. The current of a linear background is not zero: $\mathrm{d}^{*}P_{\mathsf{W}_k}F = ((\mathsf{Q}^{\mathrm{s}})^{k})^{*}\mathrm{d}^{*}_{(k)}\phi$, which is the image of a Lagrange multiplier. What is missing is the term $\langle \mathsf{H}_k C_k^{(2)}, J\rangle$ of Prop. 3.9, because $C_k^{(2)} = 0$ on a flat fibre. In the non-linear theory the current and the multiplier do vanish, at $U = \mathbf{1}$. For this reason the linearisation at that point of the minimiser of A subject to $\mathcal{M}^{k}U = V$ is the minimiser of $\frac{1}{2}\|\mathsf{da}\|^2$ subject to the linearised constraint, and the second-order part of the averages makes no contribution. Hence the model is the linearisation at $\mathbf{1}$. It serves as the template for §6.1.1.1, §6.1.1.2. ∎

Lemma 3.22 (axial gauges)**.** Consider a box of side D on which $|\partial V - \mathbf{1}| \le \epsilon$. Among the representatives $V^{\psi'}$ with $\psi'(y_P) = \mathbf{1}$, the configuration $V^{\mathrm{ax}} = V^{\psi}$, $\psi(w) = V(\Gamma_{y_P,w})$, is the only one that equals $\mathbf{1}$ on the tree. The non-abelian Stokes theorem expresses $V^{\mathrm{ax}}(b)$ as a product of conjugated plaquette variables, at most $|b_- - y_P|_1$ in number:

$$V^{\mathrm{ax}}(b) = \prod_{i=1}^{m} \psi(w_i)\,\partial V(p_i)^{\pm 1}\psi(w_i)^{-1},$$

$$|V^{\mathrm{ax}}(b) - \mathbf{1}| \le |b_- - y_P|_1\,\epsilon \le 4D\epsilon;$$

Suppose that $D\epsilon \le c$ and that $F = \frac{1}{i}\log \partial V$ is Hölder along combs; it is distinct from the field strength F_V introduced in the Notation, §2, being the logarithm of each plaquette variable. Then $\frac{1}{i}\log V_{\mu}^{\mathrm{ax}}(x) = \sum_{\rho<\mu}(x_\rho - y_\rho)F_{\rho\mu}(y_P) + O(|x-y_P|^2)\times(\text{Hölder constant} + \epsilon^2)$, which is the expansion used in § 4.2 and §4.17.1.3. On a separated sequence suppose that $U_0, U \in \mathfrak{U}_k(\Omega_\bullet, \alpha_0)$, with $\alpha_0 > 0$ below the fixed geometric ceiling, and that their raw averaged data differ by at most $\alpha_1 \ge 0$ on every interior and outward determining row. Let $\hat{g}$ be the real gauge, equal to one at every layer top, whose descending construction aligns the averaged contour variables of $U^{\hat{g}}$ with those of U_0. The construction following eq. 3.cccxx gives $|\mathcal{M}^{j}(U^{\hat{g}})(b)\mathcal{M}^{j}U_0(b)^{-1} - \mathbf{1}| \le C_L(\alpha_0+\alpha_1)$ for $0 \le j \le k$ and every carried level-j bond b inner to Ω_0 with an endpoint in Ω_j, uniformly in k. This is a raw group-element bound, before division by the local spacing. On a single level (compare the rigidity Lem. 3.8), $\mathcal{A}_k$ is defined, and is $O(\varepsilon_k)$, only after the gauge has been fixed. ∎

Proposition 3.23 (Faddeev–Popov identities with Jacobian one)**.** Let a compact group H act, and let $\mathsf{k} \ge 0$ satisfy $\int_H \mathsf{k}(h\cdot x)\,dh = 1$. Then for every finite complex measure ν and every bounded invariant F,

$$\int \nu(dx) \int_H dh\, \mathsf{k}(h \cdot x)\, F(h \cdot x) = \int F\, d\nu;$$

The measure obtained in this way is constructed as follows: one chooses h with law $\mathsf{k}(h \cdot x)dh$ and replaces x by $h \cdot x$. This measure equals $\mathsf{k}\,\bar{\nu}$, where $\bar{\nu}$ is the gauge average of ν. When ν is invariant, it is the product $\mathsf{k}\,\nu$. If $u = \mathbf{1}$ on the coarse sites, then $V^u(y,x) = V(y,x)u(x)^{-1}$. Where $V(y,x)$ is undefined, no factor is inserted at the pair (y,x), and with this convention

$$\int \prod_x du(x)\, \mathfrak{G}_k(V^u; P'') = 1,$$

$$(\mathbf{T}\rho_k)(V_{k+1}) = \int dV\, \delta(\mathcal{M}(V)V_{k+1}^{-1})\, \mathfrak{G}_k(V; P'')\, \rho_k(V).$$

In addition, $\mathfrak{G}_k(V^v) = \mathfrak{G}_k(V)$ whenever v is constant on blocks. The same holds for delta functions on spanning trees. Let T be a tree whose root lies outside the sites of the group, and let V_0 be any configuration on T. Then a unique u satisfies $(u \cdot V)|_T = V_0$, and the measure dV splits into factors along the tree:

$$\int f\, dV = \int du \int \prod_{b \notin T} dS(b)\, f(u \cdot (S \sqcup V_0)),$$

so

$$\int dV\, \delta_T(VV_0^{-1})\, \rho F = \int dV\, \rho F$$

for invariant ρ, F. Finally, the delta function can be removed: the gauge average of $\Psi\, \delta_T(VV_0^{-1})dV$ is $(\Psi \circ \pi_T)\, dV$, where π_T is the projection onto the slice along the orbits. ■

Lemma 3.24 ([stated technical lemma; Group A)**.** (the Landau gauge)] Let U be tower axial and let $W = U^{u^{-1}}$. Then $\mathsf{n}_W = u^{-1}\bar{R}_{U_0}u$, so a u with trivial averages leaves the straightened averages exactly unchanged. In linearised form this reads $Q_j^\sharp(U_0)D\lambda = D_{\mathcal{M}^j U_0} Q_j'(U_0)\lambda$. Hence $Q^\sharp A$ does not change under $A \to A - D\lambda$, $\lambda \in N(Q')$. Up to terms that contain $J(U_0)$, gradients are null directions of Δ^{W}. Indeed $D^*J(U_0) = 0$, and, writing λ_+ for $\lambda(b_+)$ transported to b_-,

$$\langle A - D\lambda, \Delta^{\mathrm{W}}(A - D\lambda)\rangle = \langle A, \Delta^{\mathrm{W}}A\rangle - \langle i[\lambda, A] - i[A, \lambda_+] - i[\lambda, D\lambda],\, J(U_0)\rangle.$$

The projection is given by

$$R = 1 - G'Q'^*(Q'G'^2Q'^*)^{-1}Q'G',$$

$$\operatorname{ran} R = \{f : Q'G'f = 0\},$$

$$\inf_{\lambda \in N(Q')} \|D^*A - \Delta\lambda\|^2 = \|(1-R)D^*A\|^2,$$

and $R\Delta\lambda = \Delta\lambda = G'^{-1}\lambda$ for $\lambda \in N(Q')$. The map $\lambda \mapsto (R\Delta\lambda, Q'\lambda)$ is a bijection onto $\operatorname{ran} R \times \{\text{functions on tops}\}$. Its inverse is $(f,\nu) \mapsto G'f + H'\nu$, where ν is a function on the tops and H' is a right inverse of Q', constructed from G', with $R\Delta H' = 0$. Let $U \in \mathfrak{U}_k(\Omega_\bullet, \alpha_0)$ and let M_1 be large. Assume that $M\alpha_0$ (and therefore $M_1\alpha_0$) lies below a number that depends only on L, and that $\mathbb{T}^{(k)}$ has at least CM_1 sites in each coordinate direction. Then the form

$$\langle A, \Delta_U^{\mathrm{W}}A\rangle + \|RD_U^*A\|^2 + \langle Q^\sharp A, aQ^\sharp A\rangle$$

is positive definite. Its inverse $\mathsf{G}_k(U)$ maps $|\cdot|_{(-3)}$ into $\|\cdot\|_1$, with a norm that depends only on L. On the set $\{RD^*A = 0,\ \xi Q^\sharp A = B\}$ the form differs from the Hessian by a constant. Consequently $\mathsf{H}_k B = \mathsf{G}Q^{\sharp *}(Q^\sharp \mathsf{G} Q^{\sharp *})^{-1}\xi^{-1}B$ minimises the Hessian itself under the constraint, and $RD^*\mathsf{G}Q^{\sharp *} = 0$. Here G stands for Bałaban's G, and not for the inverse of the displayed form, which is his G_0. The formula for $\mathsf{H}_k B$ and the identity just stated hold exactly only when the Hessian in the form is replaced by its invariant extension Δ_π. This extension is defined by $\langle A, \Delta_\pi A\rangle = \langle A - D\lambda, \Delta^{\mathrm{W}}(A - D\lambda)\rangle$, where $\lambda \in N(Q')$ is the one with $RD^*(A - D\lambda) = 0$. The replacement is a perturbation of size $CM\alpha_0$, which is small together with the current because α_0 is chosen after M. The bounds persist under this perturbation, and it vanishes where $J = 0$. In the symbols of the Notation, §5, this operator equals $\mathsf{H}\,\xi^{-1}$. There H denotes the linear minimiser constructed from G, and it satisfies $Q^\sharp \mathsf{H} = 1$. Where $J = 0$ and $\xi = 1$, the operator coincides with the H_k of the Notation. It carries the normalisation for the constraint $\xi Q^\sharp A = B$. With his Q^{B}, Bałaban uses both normalisations: the minimiser under $QA = B$ and the minimiser under $L^j \eta\, Q_j A = B$. On layer j the two differ by the factor $\xi^{-1} = (L^j \eta_k)^{-1}$. The normalisation with ξ is the one taken in his paper on the variational problem. ■

Proposition 3.25 (from the axial to the Landau gauge)**.** Work in the scheme c, in which Bałaban's average of 1985 replaces $\mathcal{M}$ in every object, and fix the block and gap numbers $\mathfrak{M}, R_1$. The constants $c_1, B_1 > 0$ may depend on $L, \mathfrak{M}, R_1$, but are independent of depth and compatible volume. Assume the hypotheses of Lem. 3.22 [stated technical lemma; Group A], with the full gauge $\mathrm{Ax}(\Omega_\bullet, U_0)$ and not Ax°, and assume $\alpha_0 + \alpha_1 \le c_1$. Then U has exactly one Landau pair that satisfies

$$|A|_{(-1)},\ |\nabla_{U_0} A|_{(-2)},\ |D^*DA|_{(-3)},\ |\Delta_{U_0} A|_{(-3)} \le B_1(\alpha_0 + \alpha_1),$$
$$\sup |u - \mathbf{1}| \le C B_1(\alpha_0 + \alpha_1),$$

that satisfies Hölder bounds on ∇A (these bounds give rise to the α_{H} below), and that has the straightened averages of U,

$$\mathcal{Q}_j^\sharp(U_0; A) = B \ \text{ on the bonds at } \mathbb{Y}_j,$$
$$B = \tfrac{1}{i}\log\left[\mathcal{M}^j U (\mathcal{M}^j U_0)^{-1}\right],$$
$$|B| \le C\alpha_1$$

(with an explicit correction entering on bonds that join two layers). For $\mathcal{M}$ itself, under the same hypotheses with $\alpha_0 + \alpha_1 \le c$, there exists a pair (A, u) in the slice of § 3.11 that has these averages and satisfies $\|A\|_1,\ |D^*DA|_{(-3)} \le C(\alpha_0 + \alpha_1)$. That slice has the same form as the Landau gauge but a different projection, whose site averages run along combs from the block corners. ■

Proposition 3.26 (a priori bounds on the slice)**.** Assume that $U_0, e^{i\eta_k A}U_0 \in \mathfrak{U}_k(\Omega_\bullet, \alpha_0)$, that $RD^*A = 0$, and that the averages are as above. Assume further that the only bound given is $|A|_{(-1)} < \alpha_2$, with $\alpha_0, \alpha_1, \alpha_2 \le c$ (c chosen for the fixed block and gap geometry of Prop. 3.25) and $C\alpha_2^2 \le \alpha_0 + \alpha_1$. Then, in the scheme c, all the bounds of the theorem on A hold, with $B_1 = CL\times$ the norms of $\mathsf{G}_k(U_0)$, $\mathsf{H}_k(U_0)$. For $\mathcal{M}$, the bounds on $\|A\|_1$ and $|D^*DA|_{(-3)}$ hold, in the slice of § 3.11. ■

Proposition 3.27 (regular means small potential, locally)**.** Let $U \in \mathfrak{U}_k(\Omega_\bullet, \alpha_0)$ and impose the fixed background geometry floors. Take M to be a positive integer multiple of $\mathfrak{r}_{\mathrm{p}}$ and take a cube of side $M\xi_j$ aligned on the $\mathfrak{r}_{\mathrm{p}}\xi_j$ grid whose concentric enlargement of side $(M + 4\rho)\xi_j$ lies in Ω_j and is shorter than half the torus. The curvature and full-current bounds are required on every complete stencil meeting this enlargement, as in eq. 3.cdxxxiii. Assume $CM\alpha_0 \le c_1$. Then on the original cube, for some u

$$U^{u^{-1}} = e^{i\eta_k A},$$

$$\xi_j|A|,\ \xi_j^2|\nabla A|,\ \xi_j^3|D_{\mathbf{1}}^* D_{\mathbf{1}} A|,\ \xi_j^3|\Delta A| \le CM\alpha_0,$$

For the additional normalization in scheme c, choose the gauge by Prop. 3.25. First put the top box datum in its box axial gauge, then impose the lower full tower gauge while fixing the top nodes, and finally take the normalized Landau pair relative to $\mathbf{1}$. The lower tower changes preserve the top datum. The Landau change has trivial nonlinear site averages, so the reduced-average identity of Lem. 3.24 preserves its straightened value. On the homogeneous top rows this gives exactly $\mathcal{Q}_j^\sharp(\mathbf{1}; A) = \frac{1}{i}\log(\mathcal{M}^j U)^{\mathrm{ax}}$. This identity uses the stated axial-to-Landau theorem and its choice of gauge. Conversely, let $U_0 \in \mathfrak{U}_k(\Omega_\bullet, \alpha_0)$ and $\|A\|_1, |D^* DA|_{(-3)} < \alpha_2$, with α_0, α_2 small. Then $e^{i\eta_k A} U_0 \in \mathfrak{U}_k(\Omega_\bullet, \alpha_0 + 3\alpha_2)$. Now take a complex $\mathbf{U} = e^{i\eta_k A'} U$ with $\xi_j|A'| < \alpha_1$ whose own plaquettes are small, $|\partial \mathbf{U} - \mathbf{1}| < \alpha_0 \eta_k^2 \xi_j^{-2}$ on the cube. (From $\|A'\|_1 < \alpha_1$ this follows only with $\alpha_0 + C\alpha_1$ in place of α_0, Prop. 3.6.) Assume also $CM(\alpha_0 + \alpha_1) \le c$. Then the averages are V^v. Here V is what the averages of $\mathbf{U}$ become in the comb gauge of the cube, and $v = v' v_{\mathrm{r}}$ is a G^c-valued function on the nodes. The factor v_{r} is G-valued and does not depend on A', the factor v' is holomorphic in A', and

$$|V - \mathbf{1}| \le CM\alpha_0,$$

$$\mathrm{cn}(v) = |v|\,|v^{-1}| \le e^{CM\alpha_1},$$

$$|v' - \mathbf{1}| \le CM\alpha_1.$$

The third bound of Bałaban, $|v - \mathbf{1}| \le CM\alpha_1$, holds for v'. For v it holds only at pairs normalised by $U(\Gamma_{y_\square, x}) = \mathbf{1}$. Indeed, for $U = \mathbf{1}^g$, $A' = 0$ one has $v = g(\cdot) g(y_\square)^{-1}$, which is arbitrary, whereas $\mathrm{cn}(v) = 1$. ■

Proposition 3.28 (transversality, locality, node factor; the choices disappear)**.** The slice is transversal. Let $\tilde{A}$ be real with $\|\tilde{A}\|_1 \le c$, and let a G-valued y near $\mathbf{1}$ be prescribed on the tops. Then some $w = e^{i\lambda}$ brings $\tilde{A}$ into the slice with $r_j = \mathsf{y}$ on $\mathbb{Y}_j$, and $\|\lambda\|_0 \le C(|D^* \tilde{A}|_{(-2)} + \sup|\mathsf{y} - \mathbf{1}|)$. Here r_j is defined as in Prop. 3.7 and formed at $\tilde{A}$; at $\tilde{A} = 0$ it is $\bar{R}_{U_0}^{(j)} w$. The pair (A, u) depends locally on the data $(J(U), B)$, with tails $Ce^{-\delta d(y,y')}$ and $\delta < \delta_0$. Distances are measured in local scales, $J(U)$ in $|\cdot|_{(-3)}$, B in the sup norm and A in $\|\cdot\|_1$. Along differentiable families of U, this locality follows from the relation

$$\delta A = \mathsf{G}_k(U_0)\big[\,\mathrm{Ad}(u^{-1})\delta J(U) + \mathcal{L}\delta A\big] + \mathsf{G}_k(U_0) Q^{\sharp *} \xi^{-3}\big[\delta B - \partial_A C(A)\delta A\big].$$

For backgrounds over a real datum $\mathbf{V}$, assume that the datum is regular in the sense of § 3.11: its test loops lie within a small ε of $\mathbf{1}$, and, where inward bonds are kept, so do the two-scale loops at the seams. For the retained-inward variant also assume the original and peeled admissions of Lem. 3.36. Under these hypotheses the pair depends holomorphically on the datum within a ball of radius c, the representative at $e^{iB}\mathbf{V}$ being $(e^{i\eta_k A(B)} U_k(\mathbf{V}))^{h(B)}$. None of these statements depends on k. The plain averages of $e^{i\eta_k A} U_0$ are the datum transformed by the *node factor*: $\mathcal{M}^j(e^{i\eta_k A} U_0)(c) = \mathsf{n}(c_-) V_j(c) \mathsf{n}(c_+)^{-1}$, where $\mathsf{n} = u^{-1}|_{\mathrm{nodes}}$. At the tops the node factor is the iterated n_W, namely $v_j[A]$. At a junction node it contains one further factor, the quotient of the datum by the reduced average on one bond ending at that node. Every ingredient of a step is gauge covariant, and the map $(A, u) \to (\mathrm{Ad}(v)A, vuv^{-1})$ takes the set of Landau pairs of U with respect to U_0 onto the set of Landau pairs of U^v with respect to U_0^v. Consequently $E^{(k+1)}(X, \cdot)$ is invariant under

$$(\mathbf{U},\mathbf{J}) \to (\mathbf{U}^u, \mathrm{Ad}(u)\mathbf{J})$$

for G-valued u. It is therefore also invariant for the G^c-valued u that are connected to these within the domain, and it can be evaluated in any gauge. A function F constructed on a slice is invariant under the subgroup that preserves the slice, and it has a unique invariant extension, $F^\natural(\mathfrak{z}) = F(\mathsf{c}[\mathfrak{z}]\cdot\mathfrak{z})$. Here $\mathsf{c}[\mathfrak{z}]$ is the transformation that takes $\mathfrak{z} = (U, A', \mathbf{J})$ to the slice; this symbol, which carries an argument, is distinct from the scheme c of Prop. 3.12. The extension retains locality, the bounds, and holomorphy in $(A', \mathbf{J})$ at fixed real U. ■

Lemma 3.29 (the block axial gauge outside the nodes)**.** Near a seam, the block of a coarse site contains nodes, and every element of $\mathcal{G}^{\mathrm{res}}$ is pinned at these nodes. In that case the gauge condition is $(\mathcal{M}^i U)(y,x) = \mathbf{1}$ for $y \in P''$ and for those $x \in B(y)\setminus y$ other than nodes. For a pair of nodes, the value $(\mathcal{M}^i U)(y,x)$ is invariant on the orbit, and the datum does not contain it. If P'' consists of nodes, the gauge is met once by every orbit of $\mathcal{G}^{\mathrm{res}}$, meaning that the averages $\mathcal{M}^i U$ on the bonds within $B(P'')$ and the nodes depend only on the orbit. Hence $V_k^{\mathrm{bg}} = \mathcal{M}^k U$, with U in the orbit $U_{k+1}(\mathbf{V})$ and in the gauge, is a function of the datum; this is the case $i = k$, with $k+1$ in place of k. In this situation

$$\mathrm{GF}_i(\mathcal{M}^i U; P'') = \sum_{y\in P''} \sum_{x\in B(y)\setminus y,\, x \text{ a node}} \big[1 - \tfrac{1}{2}\,\mathrm{Re}\,\mathrm{tr}(\mathcal{M}^i U)(y,x)\big],$$

which is constant on the orbit. Near a seam, this is what is left of the identity $\mathrm{GF}_k(V_k^{\mathrm{bg}}) = 0$. ■

Proposition 3.30 (a generalisation of Prop. 3.25, in the scheme c)**.** Fix $\gamma' > 0$. Where the constant B_1 of the theorem enters, γ' is not large; $\gamma' = 1$ is an example. Assume the hypotheses of the theorem, with c_1 depending on γ' as well; for arbitrary γ', the constant B_1 must also depend on γ'. Let $f \in \mathrm{ran}\, R$ with $|f|_{(-2)} < \gamma'(\alpha_0 + \alpha_1)$. Then the contraction in $\|\lambda\|_0$ from the proof of the theorem produces, for λ in a ball of fixed radius, a unique u whose averages are trivial and for which $R\,D^*_{U_0} A = f$. The consequence below uses only this conclusion. Bałaban's Theorem 8 [stated technical lemma; Group E] also asserts, without proof, all the bounds of the theorem, with the same B_1. The second-order and Hölder bounds require, in addition, a bound on Df in $|\cdot|_{(-3)}$. As a consequence, the set $\{A : \mathcal{Q}^\sharp(U_0; A) = B,\ RD^*A = f \text{ for some small } f\}$ consists of pieces of gauge orbits, and each piece meets the slice $f = 0$ in exactly one point. On each piece the action takes a single value. Hence a point of the slice that is critical there is critical on the thickened set as well, so that the Lagrange equations no longer involve the gauge condition. Bałaban makes use of this a single time, to obtain the second-order bounds on the minimiser. In § 3.12.1 the corresponding step, which passes from the slice to a multiplier attached to the averages only, is carried out with gauge directions the images of which under RD^* fill all of $\mathrm{ran}\, R$. The domains U_j^c have real centres that are regular, though not nearly critical, and at these centres the construction demands small local potentials outright. ■

Proposition 3.31 (a seam in dimension one)**.** Take all definitions on $\mathbb{Z} \supset L\mathbb{Z}$, and perform one step on the weight 1 on two blocks, the second of which is centred at y; the third block, $B(y')$, remains fine. The seam bond s is kept in the datum, p is the transport from s to y', and $f_{\mathfrak{G}}$ is the one-site factor of $\mathfrak{G}_k$. Let $V^+(c)$ be the coarse variable on $c = \langle y, y'\rangle$. Then the integral of the step can be computed exactly:

$$\Phi = f_{\mathfrak{G}}\big(V^+(c)\,\mathsf{p}^{-1} V(s)^{-1}\big).$$

Under the node-wise gauge group of the datum, this integral fails to be invariant. Let a transformation be g at the centre y and $\mathbf{1}$ at all remaining end points of bonds of the datum, the end of

s among them. It changes the integral into $f_{\mathfrak{G}}(gV^{+}(c)\mathsf{p}^{-1}V(s)^{-1})$. The integral is invariant under the action in which the end of s moves with the centre of its block, and with respect to this action the tree insertion is a valid identity. Under the node-wise action, Φ has gauge average equal to the constant 1. The procedure of Prop. 3.23 therefore produces the bare slice measure, not Φ times that measure, and in this case the insertion is not an identity. If s is integrated together with its block, then $\int dV(s)\Phi = 1$, and nothing remains to vary. ∎

Proofs. *Averaging.* Every covariance property follows from the identity $\log(TXT^{-1}) = T(\log X)T^{-1}$. Each expression under a logarithm is conjugated at a single site (c_- for $\log W_x$). The norms are gauge invariant, and so therefore is the choice of rule. For Lem. 3.1, in the chart $V = e^{Y}V_1$ the means are exactly the fixed points of the map $Y \mapsto Y + \frac{1}{n}\sum_i \log(V_i V_1^{-1} e^{-Y})$.

Denote this fixed-point map by Φ. For explicit radii, put $d = \operatorname{diam} V_\bullet \le 1/40$ and $T_i = V_i V_1^{-1}$. On $|Y| \le 1/8$ one has $|T_i e^{-Y} - 1| \le (1+d)e^{1/8} - 1 < 1/6$. The exponential series and the logarithmic resolvent identity give

$$\operatorname{Lip}(\Phi) \le d + (1+d)(e^{1/8}-1) + \tfrac{1}{5}(1+d)e^{1/8} < \tfrac{2}{5}, \qquad |\Phi(0)| \le \frac{d}{1-d}.$$

Thus Φ maps this closed ball into itself and its fixed point satisfies $|Y_*| \le (5/3)d/(1-d) \le 2d$. Its iterates from zero converge uniformly, which proves holomorphy in the family on the open diameter domain. For determinant-one inputs the iterates are traceless: every logarithmic argument has determinant one and lies within $1/6$ of one, so the trace of its series logarithm is zero. For unitary inputs they are also anti-Hermitian. The constructed mean therefore belongs to G^c, and to G on real inputs.

To prove uniqueness among all admissible real means, let $V' \in G$ be any mean and put $Z_i = V_i V'^{-1}$. Then $|Z_i - 1| < 1$, $\sum_i \log Z_i = 0$, and $|Z_i - Z_1| \le d$. For unitary A, B with $|A-1|, |B-1| < 1$, the identity

$$\log A - \log B = \int_0^1 (1 + t(A-1))^{-1}(A-B)(1+t(B-1))^{-1}\,dt$$

implies $|\log A - \log B| \le 2|A-B|$. Indeed each resolvent has norm at most $(1-t/2)^{-1}$, since the real parts of the eigenvalues of A and B exceed $1/2$, and $\int_0^1 (1-t/2)^{-2}\,dt = 2$. Consequently

$$|\log Z_1| = \left| \frac{1}{n}\sum_i (\log Z_1 - \log Z_i) \right| \le 2d < \tfrac{1}{8}.$$

With $Y = -\log Z_1$ we have $V' = e^{Y}V_1$; its mean equation says precisely $\Phi(Y) = Y$. Hence $Y = Y_*$ and $V' = \operatorname{av}(V_\bullet)$. All constants above are independent of the number of family members.

Under a conjugation that is not unitary, diameters change by at most $\operatorname{cn}(T)$. The isometry r permutes the centred blocks and the families $\mathcal{G}$, but it carries a comb to a comb in a different order. This is why Bałaban's first average, built on cornered blocks and combs, needed to be symmetrised. Lem. 3.2 (lattice homotopy): each interchange of two steps in a path costs one plaquette. The contours sweep out $O(L^2)$ plaquettes, and this determines $\operatorname{Dom}(c)$. In the comb gauge the bound increases with the size of the box, so small curvature yields a small potential only on boxes of bounded size. In the comb gauge one has $\mathcal{M}(e^{i\mathsf{a}}) = \exp(i\mathsf{Q}^{\mathrm{pl}}\mathsf{a} + O(|\mathsf{a}|^2))$. Since the contour terms σ cancel at the corners of p', the lattice Stokes formula yields

$$\sum_{c \in \partial p'} \pm(\mathsf{Q}^{\mathrm{pl}}\mathsf{a})(c) = L^{-4} \sum_{x \in B(y)} \sum_{p \subset S_x} \mathsf{a}(\partial p),$$

$S_x = p'$, with corner y, translated to x, L^2 plaquettes.

Consequently $\hat{\varpi}_n = \varpi(\mathcal{M}^n U)/\alpha_0(L^n\eta_k)^2$ satisfies $\hat{\varpi}_{n+1} \le \hat{\varpi}_n(1 + C\alpha_0 L^{-2(k-n)})$. Measured in its own scale, the curvature of level n is summable, and this outweighs the accumulation of k errors.

A single step (Prop. 3.5) is proved by universality and Cauchy bounds, whereas Bałaban computes $\mathsf{Q}(W_0)$ in closed form from the Campbell–Hausdorff formula. In the comb gauge everything reduces to finitely many holomorphic functions that depend on L alone, and hence $\mathcal{Q}^1 = \mathsf{Q}(W_0)\mathsf{a} + O(|\mathsf{a}|^2)$. At $W_0 = \mathbf{1}$ one has $\frac{1}{i}\log \mathsf{u} = \sigma + O(|\mathsf{a}|^2)$. Thus the block factors take away precisely the contour terms of Q^{pl}, and $\mathsf{Q}(\mathbf{1}) = \mathsf{Q}^{\mathrm{s}}$. The kernels of $\mathsf{Q}(W_0)$ and $\mathsf{S}(W_0)$ are holomorphic and coincide at $\mathbf{1}$, so they differ by $O(\varpi)$. The norms of S reduce to counting: there are $L^4 \cdot L$ pairs (x, b) for each coarse bond, each fine bond is contained in L segments, and every pair carries the weight L^{-4}. For k steps, the factorisation follows from covariance by induction. At a complex 1-form A, covariance under the G^c-valued v_n uses up part of the room in the domain, and it is applied with $\mathrm{cn}(v_n) = |v_n|\,|v_n^{-1}| \le 2$. Setting $t_n = \sup |\mathsf{a}_n|/L^n\eta_k$ and $\varpi_n = \varpi(W_{0,n})$, one has

$$t_{n+1} \le t_n(1 + C\varpi_n + CL^n\eta_k t_n),$$
$$\sum_n \varpi_n \le C\alpha_0,$$
$$\sum_{n<k} L^n\eta_k \le 2L^{-1}.$$

The recursion closes because $\|\mathsf{S}(W_{0,n})\|_{\mathrm{row}}$ does not exceed L, the ratio of the spacings, with no loss. This is the third gain of straightening. Since $\|\mathsf{Q}^{\mathrm{pl}}\|_{\mathrm{row}} \ge L + \frac{3(L^2-1)}{2L} > 2L$, a product of one-step bounds for the plain average grows geometrically in k. The derivative is bounded through column sums and Schur's test. When the plaquettes are complex, the real comb gauge does not work: at every level its error is as large as the bound itself, which gives only $1 + Ck\alpha_1$. The G^c-valued comb gauge of $\mathcal{M}^n\mathbf{U}$, whose condition number is $1 + C\alpha_1 L^n\eta_k$, gives $\varpi^c_{n+1} \le L^2\varpi^c_n(1 + C\alpha_1 L^n\eta_k)(1 + CL^2\varpi^c_n)$. The price of the non-unitary conjugation is therefore one factor per level, and these factors are summable. The determining sets are obtained by folding with reflections. The double block of order j beneath a bond of Γ_j lies in Ω_{j-1}. There the fields are, in the worst case, regular only in the next finer scale, and this costs one factor, a single time.

Intertwining: at a pure gauge $e^{i\mathsf{a}^w}W_0 = W_0^w$ one has $\mathsf{u}(W_0, \mathsf{a}^w) = w\,(\bar{R}_{W_0} w)^{-1}$. It is for the sake of this identity that $\bar{R}$ is defined as it is. Prop. 3.7 rests on a coupled recursion for the size of r_n and for its covariant difference, which the same geometric sums close. For products one has $|\mathsf{z}_{j+1}| \le |\mathsf{z}_j| + C(|\mathsf{z}_j| + \alpha L^{j+1}\eta_k)^2$, because the defect added at each step is quadratic in the variation within a block. This is the origin of the second condition in the definition of a class. Lem. 3.8: up to an error $C\varpi$, a bond inside a block is the quotient of two contour transports, and the average then determines the crossing bonds. The comparison is made factor by factor. Prop. 3.9: the constraint is solved to second order by means of the right inverse H_k. At a critical point under the constraint, $J(U) = Q_k^\sharp(U)^*\omega$ is in general not zero. It is the image of a Lagrange multiplier ω, whose size is that of the curvature of V. The extra term does not occur in abelian theories, and it gives rise to G_1, H_1 in § 3.12.1. Prop. 3.10 follows from the first identity together with $\mathcal{M}(\mathsf{r}U) = \mathsf{r}\mathcal{M}(U)$ and $(\mathsf{r}U)(\mathsf{r}y, \mathsf{r}x) = U(y, x)$. Prop. 3.11 is purely algebraic. Writing $\hat{u}_n = u\,v_n$, the axial condition at level n takes the form

$$\hat{u}_n(x) = \mathrm{Ad}(W_{0,n}(z, x))^{-1}[\hat{u}_{n+1}(z)\mathsf{u}_n(z)^{-1}\mathsf{w}_n^{\mathrm{rel}}(z, x)]$$

. This fixes u level by level, starting at the top and going down, and it yields $\bar{R}_{W_{0,n}}\hat{u}_n = \hat{u}_{n+1}$. Prop. 3.12: two chains of transports with common end points differ by the curvature that they enclose. At level n this is $O(\alpha_0 L^{-2(k-n)})$, so the differences form a geometric series. The transport t is unavoidable, because in each block the two schemes see a gauge transformation at two different sites. Prop. 3.13 follows from linearity and the Stokes formula, which give $\Theta = L^{-4}\sum_{x\in B(z)} L[\mathsf{f}^\Sigma(x_1 + L) - \mathsf{f}^\Sigma(x_1)]$, together with a count.

The transformation. Prop. 3.14 combines the definition of an image measure with a property of $\mathcal{M}$. The renormalisation transformations obey the semigroup law $\mathbf{T}^n\nu = (\mathcal{M}^n)_*\nu$, which relates different spaces. In physical units the symmetry group becomes smaller as k grows; in the units of the level it is the symmetry group of the unit lattice. Finite range does not survive, since $\mathbf{T}\rho_0$ couples all bonds. Reflection positivity is required of the bare measure only §§ 5.20 and 5.22, appendix A.6, § 5.24 and appendix A.6. Prop. 3.15: the variances are additive (taking a block mean divides by L^d, the rescaling multiplies by L^{d-2}, and the new kernel contributes $\mathfrak{a}^{-1}$). Nested backgrounds: backgrounds exist only over regular data, so minimising in two stages is not enough. The argument is instead as follows. A point that is critical on the larger fibre is critical on the smaller one, regularity improves in finer units, and uniqueness § 3.11 completes the proof. Because the argument involves critical points alone, it extends to complex data. The minimiser $\mathsf{H}B$ is the one given by the method of Lagrange multipliers. The delta kernel secures four things:

- closure under composition. Since $\mathcal{M}$ is non-linear, the composite of two soft kernels on G is not a function of W and $\mathcal{M}^2U$ alone.
- a single large term. The critical point does not depend on the coupling, the leading term is exactly $x_kA(U_{k+1})$, and terms produced at U_j can be evaluated at U_k at every later level.
- exact averages. Since $V_k = \mathcal{M}^kU$, a test on the block fields is a test on the bare field.
- no analytic loss. The mass $aQ^{\sharp *}Q^{\sharp}$ remains in G_k as a device, with $a > 0$ arbitrary.

The cost is that the fibre is curved. For the gauge fixing the opposite choice is made: it enters through a soft weight.

Prop. 3.16 (stochastic kernels, balance of masses). The mass, summed over the outcomes, is preserved by operations of three kinds. *Tests:* at any given state exactly one outcome takes the value 1. A test is counted as failed whenever the object it examines (a mean, a logarithm, a minimal orbit, a minimiser) is undefined, so every test is defined on all configurations. The domains and values of the real tests for the block average, regular critical orbit and unique attained minimum are Borel by the finite formulas for those objects in the measurability argument below. *Draws:* the kernel $\kappa_{\mathfrak{G}}(V,\cdot) = \int du\, \mathfrak{G}_k(V^u)\delta_{V^u}$. *Maps:* adjoining $\mathcal{M}(V_k)$, and forgetting a variable. No smallness is involved in any of this. The operation $\mathbf{R}$ draws the variables of a component afresh using the reference kernel specified below. Because of the partitions, single terms have only restricted symmetry. Only the totals at a base point are covariant under the full group W_4, which § 4.2 requires. Base points are required because the sum $\sum_{X\subset\Lambda_j}$ is not invariant and the cancellation against $b_jA(\varphi_j,\cdot)$ must be made at each point separately. When z lies one layer of $M\check{R}_j$-cubes inside Λ_j, the restricted pointed total differs from the unrestricted one by $O(e^{-\frac{1}{2}\kappa\check{R}_j})$.

Lem. 3.17: a compact group admits no dilation. Hence x_k *is* the normalisation of the kinetic term. Gauge invariance links the quadratic, cubic and quartic parts of the marginal term, so the renormalisations of the field strength and of the coupling are given by a single number. The substitution $\mathcal{A}_k = g_k\mathcal{A}_k^{\mathrm{s}}$ takes the place of the rescaling. Consequently there is no scaling transformation, no fixed point and no eigen-direction. The word "irrelevant" can then mean only a bound $O(\eta_{k-j}^{4+\alpha_{\mathrm{H}}})$ at regular backgrounds, where $\alpha_{\mathrm{H}} < 1$ is a Hölder exponent § 4.2. Level k is a problem on a unit lattice that carries a fine lattice of spacing $\eta_k \to 0$. Every estimate in § 3.11, § 3.12.1 must therefore hold uniformly in η_k. Lem. 3.17: the density itself does not change. Its exponent is always $-\beta A(U_k)$ together with the terms in their unrenormalised form. The point is which grouping of the terms admits uniform bounds:

- without grouping, the bound $\|E^{(j)}\| \le E_0$ yields no more than $CE_0\eta_k^{-4}|\mathbb{T}^{(k)}|$;
- the number $b = b_{k+1}$ by itself leaves a geometric sum over j;
- if the marginal terms are left among the corrections, they add up to c_0kA to leading order;
- once absorbed into x_k, they fix the next thresholds and g_{k+1}, the width of the following Gaussian.

The profiles φ_j keep track of the place at which step j was performed. In the constant, the contribution $-\frac{1}{2}(N^2-1)\log x_k$ for each free bond is the Jacobian of $\mathcal{A}_k = g_k B$. Laplace's method gives $z_{\mathfrak{G}} \approx C x_k^{-(N^2-1)/2}$. With four bonds per site, less one gauge direction, this gives $\mathsf{E}^{(j)}(T_\ell, T_\ell) = -(\frac{3}{2}(N^2-1)\log x_j + O(1))(|\mathbb{T}^{(j)}| - |\mathbb{T}^{(j+1)}|)$. The term $\log x_k$ in E_+ arises from the constants $\mathsf{E}^{(j)}(T_\ell, T_\ell)$, $k \le j < K$, which belong to the steps $k+1, \dots, K$ and remain owed in $\bar\rho_k = e^{-E}\rho_k$ (when $k = K$ no constant remains owed, and $E_+ = O(1)$). Over a large-field region, the constants differ by a volume factor $e^{C \log x_j \#_j(Z_{j+1})}$, and the small factors of §4.17.1.40 must outweigh it.

Prop. 3.18 (the division of the work among the parts). Each part supplies the following:

- § 3.11: the backgrounds;
- § 3.12.1: the propagators;
- § 4.5: the new $E^{(k+1)}$, by a polymer expansion under a criterion of Kotecký–Preiss type;
- § 4.2: the coupling and the bounds on the sums;
- §4.17.1.1: tests, regions and histories;
- §4.17.1.3: $\mathbf{R}$;
- §4.17.1.40: the large-field factor and stability;
- § 4.17: the terms that $\mathbf{R}$ leaves behind;
- §4.17.1.45: the order of the constants and the inductive form;
- § 5.2.1: the flow;
- § 5.2.2: independence from the label, the torus and the cutoff.

The last item rests on locality. A term localised in X is assembled from walks, potentials and tests within X. It therefore does not depend on the label, and, when X does not wrap around the torus, it depends on neither the torus nor the cutoff. The small-field half requires $g_j \le \gamma$. It also requires $-C \le x_i - x_j \le C(j-i)$ for $i \le j \le k$, because the analyticity radii of level j run with g_j and the radii of two levels must be comparable. For radii that do not run, no relation between the couplings is required; Bałaban's remark that asymptotic freedom is not assumed refers to this case. For the complete model, what is used is the lower half of asymptotic freedom. At the levels of creation $j \le k$ the small factors were deposited, and since $x_j \ge x_k - C$ one has $p_0(g_j) \ge c\, p_0(g_k)$. The terms $R^{(j)}$ carry the vacuum subtraction but no counterterm for the coupling, and they are marginal. On the support of the tests, the following bound holds for every $X \in \mathcal{D}_j$ that contains a site z of Ω_k and remains within cML^{k-j} of z in level-j units (a longer X satisfies $d_j(X) \ge cL^{k-j} - C$ and has only the bound $2g_j^{\kappa_0} e^{-\kappa d_j(X)}$; around a site of $\Omega_n \setminus \Omega_{n+1}$, $j \le n < k$, the right-hand side holds with n in place of k):

$$|R^{(j)}(X, U_k) - R^{(j)}(X, \mathbf{1})| \le C(d_j(X)+3)^2 (x_j/x_k)^2 \eta_{k-j}^4\, g_j^{\kappa_0} e^{-\kappa d_j(X)},$$
$$\sum_{j \le k} (x_j/x_k)^2 g_j^{\kappa_0} \le C g_k^{\kappa_0 - 2} :$$

these terms do not decrease as $k-j$ grows. Only the linear growth of x_j makes them summable, and it does so for $\kappa_0 > 6$. If one assumes no more than $x_j \ge x_k - C$, the sum can grow to order $k g_k^{\kappa_0}$. It is this summability that makes a counterterm for them unnecessary. It is also why aged R-terms change b_j by no more than $C\gamma^{\kappa_0 - C}$, so that $\lambda_\sharp > 0$ is preserved § 5.2.1. The upper half ensures that the thresholds of adjacent levels are comparable: $\varepsilon_{k+1} \le C\varepsilon_k$.

The large-field factor: the reasons for these forms. The fields at which a plaquette test fails do not form a small set for the measures contained in $\mathbf{T}_k(Z)$. They do form a small set for the Wilson weight, since $e^{-x_j A} \le e^{-c\, x_j \varepsilon_j^2} = e^{-c\, p_0(g_j)^2}$. Therefore, if no $\mathbf{R}$ has acted on a component X, the small factor that a failed plaquette test carries there is obtained from $\mathbf{T}_k(X)$ applied to $\chi\, e^{-A(x_k(\cdot), U_k)}$, and never from $\mathbf{T}_k(X)1$. This weight is evaluated at the background, which depends on the variables of all the components simultaneously. For this reason, bounds that are uniform in

the exterior variables do not combine multiplicatively. The phenomenon already occurs in measure theory. Take Lebesgue measure on $[0,\mathsf{l}]$ in each of two variables, $0<\epsilon\ll\mathsf{l}$, and $F=\mathbf{1}\{|\xi_1-\xi_2|<\epsilon\}$. Then

$$\sup_{\xi_2}\int F\,d\xi_1=2\epsilon,$$

$$\iint F\,d\xi_1 d\xi_2=2\epsilon\,\mathsf{l}-\epsilon^2\gg(2\epsilon)^2.$$

The remedy is a pointwise bound by a product of functions, each depending only on its own group of variables, the groups being disjoint, combined with Tonelli's theorem. The small factors come out as numbers from the Wilson sums near the creations, joined with a fixed fraction both of the Gaussian forms and of the kept gauge-fixing exponents. What remains of the weights is bounded by functions that no longer depend on the background. The supremum in M is placed under the integral for the same reason. The factor of X then becomes a function of ξ only, and the masses multiply. When a component has dropped out, the supremum is taken over the evaluations at ξ. These are the real configurations that are compatible with the stored variables and regular layer by layer, and at which every test listed by ω takes its recorded value, with one exception: the test whose failure turned X into a drop-out. They form a set fibred over ξ. A product set contains a flat $\mathbf{U}$, at which $e^{-A}=1$, so taking the supremum over it eliminates the Wilson weight. For a live component, a bound $e^{-c\,p_0(g_k)}$ does not reproduce itself, since a step without a creation costs $e^{+CM^4\check R_k^5(d'_k(Z)+1)}$. What is carried along is the credit. As long as nothing is created, linear sizes counted in cells decrease geometrically. At a drop of $\check R$ the two partitions coincide and nothing shrinks, and no two consecutive steps are both drops. The waiting lasts at most $\check R_j$ steps, unless two components join or a mark is set. In that case the waiting begins anew. In the count of §4.17.1.40, every joining is charged to a separate created cell belonging to it alone, and a mark sets one factor $e^{-p_0(g_t)}$ of its mass against the same $\check R_t^6$. Hence the costs still owed add up to at most $CM^4L^5\check R_j^6(d'_j(Z)+1)$. The $p_0(g_j)^2$ per cube deposited at the creation covers $\check R_j^6$ per cube, and the powers of $\log g^{-2}$ are chosen in this order. After $\mathbf{R}$ has acted, the mass bound is what is carried forward.

Three losses are made good:

- The expansions use up part of κ and of the radii. Cubes that are L times larger give back a factor of order L in the rate, and the curvature decreases by L^{-2} at each level. $\mathbf{T}$ reserves a surplus of this gain for $\mathbf{R}$, whose re-expansions consume that surplus and restore exactly κ, α_i.
- The marginal term is absorbed into x_k.
- $e^{-p_0(g_j)}$ is smaller than any power of g_j, but it is not a power of the spacing when $d=4$, so it cannot pay for all later steps. This is the reason for $\mathbf{R}$.

In the presence of large fields, $\log\rho_k$ is not a sum of local terms, and this is why the construction uses densities and sums over labels. Analyticity serves as a device. A single supremum bound on a complex domain stands in for bounds on all derivatives, and it is preserved under substitution, integration and taking logarithms.

Prop. 3.19 is § 4.5 carried out with parameters. The size of $\mathbb{P}^{(k)}$ is $g|B|^3$, and under the test $g|B|<\delta(\mathsf{t})$ this is $\le\delta(\mathsf{t})|B|^2$. The bracket of level j in $\{S\}$ is $O(\mathsf{q}_j^3\,\eta_{k-j}^{4+\alpha_{\mathrm H}})$. Here, as in Prop. 3.19, q_j is the quotient of the analyticity radii at level $k+1$ by those at level j, and it is $\le C(k+2-j)^{1/2}$ thanks to the comparability assumed there. In § 4.5 the quotient is taken with the output radii, which are larger than those of level $k+1$ by a fixed factor, and in that part it goes by the name of the ratio. What the remainders contribute to the increment b_j is a different quantity, even though § 4.2, §4.17.1.45, § 5.2.1 and § 5.2.3 write it with the same letter. Each Cauchy estimate taken

at a later background costs one power of q_j, up to the third, and on radii that do not run there is no such loss. Applied to a shift of size δ, Cauchy's estimate produces s, and a cube of level k contains η_{k-j}^{-4} cubes of π_j. What is left at the age $n = k+1-j$ is $\mathsf{q}_j^3\,\eta_{k-j}^{\alpha_{\mathrm{H}}} \le C(n+1)^{3/2}L^{-\alpha_{\mathrm{H}}(n-1)}$, and these are the weights ω_n. The $H^{(j)}$ are marginal, and their sum is controlled only through their norms. If the raw local terms are taken without the counterterms b_jA, then $\{S\}$ contains $\sum_{j\le k} b_j\{A\} \approx c_0 k\{A\}$. In that case no bound holds uniformly in k, and the statement does not hold. Keeping t (which governs the tests, the gauge-fixing weight and the scaling) separate from x, the coefficient of A, comes at the price of a quadratic term proportional to $1 - x/\mathsf{t}$. In return it allows frozen choices § 5.2.3 and complex weights §5.20.1.1, appendices A.8 and A.9. Once the choices are fixed, the steps are fixed operations that are linear in the measure, and β enters only through the weight of the action.

Prop. 3.20: $\mathrm{GF}_k(V_k^{\mathrm{bg}}) = 0$. The linear term $x_k\langle \mathsf{H}_k\mathcal{A}', J(U_{k+1})\rangle$ vanishes on $Q_{V_k^{\mathrm{bg}}}\mathcal{A}' = 0$, since the current is the image of a Lagrange multiplier. Because the fibre is curved, the term $\langle \mathsf{H}_k \mathsf{h} C^{\mathrm{pl},(2)}(B), J\rangle$ remains, and it is included in $\Delta^{(k)}$. Hence $x_k A(U_{k+1})$ is the only place where a negative power of g_k occurs. The choices are made in the following order. b_{k+1} is obtained on the infinite lattice from the choices of level k, so x_{k+1}, ε_{k+1}, $\check{R}_{k+1}$ are fixed in advance of testing V_{k+1}. *The new tests imply the old:* on Ω_{k+1}, wherever the new functions are supported, the old ones take the value 1. By the nesting, $U_{k,\square} = (e^{i\eta_k \mathbf{H}} U_{k+1,\square'})^u$. Here $\mathbf{H}$ denotes the response of § 3.11 when the datum is shifted, the shift being $O(\delta_k)$ everywhere but in a boundary layer at a distance of order $M_2\check{R}_k$. Therefore

$$|\mathbf{H}|, |\nabla \mathbf{H}| \le C\big(\delta_k + e^{-\check{R}_k}\varepsilon_k\big) \le c\,\varepsilon_k,$$
$$|\partial U_{k,\square} - \mathbf{1}| \le 2\varepsilon_{k+1}\eta_{k+1}^2 + c\,\varepsilon_k\eta_k^2 < \varepsilon_k\eta_k^2 :$$

so χ_k passes into χ_{k+1}. This holds because the new threshold is smaller by the factor $L^{-2}\varepsilon_{k+1}/\varepsilon_k \le CL^{-2}$ (by the upper half of the flow inequalities, thresholds of neighbouring levels remain comparable), and because $\delta_k = (A_1/A_0)\varepsilon_k \ll \varepsilon_k$ (both carry the same power of the logarithm, and their ratio is small and fixed). Likewise every indicator in $\mathfrak{G}_k$ is equal to 1, and χ_k' follows from $\chi^{(k)}$. Since the local backgrounds are so close to the global ones, the tests can be carried out on local objects, which factorise, while the expansions are made around global ones. *The split:* an aged $R^{(j)}$ has each of its cubes inside a single block, its total transforms covariantly under the isometries of $\mathbb{T}^{(k+1)}$, and it is counted together with $\mathbf{E}_k$. For a young one this is not so, and a young one may not be admitted to the family from which b_{k+1} is computed. The t_1-integral, which comprises boundary terms, the part of the coupling that depends on position, and the strip term $\mathsf{W}^{(k)}$, contributes only to $B^{(k+1)}$. The t_2-integral takes the expectation of the young terms in a measure which itself contains them. Consequently at least one factor $g_j^{\kappa_0}$ appears in every term of its expansion, and this integral contributes to both $R^{(k+1)}$ and $B^{(k+1)}$. The third term contains only regular terms. A further interpolation makes it independent of the exterior fluctuation field, and the resulting contribution goes to $B^{(k+1)}$. Its cluster expansion then produces, for $X \subset \Lambda_{k+1}$, the pure small-field integral's terms, $E^{(k+1)}$, and in addition boundary terms. b_{k+1} is computed from this symmetric remainder. Thus a contribution to $R^{(k+1)}$ comes from $\mathbf{T}$ already, ahead of the one that $\mathbf{R}$ adds. Prop. 3.21: iterating the Stokes formula of Prop. 3.4 gives the first display. When a standard Gaussian vector is conditioned on the value of a linear map, its conditional expectation projects orthogonally onto the complement of the kernel of that map, and its components in mutually orthogonal subspaces are independent. The slice is a Schur complement, and $\mathcal{H}_{j-1}$ transports it. The only property of it that has to be analysed is its decay, and this is the analysis of § 3.12.1 at $\mathbf{1}$.

Gauges. Lem. 3.22 is Stokes' formula on a tree. Because of the factor $|b_- - y_P|$, boxes have side $O(M)$ and $M\varepsilon_k$ has to be small; that is, the coupling is taken small after M. Lem. 3.22 is a descent through the levels, with increments $C\alpha_0 \sum_i L^{-2i}$. Prop. 3.23 follows from Fubini's theorem and the invariance of Haar measure. No determinant arises, because the gauge function is a group variable translated by $u(x)$. The mean is used because single combs break W_4. The constraint is taken soft because fixing the mean by a delta function imposes a non-linear restriction which couples all the bonds of the paths to one another and has no explicit solution. The weight is x_k, and with this weight

$$x_k \,\mathrm{GF}_k(e^{ig_k B} V_k^{\mathrm{bg}}) = \tfrac{1}{2} \sum_{y,x} \left[|B(y,x)|^2 + O(g_k |B|^3) \right]$$

is of order one. Here $g_k B(y,x)$ denotes the linear part in B of $\frac{1}{i}\log$ applied to the mean $(e^{ig_k B} V_k^{\mathrm{bg}})(y,x)$, and when $V_k^{\mathrm{bg}} = \mathbf{1}$, $B(y,x)$ coincides with the mean of $B(\Gamma)$ taken over $\mathcal{G}(y,x)$. This quantity is strictly positive on each direction $D\lambda$ with $\lambda|_{\mathrm{coarse}} = 0$ (on these $|B(y,x)| = |\lambda(x)|$), and these directions exhaust the null directions of the Hessian. The weight itself is auxiliary: the first identity of Prop. 3.23 yields an identity for every choice of weight, so the weight may be frozen § 5.2.3 and need not depend on the source §5.20.1.1. *Procedure and product:* the insertion, taken as a draw, is exact on any measure, and on invariant measures it agrees with the written product. A term with stored fields is invariant. Indeed, the distance from P'' to Z_k is $\geq cM\check{R}_k$. Hence every transformation over P'' can be lifted to a bare transformation which is constant on pillars and equal to $\mathbf{1}$ near Z_k, the region where all stored quantities enter. In the case of the trees of §4.17.1.3, the stored fields are acted on by the group via the tops of their pillars. The exact model Prop. 3.31 shows that this verification is not idle: the group that acts is decided by whether or not the seam bonds lie in the determining set. The removal identity shows that dropping δ_T from the density gives an equivalent density, not an equal one: the two coincide when integrated against invariant functions.

Lem. 3.24: in the pillars, U and U_0 have the same contour variables. Hence $W(y,x)U_0(y,x)^{-1} = u(y)^{-1}\,\mathrm{Ad}(U_0(y,x))u(x)$, and the block factor n_W becomes the definition of $u^{-1}\bar{R}_{U_0}u$. This is Bałaban's deeper reason for imposing the axial gauge first and for keeping a single contour variable throughout (with two of them, circulations of A survive in the linear part). *Origin of R:* the term sought is Feynman's $\|\partial^* A\|^2$, but only the $\lambda \in N(Q')$ leave $\delta(B - Q^\sharp A)$ unchanged. Put $N = \ker Q'$, equipped with the induced physical inner product and its Lebesgue measure $d\lambda_N$. In the two gauge integrals below we integrate with this measure on N. The Faddeev–Popov quotient with gauge parameter α_{g} is

$$e^{-\frac{1}{2\alpha_{\mathrm{g}}}\|\partial^* A\|^2} \Big/ \int_N d\lambda_N \, e^{-\frac{1}{2\alpha_{\mathrm{g}}}\|\partial^* A - \Delta\lambda\|^2} = \mathrm{const} \cdot e^{-\frac{1}{2\alpha_{\mathrm{g}}}\|R\,\partial^* A\|^2}.$$

In a real background, let $E_R = \mathrm{ran}\, R$ carry its induced physical inner product, and let δ_{E_R} be its unit delta distribution. The restriction $T = \Delta_{U_0}|_N : N \longrightarrow E_R$ is a bijection; its absolute determinant is $J_T = \det(T^*T)^{1/2}$, with the determinant taken on N. Then

$$e^{-\frac{1}{2}\langle A, \Delta_\pi A\rangle} = J_T \int_N d\lambda_N \, \delta_{E_R}(RD^*A - T\lambda)\, e^{-\frac{1}{2}\langle A - D\lambda, \Delta^{\mathrm{W}}(A - D\lambda)\rangle}.$$

The change of variables $y = T\lambda$ evaluates the integral at $\lambda_* = T^{-1}RD^*A$, with factor J_T^{-1}, and the definition of Δ_π gives the identity. The determinant here is the Landau gauge's Faddeev–Popov determinant, and axial gauges have no such determinant. In normalised expressions such as $\mathsf{H}_k B$ it cancels; in Gaussian normalisers it does not. In the one-loop coefficient § 4.2, § 5.2.1 it enters together with the determinant of the gauge-fixed Hessian. Positivity (Lem. 3.24): consider $U = \mathbf{1}$

(the remaining cases are perturbations of it). A gradient $\partial\lambda$ ($\partial = D_{\mathbf{1}}$) is detected by $Q^\sharp$ if $\partial Q'\lambda \neq 0$, and by $R\,\partial^*$ otherwise, since in that case $\lambda \in N(Q')$ once a constant is subtracted. The full DD^* is positive as well, but admissible transformations cannot reach $D^*A = 0$, and with the full operator $\mathsf{G}Q^{\sharp *}(Q^\sharp \mathsf{G} Q^{\sharp *})^{-1}$ is no longer the minimiser of the Hessian. $RD^*\mathsf{G}Q^{\sharp *} = 0$ requires the invariant extension Δ_π, which is a perturbation of size $CM\alpha_0$. (Bałaban's G_0 is defined by the form of the statement, and his G goes with the identity. Adding the term of Prop. 3.9 gives G_1. The three satisfy the same bounds, with the exception of the one with the covariant Laplacian, and they coincide where $J = 0$.)

Prop. 3.26 (elliptic regularity through $\mathsf{G}_k(U_0)$): both currents, each smaller than α_0, give $D^*DA = \mathcal{J}$ with $|\mathcal{J}|_{(-3)} \leq 2\alpha_0 + C\alpha_2|\nabla A|_{(-2)} + \dots$. The averages give $\xi Q^\sharp A = B - C(A) =: \mathsf{b}$ with $|C(A)| \leq C\alpha_2^2$ (Prop. 3.6 leaves a remainder that is of second order), and this accounts for the α_1 in the result and for the condition on α_2^2. Put $\Delta' = \Delta^{\mathrm{W}}_{U_0} - D^*D$; the plaquette Hessian comparison gives $|\Delta' A|_{(-3)} \leq C_L\alpha_0|A|_{(-1)}$. Use the fixed auxiliary row weights $a = \xi^{-2}$ in G_k for this estimate. On the slice,

$$A = \mathsf{G}_k(U_0)(\mathcal{J} + \Delta' A) + \mathsf{G}_k(U_0)Q^{\sharp *} a\xi^{-1}\mathsf{b},$$
$$\|A\|_1 \leq B_0\big(|\mathcal{J}|_{(-3)} + C_L\alpha_0|A|_{(-1)} + \sup|\mathsf{b}|\big),$$

where $a\xi^{-1} = \xi^{-3}$ for the chosen row weights. Since $|A|_{(-1)} \leq \|A\|_1$, absorption follows once $B_0C_L(\alpha_0 + \alpha_2) \leq \frac{1}{2}$. Prop. 3.25 (Bałaban's argument, written out for the scheme c) is proved by induction on k. On Ω_k the pair (A, u_1) of depth $k-1$ is a factor L worse; here u_1 denotes the explicit product from Prop. 3.11. One seeks $u = u_1 e^{i\lambda}$. By Campbell–Hausdorff, once the non-linear average has been straightened to $Q'\lambda = 0$,

$$\lambda = -G'RD^*A + G'R\,\mathfrak{N}_4(\lambda, D\lambda, A, D^*A),$$
$$|R\mathfrak{N}_4|_{(-2)} \leq CB_1(\alpha_0 + \alpha_1)\|\lambda\|_0,$$

and this is a contraction on complex λ in $\|\lambda\|_0$. (The bound is valid on the ball of radius $CB_1(\alpha_0 + \alpha_1)$, which contains the solution; within a ball of fixed radius the solution is unique.) Curvature and mismatch thus have to beat fixed norms for the chosen block and gap geometry. These norms do not grow with the depth. The new constant is of order LB_1, and Prop. 3.26 resets it to B_1; without this reset its growth in k is geometric. Uniqueness holds among small A, so no Gribov ambiguity arises. In § 3.11 the passage to the slice is redone for $\mathcal{M}$. There Brouwer's theorem replaces the contraction. It provides a pair, though not its uniqueness, and with it the bounds on $\|A\|_1$ and $|D^*DA|_{(-3)}$. For a sequence with layers, the induction is replaced by a single preliminary gauge followed by an ascent through the truncations $(\Omega_0, \dots, \Omega_j)$. Prop. 3.27: the cube is surrounded by a tower that descends to the bare scale. After passing to tower and box axial gauges, one applies the theorem to $(\mathbf{1}, U)$ within the scheme c. Only propagators at $\mathbf{1}$ enter, and this breaks the circularity with § 3.12.1. At complex fields we have $v = w^{-1}$ and $w(x) = \mathbf{U}(\Gamma_{y_\square, x}) = \Pi\, v_{\mathrm{r}}^{-1}$. Here Π is a product of factors $\exp(i\eta_k\, tA'(b)t^{-1})$, where each t is a unitary transport of U, so $\mathrm{cn}(v) = \mathrm{cn}(\Pi)$. The potential of the background inside a large-field box is obtained in §4.17.1.3 by the same sequence of steps: the box axial gauge, used for the average, beneath it the tower axial gauge, and then Landau. Every change of its gauge is compensated on the stored variables. Local gauges $\hat{k}_y$ on overlapping boxes are glued together by $k(x) = \mathcal{N}\big(\sum_y \chi_y(x)\hat{k}_y(x)\big)$, $\mathcal{N}(X) = X/\sqrt{\det X}$. In SU(2), a real combination of group elements close to one another is a positive number times a group element, and the map $\mathcal{N}$ is holomorphic.

Prop. 3.28: with weighted norms, or on complex balls, the induction incurs a loss at every level, and there is no reset. Instead one differentiates the identity of Prop. 3.26, with G_k bounded in the

sup norms that carry the weight $e^{\delta d(\cdot,y')}$. This is a single linear estimate and needs no induction. That the averages are trivial does not force u to be trivial at the nodes, and this gives rise to the node factor. Invariant functions do not detect it. At sites that carry stored fields but have ceased to be tops, n^{-1} is continued into each pillar by means of a smooth bump, and in this way the stored data are not acted on. Prop. 3.28: the objects are words in transports and logarithms, each typed at a site, and fixed points are covariant by uniqueness. Prop. 3.25 gives the uniqueness of its Landau pairs only in the scheme c; the set of these pairs is nevertheless covariant, since every one of the three defining conditions of a pair is covariant. The case of complex u follows by the identity theorem, because the G-valued u form a totally real submanifold of full dimension. Lem. 3.29 is a matter of covariance only: $(\mathcal{M}^i U^w)(y,x) = w(y)(\mathcal{M}^i U)(y,x)w(x)^{-1}$ with $w = \mathbf{1}$ at the nodes. Prop. 3.30: the equation becomes $\lambda = G'(f - RD^*A) + G'R\,\mathfrak{N}_4$, whose inhomogeneity is of the size of the other terms. Bałaban states that the remaining proofs carry over with only minor changes. However, $\Delta_{U_0}A - D^*DA$ equals $Df + D(1-R)D^*A$ up to curvature terms, so the bounds of the theorem force $|Df|_{(-3)} \le C(\alpha_0 + \alpha_1)$. On the other hand, $|Df|$ is of order $\eta_k^{-1}|f|$ for $f = \Delta\lambda$ with $\lambda \in N(Q')$ oscillating at the bare spacing. Prop. 3.31: the contour variables of a block are coordinates that preserve Haar measure. All the integrals except one give $\int f_{\mathfrak{G}} = 1$, and the remaining one, $\int dt\, f_{\mathfrak{G}}(t)\, \delta(tV(s)\mathsf{p}V^+(c)^{-1})$, is the display. In four dimensions the same occurs at each coarse site whose block contains an end of a seam bond.

Routine and delicate. Routine are the algebra of means, of logarithms and of covariance, the exact identities, Stokes' formula and the Haar identities. The delicate points are the following:

- uniformity in k, which is reached solely via the straightened average, and only because curvature and potentials are measured on the scale of each level;
- complex arguments, where each use of covariance costs room in the domain;
- the two averages, together with the invariances of the constraints they impose, which have to be kept apart;
- normalisation by averages instead of pointwise normalisation, the group property that is lost, and the node factor that is left over;
- the junctions of layers;
- the invariance of whatever an insertion encounters after fields have been stored.

For the construction as a whole, the difficulty lies in the words "with the same constants".

3.2. **Nonlinear averaging and the Wilson energy.** The four-dimensional normalization of the contour average gives an almost-contraction of the Wilson energy. Its leading constant is one. This matters when the average is repeated: a fixed larger constant at each step would grow with the number of levels. We prove the estimate for the symmetric contour map in eq. 2.iv, using its near-identity means as in [B85a].

Work first on a periodic lattice of spacing one. Its side lengths are divisible by a fixed odd integer $L \ge 3$. The coarse sites form $L\mathbb{Z}^4$, and $B(y) = y + \mathcal{B}$ is the translated centred block of L^4 fine sites belonging to y. A translated choice of the block origins gives the same proof. Each independently oriented fine plaquette is counted once. For a real SU(2) configuration W, write

$$F_p = -i \log \partial W(p), \qquad \varepsilon(W) = \max_p |F_p|, \qquad A(W) = \sum_p \Big(1 - \tfrac{1}{2}\operatorname{Tr} \partial W(p)\Big). \tag{3.i}$$

The logarithms are the small branches. Lie algebra norms use $\langle X, Y\rangle = \frac{1}{2}\operatorname{Tr}(XY)$, so $1 - \frac{1}{2}\operatorname{Tr} e^{iF} = 1 - \cos|F|$. All constants below can depend on L, and none depends on the fine spacing, number of blocks or number of averaging steps.

Proposition 3.32 (One averaging step)**.** There are $\varepsilon_L > 0$ and $C_L < \infty$ such that $\varepsilon(W) \le \varepsilon_L$ admits every local contour mean and logarithm defining $\mathcal{M}(W)$, and

$$\varepsilon(\mathcal{M}(W)) \le L^2 \varepsilon(W) + C_L \varepsilon(W)^2, \tag{3.ii}$$

$$A(\mathcal{M}(W))^{1/2} \le (1 + C_L\varepsilon(W))A(W)^{1/2}. \tag{3.iii}$$

These estimates hold for real fields. No critical-point equation or inverse Hessian estimate is required. ■

3.2.1. *The linear flux weights.* Let a be a Lie algebra one-cochain. If $t_a(y,x)$ denotes the mean of its line integrals over the prescribed shortest contour paths, differentiation of the actual contour formula at the identity gives, for $c = (y, y + Le_\mu)$,

$$\begin{aligned}(Qa)_\mu(y) &= L^{-4} \sum_{x\in B(y)} \sum_{i=0}^{L-1} a_\mu(x + ie_\mu) + h_a(y) - h_a(y + Le_\mu),\\ h_a(y) &= L^{-4} \sum_{x\in B(y)} t_a(y,x).\end{aligned} \tag{3.iv}$$

Indeed the logarithm of a product has, at the identity, the sum of the logarithmic increments. The derivative of a symmetric mean of nearby transports is their arithmetic mean. The central straight transport in the contour formula cancels its copy inside the averaged logarithm. The two endpoint transports give the displayed coarse gradient of h_a.

The curl of this gradient vanishes. The remaining straight transports bound an L-by-L plaquette, so exact discrete Stokes gives

$$(\mathrm{d}_c Qa)_{\mu\nu}(y) = L^{-4} \sum_{x\in B(y)} \sum_{i,j=0}^{L-1} (\mathrm{d}a)_{\mu\nu}(x + ie_\mu + je_\nu) = \sum_p T_{C,p}(\mathrm{d}a)_p. \tag{3.v}$$

Here $C = (y, \mu, \nu)$ is a coarse plaquette, and $T_{C,p}$ is zero for other fine orientations. Every coefficient is nonnegative. Its row and column sums are exactly

$$\sum_p T_{C,p} = L^2, \qquad \sum_C T_{C,p} = L^{-2}. \tag{3.vi}$$

The row sum counts L^4 starting sites and L^2 plaquettes per surface, each with weight L^{-4}. For the column sum fix a fine plaquette and its orientation. In each of its two coordinate directions, each of the L choices of surface offset determines one block residue and one coarse origin. In the transverse directions the block residue determines the coarse origin uniquely. There are therefore L^2 representations, with total weight L^2L^{-4}. This count also holds modulo the periodic side lengths, with multiplicity.

More generally let $O_{C,p}$ be arbitrary orthogonal color matrices. Cauchy–Schwarz and eq. 3.vi imply

$$\sum_C \left| \sum_p T_{C,p} O_{C,p} f_p \right|^2 \le L^2 \sum_{C,p} T_{C,p}|f_p|^2 = \sum_p |f_p|^2. \tag{3.vii}$$

Thus independent local gauge frames do not change the leading constant. In dimension d the same argument gives norm $L^{2-d/2}$; it equals one in dimension four.

3.2.2. *Local gauges and the nonlinear remainder.* For each coarse plaquette C, choose a rectangular fine box D_C containing all paths in its four contour averages, with a fixed additional layer. Its side lengths are at most cL. The family of these boxes has bounded overlap. If a box crosses a periodic seam, perform this construction on a lift to the covering lattice. Path identities and the following overlap counts include the resulting periodic multiplicities.

Choose a coordinate comb tree in D_C, rooted at the initial vertex of C, and gauge its edge transports to one. Write the resulting local field as $W_b^{u_C} = e^{ia_b}$. There are constants depending

only on L such that

$$\max_{b\subset D_C}|a_b|\le C_L\varepsilon(W),\qquad \left(\sum_{b\subset D_C}|a_b|^2\right)^{1/2}\le C_L\left(\sum_{p\subset D_C}|F_p|^2\right)^{1/2}. \tag{3.viii}$$

Enlarge D_C by another fixed layer if needed for the plaquettes in the right side.

Here are finite proofs of these bounds. A remaining edge, together with its two comb paths, forms a loop. Move the coordinate steps of one path past those of the other, cancelling immediate backtracks. Each interchange inserts one elementary plaquette, conjugated by a prefix transport. There are at most C_L such interchanges. This gives an exact product of conjugated plaquette holonomies for $W_b^{u_C}$. All factors and conjugating transports are unitary, and $\|1-\prod_i V_i\|_{\mathrm{op}}\le\sum_i\|1-V_i\|_{\mathrm{op}}$. The small logarithm has a uniformly bounded derivative near one. Consequently $|a_b|\le C\sum_p n_{b,p}|F_p|$, where the nonnegative integers $n_{b,p}$ belong to a finite matrix of bounded row and column sums depending only on L. Its Schur bound gives the second inequality in eq. 3.viii; its row bound gives the first.

These same local charts admit the actual means. For finitely many nearby transports V_i, the defining equation $\sum_i\log(V_iV^{-1})=0$ has derivative minus the number of transports times the identity in the logarithmic coordinate of V, at the identity. The analytic implicit function theorem therefore gives a unique small mean on a fixed ball. There are only finitely many local patterns for fixed L. Decrease ε_L so that eq. 3.viii places all their transports in these balls. Gauge covariance of the mean follows from uniqueness and conjugation of the small logarithm. Means constructed in different local gauges therefore give the same original coarse transport.

Let $F_p^{(C)}=\mathrm{Ad}(u_C(p_-))F_p$. Taylor's formula for the fine plaquette logarithm on this local chart gives

$$F_p^{(C)}=(\mathrm{d}a)_p+r_p(a),\qquad \left(\sum_{p\subset D_C}|r_p(a)|^2\right)^{1/2}\le C_L\varepsilon(W)\left(\sum_{p\subset D_C}|F_p|^2\right)^{1/2}. \tag{3.ix}$$

For clarity, the Taylor remainder of one plaquette is bounded by $C\max_b|a_b|\sum_{b\subset\partial p}|a_b|$ on this fixed matrix ball. Sum its square, use the bounded incidence of edges and plaquettes, and apply eq. 3.viii. This proves the displayed estimate, including its dependence on the curvature rather than merely on the number of edges.

The coarse plaquette logarithm is an analytic function of the same finite list a, vanishes at zero, and has derivative $(\mathrm{d}_cQa)_C$ by eq. 3.iv. Its Taylor remainder has the bound

$$|r_C^{\mathrm{av}}(a)|\le C_L\max_b|a_b|\left(\sum_{b\subset D_C}|a_b|^2\right)^{1/2}.$$

Indeed the second derivative is bounded on a smaller fixed analytic ball, and the equivalence of the finite-dimensional norms costs only a constant depending on L. Substitute eq. 3.ix in eq. 3.v. After conjugating the coarse logarithm back, this gives

$$F_C^{\mathrm{av}}=\sum_p T_{C,p}O_{C,p}F_p+R_C,\qquad |R_C|\le C_L\varepsilon(W)\left(\sum_{p\subset D_C}|F_p|^2\right)^{1/2}, \tag{3.x}$$

Here the sum keeps separate the fine plaquette occurrences in the chosen lift of D_C. Each $O_{C,p}$ is an adjoint rotation and hence orthogonal. If several lifted occurrences project to the same physical plaquette, their rotations need not agree. In the global column sum group their scalar weights, retaining the separate rotations in the flux sum. The resulting physical column weight is still L^{-2}, and every row weight is still L^2. Thus the coefficients are exactly the weights of eq. 3.v, with their periodic multiplicities; no nonlinear coefficient replaces either leading sum.

Proof of Prop. 3.32. The row bound in eq. 3.vi and the finite size of D_C give eq. 3.ii from eq. 3.x. Bounded overlap and eq. 3.vii give

$$\left(\sum_C |F_C^{\mathrm{av}}|^2\right)^{1/2} \le (1 + C_L\varepsilon(W)) \left(\sum_p |F_p|^2\right)^{1/2}. \tag{3.xi}$$

The scalar Taylor estimate

$$\tfrac{1}{2}t^2(1 - Ct^2) \le 1 - \cos t \le \tfrac{1}{2}t^2$$

holds for small real t. Apply the upper estimate to the coarse field and the lower estimate to the fine field. Absorbing $(1 - C\varepsilon(W)^2)^{-1/2}$ in $1 + C_L\varepsilon(W)$ proves eq. 3.iii. □

3.2.3. *Iteration without a loss in the number of levels.*

Corollary 3.33 (An all-depth energy bound)**.** There is $\alpha_L > 0$ such that, for every integer $k \ge 0$ and every lattice admitting k block averages, the condition

$$\varepsilon(U) \le \alpha L^{-2k}, \qquad 0 < \alpha \le \alpha_L, \tag{3.xii}$$

admits all the near-identity branches used in those averages and implies

$$\varepsilon(\mathcal{M}^j U) \le 2\alpha L^{-2(k-j)} \quad (0 \le j \le k), \qquad A(\mathcal{M}^k U) \le 2A(U). \tag{3.xiii}$$

■□

Proof. Write $\varepsilon_j = \varepsilon(\mathcal{M}^j U)$. The first recurrence of Prop. 3.32 gives

$$\varepsilon_{j+1} \le L^2\varepsilon_j(1 + C_L\varepsilon_j/L^2).$$

Suppose the curvature bound in eq. 3.xiii holds up to a given level. Up to that level,

$$\sum_{j<k} \varepsilon_j \le 2\alpha \sum_{s\ge 1} L^{-2s} = \frac{2\alpha}{L^2 - 1}.$$

Iterating the recurrence therefore bounds $\varepsilon_j/(\alpha L^{-2(k-j)})$ by $\exp[2C_L\alpha/(L^2(L^2-1))]$. Choose α_L so that this is strictly less than two and $2\alpha_L < \varepsilon_L$. The first possible failure of the curvature bound is then impossible, and every mean used at the next level is admitted.

Iterate eq. 3.iii, retaining its leading constant one. It gives

$$A(\mathcal{M}^k U)^{1/2} \le \exp\left(C_L \sum_{j<k} \varepsilon_j\right) A(U)^{1/2} \le \exp\left(\frac{2C_L\alpha}{L^2 - 1}\right) A(U)^{1/2}.$$

Decrease α_L so that the last exponential is at most $\sqrt{2}$. Squaring proves the energy assertion. □

For example, if $\nu(p) \ge \nu_* > 0$ and one coarse plaquette obeys $\|1 - \partial\mathcal{M}^k U(C)\|_{\mathrm{op}} \ge a$, then

$$A(\nu, U) \ge \nu_* A(U) \ge \tfrac{1}{4}\nu_* a^2. \tag{3.xiv}$$

The last inequality uses $1 - \frac{1}{2}\operatorname{Tr} V = \frac{1}{2}\|1 - V\|_{\mathrm{op}}^2$ for $V \in \mathrm{SU}(2)$, and eq. 3.xiii. This is a global one-event certificate under eq. 3.xii. Several history events require disjoint ownership or a bounded-overlap allocation of the action. A field containing an unregularized old core does not satisfy the hypotheses of this corollary.

3.3. **The block average and its pivot chart.** The finite calculation here concerns the actual centered one-step average. Its definition uses an implicit group mean for each internal contour transport, followed by the exponential of an arithmetic mean of closed logarithms for the block bond. We use both operations. The calculation proves the local pivot and quadratic-remainder estimates; it does not prove a many-level background theorem or an exterior-force estimate.

The exact finite map. Work on a unit-spacing lattice in dimension four, with odd $L \geq 3$. The block at a coarse site y is $B(y) = \{x : |x-y|_\infty \leq (L-1)/2\}$. For a positive coarse bond $c = (y, y+Le_\mu)$, put $y' = y + Le_\mu$ and $D_c = B(y) \cup B(y')$. On a torus we assume that this double block and its one-bond neighborhood have an embedded rectangular lift preserving their unit bond graph, with no periodic edge joining opposite faces of the patch. A sufficient condition for a cubic torus is that its period exceeds $4L+4$. All bonds used below have both endpoints in D_c, with the rectangular bond graph of this lift.

For $x \in B(y)$, let $\mathcal{G}(y,x)$ be the shortest paths which complete one coordinate displacement before starting the next. There are at most 24 such paths, each of length at most $2L$. Repeated paths, if retained, are counted with their prescribed equal weights. The transport along an oriented path is the ordered product of its bond matrices; reversed bonds use the inverse matrix. For nearby matrices $T_1, \dots, T_n$, define their contour mean as the solution near them of

$$\frac{1}{n}\sum_{j=1}^{n} \log(T_j T^{-1}) = 0. \tag{3.xv}$$

All logarithms below are the local analytic logarithm near the identity. Set

$$U(y,x) = \operatorname{av}\big(U(\Gamma) : \Gamma \in \mathcal{G}(y,x)\big), \qquad U(x,y) = U(y,x)^{-1}. \tag{3.xvi}$$

With $x' = x + Le_\mu$, the actual block map is

$$\begin{aligned} Z_x(U) &= U(y,x)U([x,x'])U(x',y')U[c]^{-1}, \\ \mathcal{M}(U)(c) &= \exp\left[L^{-4}\sum_{x\in B(y)} \log Z_x(U)\right] U[c]. \end{aligned} \tag{3.xvii}$$

Here $[x,x']$ and $[c]$ are straight segments of length L. In particular, the outer operation in eq. 3.xvii is not the implicit mean eq. 3.xv. The cruder Borel definitions of the block map away from this analytic neighborhood do not enter the calculation.

For a background V, let $W = \mathcal{M}(V)$. In physical bond logarithms, with no scale factor in the exponential, put

$$q_{V,c}(a) = \frac{1}{i}\log\left[\mathcal{M}(e^{ia}V)(c)\mathcal{M}(V)(c)^{-1}\right]. \tag{3.xviii}$$

The matrices $a(b)$ are complex traceless 2 by 2 matrices, and their norm is the supremum of the operator norms over positive bonds. On real variables they are Hermitian. All constants denoted C, c below are universal; their values may be enlarged or decreased at successive occurrences.

The contour mean, with quantitative bounds. The elementary matrix inequalities

$$\|e^X - I - X\| \leq \tfrac{1}{2}e^{\|X\|}\|X\|^2, \qquad \|\log(I+H) - H\| \leq \frac{\|H\|^2}{2(1-\|H\|)} \tag{3.xix}$$

hold for $\|H\| < 1$, by the power series and submultiplicativity. They show, on a fixed small ball, that

$$\begin{aligned} \log(e^X e^{-Z}) &= X - Z + E(X,Z), \\ \|E(X,Z)\| &\leq C(\|X\| + \|Z\|)^2, \\ \|D_Z E(X,Z)\| &\leq C(\|X\| + \|Z\|). \end{aligned} \tag{3.xx}$$

For the derivative estimate one can differentiate the convergent logarithm series term by term and use $De^Z[H] = \int_0^1 e^{(1-t)Z} H e^{tZ}\, dt$. The derivative of each remainder in eq. 3.xix is bounded by a constant times the radius. Thus the constants in eq. 3.xx depend on no number of contour paths.

Write $T_j = e^{X_j}$, with $\max_j \|X_j\| \leq t$, and seek $T = e^Z$. eq. 3.xv is equivalent to

$$Z = \overline{X} + \frac{1}{n}\sum_j E(X_j, Z), \qquad \overline{X} = \frac{1}{n}\sum_j X_j. \tag{3.xxi}$$

For a fixed sufficiently small t, the right side maps $\|Z\| \le 2t$ into itself and has Lipschitz constant at most $1/2$. Iteration from $\overline{X}$ proves existence and uniqueness there. It also proves $Z = \overline{X} + O(t^2)$, uniformly in n. The iterates are holomorphic in all X_j, and convergence is locally uniform on a slightly smaller fixed ball. Their limit is therefore holomorphic. Trace zero is preserved in eq. 3.xxi. For anti-Hermitian X_j, anti-Hermiticity is preserved as well, so the mean lies in SU(2) on real group inputs.

Uniqueness proves permutation symmetry and left-right covariance. Indeed under $T_j \mapsto uT_jv$, with $T \mapsto uTv$, every logarithm in eq. 3.xv is conjugated by u, whenever the transformed families remain in their analytic domains. The inverse property follows from $\log(T_j^{-1}T) = -\mathrm{Ad}(T^{-1})\log(T_jT^{-1})$. Thus the locally constructed mean is the mean in eq. 3.xvi, including families centered at a unitary matrix other than I.

Local gauges do not constrain coarse holonomies. For a real background V_0 on D_c, put $\varpi_c = \sup_{p\subset D_c}\|\partial V_0(p) - I\|$. There is a unitary gauge s_c on this rectangle such that

$$\sup_{b\subset D_c}\|V_0^{s_c}(b) - I\| \le CL\varpi_c. \tag{3.xxii}$$

Here $V^s(b) = s(b_-)V(b)s(b_+)^{-1}$. To prove eq. 3.xxii, fix a coordinate-order comb from y to every site of the rectangle and set $s_c(x) = V_0(\Gamma_{y,x})$. For any bond b, the product $s_c(b_-)V_0(b)s_c(b_+)^{-1}$ is its comb loop. Slide the additional bond past the later coordinate segments of the comb. Each slide exchanges two adjacent perpendicular steps and inserts one plaquette, conjugated by a partial transport. There are at most CL slides, since every coordinate interval in the rectangle has length at most $2L$. All these conjugations are unitary. The norm of a product of such plaquette factors minus I is at most the sum of their deviations, proving eq. 3.xxii.

The same gauge, fixed from the real background, works for $V = e^{iE}V_0$: its distance from I is at most $C(L\varpi_c + \|E\|_\infty)$, when these quantities are small. More generally we can start directly with a unitary local gauge in which

$$\sup_{b\subset D_c}\|V^{s_c}(b) - I\| \le \epsilon. \tag{3.xxiii}$$

Different double blocks may use different gauges. We never require one gauge close to I on an entire observation window.

The group mean and eq. 3.xvii are gauge covariant. The internal transport transforms with its two endpoint factors; each Z_x transforms by conjugation at y. Consequently

$$q_{V^{s_c},c}(a^{s_c}) = \mathrm{Ad}(s_c(y))q_{V,c}(a), \qquad a^{s_c}(b) = \mathrm{Ad}(s_c(b_-))a(b). \tag{3.xxiv}$$

All these adjoint actions have norm one. A coarse bond value $\mathcal{M}(V)(c)$ in the original gauge may be anywhere in SU(2). It is the ratio in eq. 3.xviii, rather than that coarse bond itself, whose logarithm is taken near I. Nontrivial coarse holonomies therefore cause no loss in these local estimates.

Uniform Taylor estimates for the actual average. We first work in the gauge eq. 3.xxiii, so $V = e^{iv}$ with $\|v\|_\infty \le C\epsilon$. If $\|v\|_\infty, \|a\|_\infty < c_0/L$, every path product entering eq. 3.xvi stays in a fixed small neighborhood of I. For example, a product of N factors, each within t of I, is within $e^{CNt} - 1$ of I. Its reversed factors satisfy the same bound. Here the internal paths have $N \le 2L$. The contour-mean estimate just proved applies, and the closed products in eq. 3.xvii, of total path length at most $6L$, are also in a fixed logarithm neighborhood. The outer logarithm average is normalized by L^{-4}; its size is bounded by its largest summand, without a factor L^4.

It follows that

$$F_c(v,a) = \frac{1}{i}\log\left[\mathcal{M}(e^{ia}e^{iv})(c)\mathcal{M}(e^{iv})(c)^{-1}\right] \tag{3.xxv}$$

is holomorphic and bounded by a universal constant on the joint supremum balls of radius c_0/L. It vanishes at $a = 0$. This establishes the domain before any derivative estimate. On balls a fixed

fraction smaller, two scalar Cauchy formulas give

$$\|D_a F_c\|_{\infty\to\mathrm{op}} \le CL, \qquad \|D_a^2 F_c\| + \|D_v D_a F_c\| \le CL^2. \tag{3.xxvi}$$

For example, for unit supremum directions u, w, apply Cauchy to $F_c(v, a + zu + tw)$, with both scalar circles of radius c/L. This proves the mixed bilinear bound without dividing the radius by the number of bond coordinates.

Let $K_V = Dq_V(0)$ and $R_V(a) = q_V(a) - K_V a$. Taylor's formula with integral remainder gives

$$\begin{aligned} \|K_V\|_{\infty\to\infty} &\le CL, \\ \|R_V(a)\|_\infty &\le CL^2 \|a\|_\infty^2, \\ \|DR_V(a)\|_{\infty\to\infty} &\le CL^2 \|a\|_\infty. \end{aligned} \tag{3.xxvii}$$

for $\|a\|_\infty < c/L$ and $\epsilon < c/L$. The estimates transfer to the original frame by eq. 3.xxiv. They are uniform over all coarse bonds, hence over the volume. In addition, varying the background in eq. 3.xxvi gives

$$\|Dq_{e^{iv}}(0) - Dq_I(0)\|_{\infty\to\infty} \le CL^2 \|v\|_\infty. \tag{3.xxviii}$$

These are estimates for the explicit nonlinear average in eq. 3.xvii, not for a model linear average.

The pivot coefficient and finite elimination. Write $h = (L-1)/2$. The pivot of $c = (y, y + Le_\mu)$ is $b_0(c) = (y + he_\mu, y + (h+1)e_\mu)$. It crosses from $B(y)$ to $B(y')$. No internal contour path contains it. Among all coarse pivots, only $b_0(c)$ occurs in the support of $q_{V,c}$. Indeed internal contours stay inside one block; each straight segment in eq. 3.xvii crosses only the face between these two blocks and is parallel to e_μ. The only coarse pivot on that face is $b_0(c)$. This support assertion, rather than a claim about all bonds joining two vertices of a periodic double block, is what is used below.

At the identity background define $\overline{a}(y, x)$ to be the arithmetic mean of the oriented path sums of a over $\mathcal{G}(y, x)$, and $\sigma_a(y) = L^{-4} \sum_{x\in B(y)} \overline{a}(y, x)$. The first derivative of the contour mean is this arithmetic mean. Differentiating eq. 3.xvii, the negative derivative of $U[c]$ in each closed logarithm cancels its final positive derivative. Thus

$$(K_I a)(c) = \sigma_a(y) + L^{-4} \sum_{x\in B(y)} a([x, x']) - \sigma_a(y'). \tag{3.xxix}$$

The two σ_a terms contain no pivot. Exactly L segments in the remaining sum contain $b_0(c)$: their transverse coordinates equal those of y, and their longitudinal starting coordinate can be any of the L coordinates in the block. All occurrences have positive orientation. Therefore

$$J_c(I) := D_{a(b_0(c))} q_{I,c}(0) = L^{-3} I_3. \tag{3.xxx}$$

For a pure gauge $V^s = I$, the coefficient in its original frame is

$$J_c(V) = L^{-3} \operatorname{Ad}(s(y)^{-1} s(b_0(c)_-)). \tag{3.xxxi}$$

The unitary matrix in this formula is the prefix transport from y to the start of the pivot. Replacing it by I in the original gauge would be incorrect.

From eq. 3.xxviii, after the unitary local change of frame, we have $\|J_c(V^{s_c}) - L^{-3} I_3\| \le CL^2\epsilon$. Consequently, under the conservative condition

$$\epsilon \le cL^{-5}, \qquad \text{in particular if} \quad \|E\|_\infty + L\varpi_c \le cL^{-5}, \tag{3.xxxii}$$

every J_c is invertible and $\|J_c^{-1}\| \le 2L^3$. There is no off-diagonal pivot coefficient. Set

$$(h_V \nu)(b_0(c)) = J_c^{-1} \nu(c), \qquad (h_V \nu)(b) = 0 \ (b \text{ nonpivot}), \qquad \mathsf{C}_V = \iota - h_V K_V \iota, \tag{3.xxxiii}$$

where ι extends the nonpivot coordinates by zero. Then

$$K_V h_V = 1, \quad K_V \mathsf{C}_V = 0, \quad (\mathsf{C}_V u)|_{\mathrm{free}} = u, \qquad \|h_V\| \le 2L^3, \quad \|\mathsf{C}_V\| \le CL^4. \tag{3.xxxiv}$$

These are supremum operator norms. The same powers bound column norms. Indeed a fine bond belongs to at most a fixed number of double blocks, and eq. 3.xxvi bounds the coefficient in each of

their rows. The maps are local: a pivot row uses only its own double block. They are holomorphic in the background, by the Neumann series for J_c^{-1}.

For comparison with a convention which inserts a/L in the one-step exponential, its linear average is $Q_V = K_V/L$, and its pivot coefficient is

$$\mathsf{m}_c = J_c/L, \qquad \mathsf{m}_c(I) = L^{-4} I_3, \qquad \det J_c = L^3 \det \mathsf{m}_c. \tag{3.xxxv}$$

This accounts for the factor L^{-3} in a real elimination Jacobian; it is not a change in the number of color coordinates.

The nonlinear graph, constructed rather than assumed. For a full physical bond variable t, solve

$$d = R_V(t - h_V d), \qquad \Psi_V(t) = t - h_V d(t). \tag{3.xxxvi}$$

On $\|t\|_\infty < r_1 = cL^{-5}$, eq. 3.xxvii maps the ball $\|d\|_\infty \le CL^2\|t\|_\infty^2$ into itself, after choosing its fixed prefactor large enough. Its Lipschitz constant in d is at most $CL^5 r_1 < 1/2$. Iteration proves the unique solution, its holomorphic dependence, and

$$\begin{aligned} q_V(\Psi_V(t)) &= K_V t, & \|d(t)\| &\le CL^2\|t\|^2, \\ \|D_t d(t)\| &\le CL^2\|t\|, & \|D\Psi_V(t) - 1\| &\le CL^5\|t\|. \end{aligned} \tag{3.xxxvii}$$

The derivative estimate follows by differentiating the contraction and inverting $1 + DR_V h_V$ by its convergent Neumann series. Only the pivot values are changed. There is even an explicit inverse, on a smaller neighborhood: $\Psi_V^{-1}(a) = a + h_V R_V(a)$. Substitution in eq. 3.xxxvi verifies this formula by uniqueness.

Each equation for $d(c)$ uses only its own pivot value and the nonpivot data in D_c. The equations for different coarse bonds are independent once the nonpivot data are fixed. Thus the graph is exactly finite range, not merely exponentially local. In particular

$$a(u) = \Psi_V(\mathsf{C}_V u), \quad q_V(a(u)) = 0, \quad a(u)|_{\mathrm{free}} = u, \qquad \|u\|_\infty < cL^{-9} \tag{3.xxxviii}$$

is the actual small fibre chart. It obeys $\|a(u)\|_\infty + \|D_u a(u)\|\|u\|_\infty \le CL^4\|u\|_\infty$. Conversely, any sufficiently small solution of $q_V(a) = 0$ has this form: $t = a + h_V R_V(a)$ satisfies $K_V t = 0$, hence $t = \mathsf{C}_V(a|_{\mathrm{free}})$, and eq. 3.xxxvii gives uniqueness.

For the canonical Gaussian coordinate $u = gy$, the physical chart therefore contains $\|y\|_\infty < cL^{-9}/g$. At weak coupling it contains any radius $c_*\alpha/g$ with fixed c_* and sufficiently small α. This establishes the one-step primitive radius; inclusion in all the older background domains remains a different estimate.

Real coarea normalization and complex continuation. We record the normalization only on the real positive chart first. Let $\mathcal{E}, \mathcal{C}, \mathcal{F}$ be the fine positive bonds, coarse positive bonds and nonpivots, respectively. Thus $|\mathcal{F}| = |\mathcal{E}| - |\mathcal{C}|$. In real Lie algebra coordinates Haar measure is $d(e^{ia}) = \sigma(a) d^3a$, where $\sigma(a) = \sigma_0(\sin|a|/|a|)^2$ and $\sigma_0 > 0$. Group delta in the same chart satisfies $\delta_G(e^{iq}) = \sigma_0^{-1}\delta_{\mathbb{R}^3}(q)$.

In the linear variables $t = \mathsf{C}_V u + h_V v$, free coordinates are u and $K_V t = v$. Its determinant is $\prod_c \det J_c^{-1}$. The full straightening $a = \Psi_V(t)$ has derivative close to the identity by eq. 3.xxxvii. At real backgrounds, the determinants $\det J_c$ are positive: in the local unitary frame J_c is within half of the positive scalar matrix $L^{-3} I_3$, and the real adjoint frame transformations have determinant one. Also $\det D\Psi_V > 0$, by continuity from its value one at zero and the uniform derivative bound. The ordinary real change of variables therefore gives, on the fibre,

$$\begin{aligned} &\prod_{b\in\mathcal{E}} dU_b \prod_{c\in\mathcal{C}} \delta_G(\mathcal{M}(U)(c) W(c)^{-1}) \\ &\quad = \sigma_0^{|\mathcal{F}|} \prod_c (\det J_c)^{-1} \det D\Psi_V(\mathsf{C}_V u) \prod_{b\in\mathcal{E}} \frac{\sigma(a_b(u))}{\sigma_0} \prod_{b\in\mathcal{F}} d^3u_b. \end{aligned} \tag{3.xxxix}$$

This is an identity of local fibre measures, with the group delta interpreted by this change of coordinates. The straightening derivative is block triangular: its free block is the identity, and its pivot diagonal has one three by three block per coarse bond. Hence its log determinant is a sum of local trace logarithms. Substituting $u = gy$ in eq. 3.xxxix supplies $(\sigma_0 g^3)^{|\mathcal{F}|}$, while $(\det J_c)^{-1} = L^{-3}(\det \mathsf{m}_c)^{-1}$.

For complex backgrounds the coefficient functions in eq. 3.xxxix have their coherent holomorphic continuations on the chart just constructed. In particular $(\det J_c)^{-1}$ and the branch of $\log\det J_c$ continuing its real value are used, not an absolute value of a complex determinant. The Haar density is continued by the entire power series $\sigma_0[\sin\sqrt{z}/\sqrt{z}]^2$, $z = \frac{1}{2}\operatorname{tr} a^2$, rather than by a complex operator norm. No complex measure or complex delta function is being asserted by this continuation.

Dependence on the remaining scales. The average, its raw Taylor constant CL^2, and the local pivot construction contain no M, observation radius or number of free variables. If the supplied local near-pure-gauge bound is only $\|V^s - I\| \le C_b M a$, eq. 3.xxxii requires $a \le c/(C_b M L^5)$. Alternatively the direct real condition $\varpi_c \le cL^{-6}$, with a small complex perturbation, suffices. The input-to-chart constants are conservative fixed powers of L; no claim of optimal powers is needed.

If only a complex gauge with condition numbers at most $K \ge 1$ is available, conjugation charges one factor K per input direction and one for the output. Thus safe bounds are CK^3L^2 for the quadratic residual, $2K^2L^3$ for h_V, and CK^4L^4 for C_V. The conservative physical nonpivot radius becomes $cK^{-9}L^{-9}$. A condition number growing with a larger window must therefore be charged; it cannot be discarded by calling the one-step chart local.

The calculation discharges the one-step pivot and Taylor primitives in these actual physical coordinates. It does not bound the many-level response or a further coordinate transformation on a large run window. In particular, a polynomial loss in that window radius in the background/core inclusion must still be retained in a later Cauchy radius. The free precision gap, the all-window core and tower estimates, the conditional exterior forces and the clean-class law remain separate assertions.

3.4. **A gap for the classical flat precision.** The gauge form in this section is the actual soft contour gauge. It is not a divergence projector. At the flat field its quadratic form is the sum of the squares of the arithmetic internal contour path sums. The constraint is the plain derivative of the nonlinear block average, rather than the straight average alone. With these operators the classical flat precision has a gap uniform in the torus volume and in the number of finer averaging levels.

The statement concerns the unweighted Wilson action at a flat background, with its prescribed positive soft gauge coefficient. Signed counterterms, nonconstant layer weights, nonzero-current constraint corrections and complex decoupling matrices are not included in the conclusion.

The actual quadratic forms and their normalization. Use raw bond logarithms on a unit-spacing four-dimensional lattice. For a scalar site function f and a positively oriented bond field a, set

$$\begin{aligned}(\mathrm{d}f)_\mu(x) &= f(x+e_\mu) - f(x),\\ (\mathrm{d}a)_{\mu\nu}(x) &= a_\mu(x) + a_\nu(x+e_\mu) - a_\mu(x+e_\nu) - a_\nu(x).\end{aligned} \tag{3.xl}$$

The same convention, with step n, is written d_n on a lattice of spacing n. Norms are counting ℓ^2 norms of sites, positive bonds or plaquettes, with each unordered direction pair counted once. One color suffices for the proof; the flat SU(2) forms are three identical copies.

The Wilson convention $A(U) = \sum_p[1 - \frac{1}{2}\operatorname{Re}\operatorname{tr} U_p]$ gives $A(e^{ita}) = \frac{1}{2}t^2\|\mathrm{d}a\|^2 + O(t^3)$. For the actual soft gauge,

$$\mathrm{GF}(V) = \sum_y \sum_{x\in B(y)\setminus\{y\}} [1 - \tfrac{1}{2}\operatorname{Re}\operatorname{tr} V(y,x)]. \tag{3.xli}$$

Here $V(y,x)$ is the implicit mean of the transports along the coordinate-order internal paths. Its first derivative at the identity is the arithmetic mean of the corresponding oriented path sums. Denote this linear functional by $\gamma_{y,x}(a)$, and put $(Ga)_{y,x} = \gamma_{y,x}(a)$. Consequently

$$\mathrm{GF}(e^{ita}) = \tfrac{1}{2}t^2\|Ga\|^2 + O(t^3). \tag{3.xlii}$$

Internal paths contain no crossing pivot. Thus the gauge form on nonpivot variables is local to each block and has no pivot coordinate. For a gradient, $\gamma_{y,x}(\mathrm{d}f) = f(x) - f(y)$.

The physical step uses the scale $g = \theta^{-1/2}$ and gauge weight θ. For the real unweighted step the action coefficient is also θ. Hence $\theta g^2 = 1$, and the two quadratic forms above have coefficient one in the canonical Gaussian variables. Normalizing constants and the Haar Jacobian belong to other parts of the step; they do not change this definition of its free precision.

Plain and straight averaging. For odd n, let $B_n(y)$ be the centered block of n^4 sites. The raw straight bond average is

$$(S_n a)_\mu(y) = n^{-4} \sum_{x \in B_n(y)} \sum_{t=0}^{n-1} a_\mu(x + te_\mu). \tag{3.xliii}$$

At one step define $\sigma(a)(y) = L^{-4}\sum_{x\in B_L(y)} \gamma_{y,x}(a)$. Direct differentiation of the actual outer exponential of closed logarithms gives the plain derivative

$$P_L a = S_L a - \mathrm{d}_L \sigma(a). \tag{3.xliv}$$

The derivative of its reference straight segment cancels its negative occurrence in every closed logarithm. This explains why no extra reference-segment term is present in eq. 3.xliv.

Let $q_L f$ be the arithmetic site average over $B_L(y)$, and $r_L f = f|_{\text{block centers}}$. Telescoping along paths proves

$$S_L \mathrm{d}f = \mathrm{d}_L q_L f, \qquad \sigma(\mathrm{d}f) = q_L f - r_L f, \qquad P_L \mathrm{d}f = \mathrm{d}_L r_L f. \tag{3.xlv}$$

In particular it is restriction at the centers, not a site average, that intertwines with the plain constraint.

Write $P^{[k]}$ for the derivative at the identity of the plain k-fold nonlinear average, with raw logarithms at both ends. For $n = L^k$,

$$P^{[k]} a = S_n a + \mathrm{d}_n \psi_k(a) \tag{3.xlvi}$$

for a linear site functional ψ_k. Here is a direct verification. Composition of the straight averages equals S_{nL}: in each coordinate the centered digits $nr + u$, with $r \in \{-(L-1)/2, \dots, (L-1)/2\}$ and $u \in \{-(n-1)/2, \dots, (n-1)/2\}$, tile the larger centered block, and the segment indices $nt + j$, $0 \le t < L$, $0 \le j < n$, tile the longer straight segment. All weights multiply to $(nL)^{-4}$. Applying the next plain step to the gradient in eq. 3.xlvi gives another coarse gradient by eq. 3.xlv. Its application to $S_n a$ differs from the next straight average by a gradient, by eq. 3.xliv. This proves eq. 3.xlvi inductively, starting with eq. 3.xliv.

Curvature averaging is a contraction in dimension four. Expanding the boundary of an n by n square gives

$$(\mathrm{d}_n S_n a)_{\mu\nu}(y) = n^{-4} \sum_{x \in B_n(y)} \sum_{r,s=0}^{n-1} (\mathrm{d}a)_{\mu\nu}(x + re_\mu + se_\nu). \tag{3.xlvii}$$

Every interior bond cancels in this expansion; its four remaining sides are exactly the four straight averages in $\mathrm{d}_n S_n$. Call the positive averaging operator on plaquettes on the right T_n. Each row has sum n^2. Each fine plaquette has total column weight n^{-2}: for each pair (r,s) its starting point determines exactly one block $B_n(y)$, since those blocks partition the fine sites. There are n^2 such pairs, each with weight n^{-4}.

For nonnegative weights t_{Pp}, weighted Cauchy gives

$$\sum_P \left|\sum_p t_{Pp}F_p\right|^2 \le \sum_P \left(\sum_p t_{Pp}\right)\left(\sum_p t_{Pp}|F_p|^2\right) \le n^2 n^{-2}\sum_p |F_p|^2. \tag{3.xlviii}$$

Thus $\|T_n\|_{2\to 2} \le 1$. Counting with multiplicities makes the same proof valid on a periodic lattice. The product of row and column sums in dimension d would be n^{4-d}; its cancellation here uses dimension four. Taking curls of eq. 3.xlvi therefore proves the exact uniform bound

$$\|\mathrm{d}_n P^{[k]} w\| \le \|\mathrm{d}w\|. \tag{3.xlix}$$

No bound on a background propagator was used.

The classical constrained pullback. For current bond data a, on the level-k lattice, define the classical flat quadratic value

$$E_k(a) = \min\{\|\mathrm{d}w\|^2 : P^{[k]}w = a\}. \tag{3.l}$$

The affine set is nonempty. For instance place the value of a coarse bond on every fine bond crossing its block face and put zero on fine bonds internal to a block of side $n = L^k$. The nonlinear group lift with internal bonds I has exactly the prescribed average: all parallel segments cross the same face value and all closed logarithms vanish. Applying this observation successively through the centered subdivisions gives the same assertion at k levels. Its derivative is a right inverse for $P^{[k]}$.

Existence of the minimum in eq. 3.l needs no uniform inverse theorem. The image under d of the finite-dimensional affine constraint set is a closed affine subspace; its point nearest zero exists. Equivalently, quotient $\ker P^{[k]} \cap \ker \mathrm{d}$, restrict to its orthogonal complement, and solve the positive finite-dimensional normal equations there. This also shows that the minimum is a quadratic form in a. Its construction at this stage has no claimed uniform inverse bound. eq. 3.xlix, applied to every admissible lift, gives

$$E_k(a) \ge \|\mathrm{d}_n a\|^2. \tag{3.li}$$

We henceforth express the current lattice in units of its own spacing, so the curl on the right is written $\mathrm{d}a$.

This is the classical action part of the actual flat precision. Indeed the first variation of the bare action at the identity is zero. A differentiable exact background lift has a tangent w with $P^{[k]}w = a$; its action Hessian is $\|\mathrm{d}w\|^2$, because its second derivative is multiplied by that zero first variation. Linearized constrained stationarity makes this tangent minimize the quadratic form in eq. 3.l, modulo its gauge null space. The same observation eliminates the second-order one-step constraint correction at a flat point. In particular, no nonzero-current correction has been dropped in establishing eq. 3.l at the flat point. The finite Gaussian form in eq. 3.l is defined without assuming a nonlinear background theorem; when that background is used, this argument identifies its flat quadratic pullback. Even an arbitrary exact differentiable lift would suffice for the lower bound in eq. 3.li.

Let C be the actual flat pivot inclusion, with identity on nonpivot coordinates. The physical flat free precision is characterized by

$$\langle u, A_k^{\mathrm{flat}} u\rangle = E_k(Cu) + \|GCu\|^2 \ge \|\mathrm{d}Cu\|^2 + \|GCu\|^2. \tag{3.lii}$$

This formula is for the actual contour gauge and the actual plain fibre. It is not obtained by substituting a Landau projection for G.

A fixed-cell Fourier calculation. Group the current lattice into blocks of side L. In one cell let $R = \{-(L-1)/2, \dots, (L-1)/2\}^4$. A bond is indexed by its starting site $r \in R$ and direction. There are $4L^4$ bond coordinates and four pivot coordinates. The free space consequently has dimension $4L^4 - 4$, independently of the volume. For a coarse Bloch parameter $p \in (\mathbb{R}/2\pi\mathbb{Z})^4$, extend a cell field by

$$a(Lm + r, \mu) = e^{ip\cdot m} a(r, \mu). \tag{3.liii}$$

The curl matrix d_p has entries which are constants or $e^{\pm ip_\mu}$. The internal-contour matrix G uses only edges within its cell, hence has no p dependence. The plain constraint matrix $P(p)$, obtained from eq. 3.xliv, is also a finite matrix with such phase entries.

The middle pivot of direction μ is the crossing bond from he_μ to $(h+1)e_\mu$, $h=(L-1)/2$. At the identity its coefficient in the raw constraint is L^{-3}, since exactly L of the L^4 parallel segments contain it. There is no other pivot in that constraint. It is the own pivot in the cell of the coarse bond's start, so this coefficient has no Bloch phase. Thus the pivot block of $P(p)$ is $L^{-3}I_4$ for every p. If h_0 inserts L^3 on those pivots and ι inserts free coordinates with zero pivots, then

$$C(p)=\iota-h_0P(p)\iota,\quad P(p)C(p)=0,\quad C(p)|_{\mathrm{free}}=1,\quad \operatorname{Ran}C(p)=\ker P(p). \tag{3.liv}$$

The last equality follows by solving each pivot equation. It also proves the rank $4L^4-4$ for all p. All entries of $C(p)$ are continuous Laurent polynomials in the Bloch phases. This is the same finite-range pivot map as in the physical chart, evaluated at the flat field.

Define the Hermitian finite matrix

$$B(p)=C(p)^*(\mathrm{d}_p^*\mathrm{d}_p+G^*G)C(p). \tag{3.lv}$$

We prove that it has no zero vector for every p, including $p=0$. Suppose $a=C(p)u$ and $\mathrm{d}_pa=0$, $Ga=0$. Extend it by eq. 3.liii. Within a block, two coordinate-order paths to the same site differ by plaquette swaps. Zero curl makes their sums equal. The same swaps express a comb loop with one additional internal bond as a sum of internal plaquette curls. Consequently zero G forces every internal path sum, and then every internal bond, to vanish.

Across a face perpendicular to e_μ, a plaquette with one transverse step compares two neighboring crossing values. Its other two bonds are internal to the two blocks, hence zero. The crossing values are therefore equal. The transverse face grid is connected, so all crossing bonds on that face have a common value $\beta_{y,\mu}$. Every straight segment from $x\in B(y)$ to $x+Le_\mu$ then has sum $\beta_{y,\mu}$, and all internal contour sums are zero. The actual constraint gives $(P_La)(y,\mu)=\beta_{y,\mu}$. It vanishes by eq. 3.liv, killing every crossing bond as well. Thus $a=0$, and $u=0$ by its free restriction. The argument is valid for every real Bloch parameter, with complex fiber vectors.

One can also describe the possible closed fields explicitly. On the cell, the L^4 functions $L^{-2}\exp(i\xi_\ell\cdot r)$, $\xi_\ell=(p+2\pi\ell)/L$, form an orthonormal basis, where each component of ℓ runs from 0 to $L-1$. Orthogonality is the finite geometric-series identity. Fine differences multiply a mode by $t_\mu=e^{i\xi_{\ell,\mu}}-1$. The closedness equations are $t_\mu a_\nu-t_\nu a_\mu=0$. If one $t_\mu\neq0$, they say exactly $a=t\phi$, a gradient. The only remaining case is $p=0,\ell=0$, giving a constant harmonic vector. The local argument above kills that case as well; no zero-frequency mode has been silently omitted.

The entries of $B(p)$ are continuous on the compact Bloch torus. Its least Rayleigh quotient therefore has a positive uniform minimum $c(L)>0$. Explicitly, if the infimum were zero, a sequence of parameters and unit free vectors would have a convergent subsequence. Their limit would be a unit zero vector for the limiting $B(p)$, contradicting the previous paragraph. Thus

$$B(p)\geq c(L)1\qquad\text{for every } p. \tag{3.lvi}$$

On a torus with N_μ coarse blocks in each direction, the allowed parameters are $p_\mu=2\pi j_\mu/N_\mu$. The normalized discrete Fourier transform in the block index is unitary, again by the same geometric-series identity. It converts the comparison form on the right of eq. 3.lii into the sum of eq. 3.lv over these parameters. Parseval and eq. 3.lvi therefore prove

$$A_k^{\mathrm{flat}}\geq c(L)1 \tag{3.lvii}$$

on the actual free nonpivot coordinates, uniformly in the torus volume and in k. Local formulas can first be used on the admissible large tori; no small-torus identification of different pivots is needed. The three color copies have the same constant.

Flat holonomies and the limit of the conclusion. The same conclusion holds for a real flat background in its prescribed block axial representative. Flatness makes internal transports path independent. Since their means in this representative are I, every internal bond is I. Flat plaquettes make the crossing value constant on each block face. The background is therefore the lift of a flat coarse connection. A gauge constant on each block flattens it on the universal cover and preserves the soft contour gauge norm. Only twisted periodicity remains.

The four torus holonomies commute: their commutator is the product of the plaquettes of a fundamental rectangle, all equal to I. Commuting unitary matrices have a common orthonormal eigenbasis; choose an eigenspace of any noncentral holonomy and use its invariance under the others, or any basis if all are central. Their adjoint actions are consequently commuting unitaries on the complexified color space. Decomposing into their common eigenspaces gives characters $e^{i\chi_\mu}$. The allowed block momenta in that character are $(2\pi j_\mu + \chi_\mu)/N_\mu$, up to the sign convention for the boundary twist. The local matrices and the curvature averaging proof are unchanged: the boundary phases have modulus one, so the absolute row and column counts in eq. 3.xlviii still apply. Since eq. 3.lvi holds for every real Bloch parameter, all these shifted sets satisfy the same gap. No smallness of global holonomies is required.

The result proves the classical flat gap for the actual contour gauge and plain constraint. It is a lower bound, and does not prove a uniform upper bound or a decay estimate for a dressed precision. Nonzero-current terms from curved constraints, signed layer profiles, counterterm arrays, non-Abelian perturbations and enlarged complex decoupling parameters still need their own quantitative comparison with this positive flat form. No full background or interacting Gaussian-law assertion follows from eq. 3.lvii alone.

3.5. **An upper bound for the classical flat action.** This section concerns the same unweighted classical Gaussian value as the flat-gap calculation. Let $n = L^k$, with L odd, and let $P^{[k]}$ be the raw derivative of the actual plain iterated average. For a coarse bond field a, put

$$E_k(a) = \min\{\|\mathrm{d}w\|^2 : P^{[k]}w = a\}. \tag{3.lviii}$$

We construct an exact lift with energy at most $256\|\mathrm{d}_n a\|^2$, uniformly in k and in the volume. No bound on a non-Abelian background response is used.

Discrete interpolation on the actual centered grids. Fine sites are integers and coarse sites are nm, $m \in \mathbb{Z}^4$. Write

$$\varphi_n(t) = \max\{1 - |t|/n, 0\}, \qquad \beta_n(t) = \mathbf{1}_{\{0 \le t < n\}}, \quad t \in \mathbb{Z}. \tag{3.lix}$$

Periodize these functions on a finite torus. The identities $\sum_m \varphi_n(x - nm) = 1$, $\sum_m \beta_n(x - nm) = 1$, and $\sum_{x\in\mathbb{Z}} \varphi_n(x) = n$ follow by summing the two linear pieces. Also

$$\varphi_n(t+1) - \varphi_n(t) = n^{-1}\big[\beta_n(t+n) - \beta_n(t)\big]. \tag{3.lx}$$

Define interpolation of sites, bonds and plaquettes by

$$\begin{aligned}
(I_0 f)(x) &= \sum_m f(m) \prod_\lambda \varphi_n(x_\lambda - nm_\lambda),\\
(I_1 a)_\mu(x) &= n^{-1} \sum_m a_\mu(m)\beta_n(x_\mu - nm_\mu) \prod_{\lambda\neq\mu} \varphi_n(x_\lambda - nm_\lambda),\\
(I_2 F)_{\mu\nu}(x) &= n^{-2} \sum_m F_{\mu\nu}(m)\beta_n(x_\mu - nm_\mu)\beta_n(x_\nu - nm_\nu)\\
&\qquad \times \prod_{\lambda\notin\{\mu,\nu\}} \varphi_n(x_\lambda - nm_\lambda).
\end{aligned} \tag{3.lxi}$$

The coarse arrays in these formulas are indexed by their starting node m. Their values are raw bond or plaquette values; no length factor has been included in the coarse difference d_n. eq. 3.lx,

followed by reindexing m, proves

$$\mathrm{d}I_0 = I_1\mathrm{d}_n, \qquad \mathrm{d}I_1 = I_2\mathrm{d}_n. \tag{3.lxii}$$

For example, differentiating a transverse nodal hat in I_1 replaces it by the difference of two interval indicators divided by n; their coefficients are precisely the two terms of the corresponding coarse plaquette boundary. This proves the second identity with the same orientation as $(\mathrm{d}a)_{\mu\nu} = a_\mu + \nabla_\mu a_\nu - a_\mu(\cdot + e_\nu)$.

For a fixed plaquette direction, I_2 has nonnegative weights. Their row sum is n^{-2}, by the two partition identities. Their column sum is n^2: each interval contributes n fine positions, each of the remaining two nodal hats has sum n, and the prefactor is n^{-2}. Weighted Cauchy therefore gives

$$\|I_2F\|^2 \le n^{-2}n^2\|F\|^2 = \|F\|^2. \tag{3.lxiii}$$

These counting norms are those of the four-dimensional Wilson quadratic energy. As for curvature averaging, dimension four is used in the cancellation of the powers of n.

The exact averaging symbol. With centered blocks, the raw straight average is

$$(S_nw)_\mu(y) = n^{-4}\sum_{x\in B_n(y)}\sum_{j=0}^{n-1} w_\mu(x + je_\mu).$$

We compute S_nI_1 exactly to obtain a right inverse. Put $h = (n-1)/2$. In a transverse direction the coefficient of the neighboring coarse index m is $n^{-1}\sum_{x=-h}^{h}\varphi_n(x - nm)$. In the component direction it is $n^{-2}\#\{(x,j) : -h \le x \le h,\ 0 \le j < n,\ nm \le x + j < n(m+1)\}$. Both expressions are zero unless $m = 0, \pm 1$, and both have the same three values:

$$a_0 = 1 - \frac{h(h+1)}{n^2} = \frac{3}{4} + \frac{1}{4n^2}, \qquad a_1 = \frac{h(h+1)}{2n^2} = \frac{1-n^{-2}}{8} \quad (m = \pm 1). \tag{3.lxiv}$$

For the longitudinal count, the negative and positive overshoots each number $1+\cdots+h = h(h+1)/2$; the remaining $n^2 - h(h+1)$ pairs give the central coefficient. For the transverse hat, its positive-side and negative-side linear sums give the same two triangular numbers.

Let T_λ translate a coarse array by one node in direction λ. The tensor product in eq. 3.lxi and the identical one-dimensional coefficients just computed show

$$S_nI_1 = \mathcal{A}_n, \qquad \mathcal{A}_n = \prod_{\lambda=1}^{4}[a_0I + a_1(T_\lambda + T_\lambda^{-1})]. \tag{3.lxv}$$

Crucially, this is the same scalar convolution on all four bond components. Each one-dimensional symbol is

$$a_n(t) = \frac{3}{4} + \frac{1}{4n^2} + \frac{1-n^{-2}}{4}\cos t, \qquad \frac{1}{2} \le a_n(t) \le 1. \tag{3.lxvi}$$

Fourier transform on the coarse torus, or the quadratic-form bound $a_0 - 2a_1 \ge 1/2$ for a unitary shift, proves

$$\|\mathcal{A}_n^{-1}\|_{2\to 2} \le 16. \tag{3.lxvii}$$

All shifts commute. Their scalar convolution commutes with every coarse difference, on sites, bonds and plaquettes. Its inverse has the same property.

An exact lift for the plain constraint. For prescribed coarse a, take $w_0 = I_1\mathcal{A}_n^{-1}a$. eq. 3.lxii, eq. 3.lxiii, eq. 3.lxv and eq. 3.lxvii imply

$$S_nw_0 = a, \qquad \|\mathrm{d}w_0\| \le \|\mathrm{d}_n\mathcal{A}_n^{-1}a\| \le 16\|\mathrm{d}_na\|. \tag{3.lxviii}$$

This is an exact straight lift. The actual constraint is plain. For completeness its two relevant identities are

$$P^{[k]}w = S_nw + \mathrm{d}_n\psi_k(w), \qquad P^{[k]}\mathrm{d}f = \mathrm{d}_n(r_nf), \tag{3.lxix}$$

where r_n restricts a fine site function to the centers $n\mathbb{Z}^4$. At one step these follow by differentiating the actual closed-logarithm formula: $P_L = S_L - \mathrm{d}_L\sigma$, and on gradients an internal contour is $f(x) - f(y)$, so $P_L\mathrm{d}f = \mathrm{d}_L r_L f$. Iterating proves the second identity. Composition of straight averages is S_n; applying a plain average to a gradient again gives a gradient, proving the first by induction.

Nodal interpolation satisfies $r_n I_0 f = f$. Set

$$f = -\psi_k(w_0), \qquad w = w_0 + \mathrm{d}I_0 f. \tag{3.lxx}$$

Then eq. 3.lxviii–eq. 3.lxix give $P^{[k]}w = a$ exactly, while $\mathrm{d}w = \mathrm{d}w_0$. The gradient correction has no classical curvature cost. The energy estimate itself needs no amplitude bound; such a bound is proved below. We have proved

$$E_k(a) \le 256\|\mathrm{d}_n a\|^2. \tag{3.lxxi}$$

The complementary lower bound follows from the exact curvature average: $\mathrm{d}_n P^{[k]}w = T_n\mathrm{d}w$, where T_n has row sum n^2 and total column weight n^{-2}. The same weighted Cauchy argument gives $\|T_n\| \le 1$. Thus

$$\boxed{\|\mathrm{d}_n a\|^2 \le E_k(a) \le 256\|\mathrm{d}_n a\|^2}. \tag{3.lxxii}$$

All statements include $n = 1$, where the interpolations and $\mathcal{A}_1$ are identities. No zero-frequency inverse is taken: $\mathcal{A}_n$ itself is strictly positive even on constants.

Consequences and scope. For the actual flat free nonpivot precision, $\langle u, A_k^{\mathrm{flat}}u\rangle = E_k(Cu) + \|GCu\|^2$. The local pivot basis has counting ℓ^2 norm at most CL^4, from its row and column bounds. Also $\|\mathrm{d}\|^2 \le 24$ on one-forms in four dimensions. The internal contour matrix has row sum at most CL and column sum at most CL^4, hence $\|G\|^2 \le CL^5$. It contains no pivot, so $GC = G\iota$, where ι inserts free coordinates. eq. 3.lxxi and these bounds give the conservative uniform upper bound

$$A_k^{\mathrm{flat}} \le CL^8 I. \tag{3.lxxiii}$$

Together with the separate flat-gap theorem this bounds the same classical precision above and below independently of the number of finer levels and the volume.

Supremum norms of the constructed linear lift. The same scalar inverse is bounded in the supremum norm. For one direction the off-diagonal part of $a_0 I + a_1(T + T^{-1})$, divided by a_0, has supremum operator norm at most $2a_1/a_0 < 1$. Its inverse Neumann series therefore has norm at most $(a_0 - 2a_1)^{-1} \le 2$. Multiplying the four commuting direction inverses gives

$$\|\mathcal{A}_n^{-1}\|_{\infty\to\infty} \le 16, \qquad \|w_0\|_\infty \le \frac{16}{n}\|a\|_\infty. \tag{3.lxxiv}$$

The second inequality uses the row sum $1/n$ of I_1.

There is an explicit choice of the scalar in eq. 3.lxix. Let $\psi_0 = 0$. When the current spacing is L^j, apply $P_L = S_L - \mathrm{d}_L\sigma_L$ to $P^{[j]}w_0 = S_{L^j}w_0 + \mathrm{d}_{L^j}\psi_j$. The next plain step sends the last gradient to the gradient of the center restriction. Thus

$$\psi_{j+1} = r_L\psi_j - \sigma_L(S_{L^j}w_0). \tag{3.lxxv}$$

All fields in this recurrence are raw bond or site values on their current lattices. There is no missing spacing factor. Internal paths have at most $2(L-1)$ steps, so $\|\sigma_L\|_{\infty\to\infty} \le 2(L-1)$. Also $\|S_{L^j}\|_{\infty\to\infty} = L^j$, whereas restriction has norm one. The geometric sum yields $\|\psi_k\|_\infty \le 2(L-1)\sum_{j<k} L^j\|w_0\|_\infty = 2(n-1)\|w_0\|_\infty \le 32\|a\|_\infty$.

Since $\mathrm{d}I_0 f = I_1\mathrm{d}_n f$, the correcting gradient in eq. 3.lxx has norm at most $2\|f\|_\infty/n$. Consequently the particular exact lift constructed above obeys

$$\|\mathrm{d}I_0 f\|_\infty \le \frac{64}{n}\|a\|_\infty, \qquad \|w\|_\infty \le \frac{80}{n}\|a\|_\infty. \tag{3.lxxvi}$$

The scalar convolution and its inverse commute with curl. The row sum n^{-2} of I_2 and eq. 3.lxxiv also give

$$\|\mathrm{d}w\|_\infty = \|\mathrm{d}w_0\|_\infty \le \frac{16}{n^2}\|\mathrm{d}_n a\|_\infty. \tag{3.lxxvii}$$

These are norms of one explicitly defined linear right inverse. They are not estimates for a minimizing response.

The interpolation identities also hold with commuting unitary boundary twists. Work on the universal cover and periodize with the corresponding character; absolute row and column sums are unchanged. Twisted shifts remain unitary and commuting, so eq. 3.lxvi–eq. 3.lxvii retain their lower bound for every shifted Bloch parameter. Thus the same energy comparison applies to real flat holonomies in the block axial gauge.

The construction gives energy and supremum estimates for a particular linear lift. It does not bound a minimizing or nonlinear background map, or its complex core and tower substitutions. It does not prove exponential decay of the effective Hessian. Nor does it control signed layer profiles, nonzero-current corrections, counterterm perturbations or complex decoupling arrays. Those estimates must compare their actual operators with this unweighted classical flat form.

3.6. **Exponential kernels of the classical flat precision.** We compute the classical flat quadratic form of the actual plain iterated average, and then the covariance on its next-step nonpivot fiber with the actual soft contour gauge. A spectral gap by itself does not imply kernel decay. The proof below supplies a uniform complex strip for the exact symbols before using the flat gap. All fields are in raw bond coordinates, indexed by their starting sites. No midpoint phase is suppressed.

Let $n = L^k$, with L odd. The current lattice is in units of its own spacing; its finer lattice has n subdivisions per direction. We first use one scalar color. At the identity the three SU(2) colors give identical copies. The normalization of the action is $A(e^{ita}) = \frac{1}{2}t^2\|\mathrm{d}a\|^2 + O(t^3)$. After the canonical scaling $g = \theta^{-1/2}$, the real unweighted step has $\theta g^2 = 1$. Thus the matrices calculated here are precisely its classical quadratic precision matrices.

The two constrained minima are equal. Write $P^{[k]}$ for the raw derivative of the actual plain k-fold average. The straight average is

$$(S_n w)_\mu(ny) = n^{-4} \sum_{r\in B_n(0)} \sum_{j=0}^{n-1} w_\mu(ny + r + je_\mu). \tag{3.lxxviii}$$

Here $B_n(0) = \{-(n-1)/2, \dots, (n-1)/2\}^4$. The actual one-step map is that of § 3.3. Let $\mathcal{G}_L(y,x)$ be its coordinate-order shortest-path multiset from y to $x \in B_L(y)$, with its prescribed multiplicities and equal weights. In positive bond coordinates set

$$\begin{aligned} \gamma_{y,x}(a) &= \frac{1}{\#\mathcal{G}_L(y,x)} \sum_{\Gamma\in\mathcal{G}_L(y,x)} \sum_{b\in\Gamma} \varepsilon_\Gamma(b)a(b), \\ (Ga)_{y,x} &= \gamma_{y,x}(a) \quad (x \ne y), \qquad \sigma(a)(y) = L^{-4} \sum_{x\in B_L(y)} \gamma_{y,x}(a). \end{aligned} \tag{3.lxxix}$$

Here the signs record the path orientation and $\gamma_{y,y} = 0$. Differentiation gives $P_L = S_L - \mathrm{d}_L\sigma$. On gradients the plain map intertwines with restriction at the centers, whereas the straight map intertwines with the site average. Iteration gives

$$P^{[k]}w = S_n w + \mathrm{d}_n\psi_k(w), \qquad P^{[k]}\mathrm{d}f = \mathrm{d}_n r_n f, \qquad S_n\mathrm{d}f = \mathrm{d}_n q_n f. \tag{3.lxxx}$$

Both site maps are onto: for r_n assign the values at the centers, and for q_n use a function constant on each centered block. These are statements about finite linear cochains; no regularity bound for those corrections is required.

Suppose $P^{[k]}w = a$. Then $S_n w = a - \mathrm{d}_n \psi_k(w)$. Choose $q_n f = \psi_k(w)$. The field $w + \mathrm{d}f$ has straight average a and the same curl. Conversely, for $S_n w = a$, choose $r_n f = -\psi_k(w)$ to correct the plain average. Consequently the actual classical quadratic value is

$$E_n(a) := \min_{P^{[k]}w=a} \|\mathrm{d}w\|^2 = \min_{S_n w=a} \|\mathrm{d}w\|^2. \tag{3.lxxxi}$$

Nonemptiness also follows from the filter calculation below: its central alias is nonzero in every component at $p \neq 0$, and a constant fine field lifts a constant coarse field. The two gradient corrections transfer feasibility between the constraints. Finite dimensional projection after quotienting the curl-null directions then gives both minima. The equality does not change the actual soft gauge, which is added later on the current one-step fiber.

Fourier normalization and the auxiliary covariance. Take a coarse torus with s sites per direction and a fine torus with $n\mathsf{s}$. Use the unitary transforms

$$\widehat{w}(\xi) = (n\mathsf{s})^{-2} \sum_x e^{-i\xi\cdot x} w(x), \qquad \widehat{a}(p) = \mathsf{s}^{-2} \sum_y e^{-ip\cdot y} a(ny). \tag{3.lxxxii}$$

Fine aliases of a coarse momentum p are $\xi_m = (p+2\pi m)/n$, with $m \in I_n^4$, $I_n = \{-(n-1)/2, \dots, (n-1)/2\}$. Put

$$b_n(z) = \frac{\sin(nz/2)}{n\sin(z/2)}, \qquad B_n(\xi) = \prod_\nu b_n(\xi_\nu), \qquad h = (n-1)/2. \tag{3.lxxxiii}$$

The centered block sum is B_n, and the straight segment sum is $ne^{ih\xi_\mu} b_n(\xi_\mu)$. Thus the exact filter of component μ in eq. 3.lxxviii is

$$s_{\mu,n}(\xi) = ne^{ih\xi_\mu} B_n(\xi) b_n(\xi_\mu), \qquad \widehat{a}_\mu(p) = n^{-2} \sum_{m\in I_n^4} s_{\mu,n}(\xi_m)\widehat{w}_\mu(\xi_m). \tag{3.lxxxiv}$$

The factor n^{-2} is the square root of the ratio of the coarse and fine numbers of sites. In particular its square, not an unnormalized alias sum, enters a covariance.

The auxiliary fine Feynman form is $\|\mathrm{d}w\|^2 + \|\mathrm{d}^* w\|^2$. Its symbol is component-diagonal, with $\lambda(\xi) = 4\sum_\nu \sin^2(\xi_\nu/2)$. For $p \neq 0$, every alias has positive λ. The coarse covariance of this auxiliary form is diagonal:

$$D_{\mu,n}(p) = n^{-4} \sum_m \frac{|s_{\mu,n}(\xi_m)|^2}{\lambda(\xi_m)}. \tag{3.lxxxv}$$

This formula can equally be obtained by minimizing the positive fine Feynman form under its linear constraint; no probability measure on the fine constant mode is needed.

For complex continuation define

$$\begin{aligned} q_{\nu,m}(p) &= \frac{\sin((p_\nu + 2\pi m_\nu)/2)}{n\sin((p_\nu + 2\pi m_\nu)/(2n))}, \\ f_{\mu,m}(p) &= \left(\prod_\nu q_{\nu,m}(p)^2\right) q_{\mu,m}(p)^2, \\ s_{n,m}(p) &= 4n^2 \sum_\nu \sin^2((p_\nu + 2\pi m_\nu)/(2n)). \end{aligned} \tag{3.lxxxvi}$$

Removable ratios are filled in at zero. On real momenta the phase $e^{ih\xi_\mu}$ in eq. 3.lxxxiv cancels with its conjugate. Its analytic version is the product of the filters at ξ and $-\xi$, giving exactly

$$D_{\mu,n}(p) = \sum_{m\in I_n^4} \frac{f_{\mu,m}(p)}{s_{n,m}(p)}. \tag{3.lxxxvii}$$

Indeed $s_{\mu,n}(\xi)s_{\mu,n}(-\xi) = n^2 B_n(\xi)^2 b_n(\xi_\mu)^2$, and $s_{n,m} = n^2\lambda(\xi_m)$. This checks every power of n. Squared absolute values in eq. 3.lxxxv are not used as holomorphic functions.

Recovering the gauge-invariant energy. For real p, let $t^+_\mu(p) = e^{ip_\mu} - 1$ and $t^-_\mu(p) = e^{-ip_\mu} - 1$. The latter is the conjugate of the former only on real momenta. In analytic formulas below $(t^-)^{\mathsf{T}}$ is a holomorphic row, not a conjugation of a complex variable.

At nonzero fine frequency, the elementary Hodge identity is $\|\mathrm{d}\widehat{w}\|^2 + \|\mathrm{d}^*\widehat{w}\|^2 = \lambda\|\widehat{w}\|^2$. Subtracting a fine gradient makes a field divergence free without changing its curl. Its straight average changes by a coarse gradient, by eq. 3.lxxx. Conversely any coarse gradient can be corrected by a fine gradient, since q_n is onto. It follows that the curl minimum in eq. 3.lxxxi equals the minimum of the Feynman quadratic value over coarse gauge changes:

$$E_n(p;a) = \min_{z\in\mathbb{C}} (a + t^+ z)^* D_n(p)^{-1} (a + t^+ z). \tag{3.lxxxviii}$$

For clarity, the two inequalities use different simple steps. A divergence-free representative of a curl-minimizing field has Feynman energy equal to its curl energy, with coarse value $a + t^+ z$. In the other direction a Feynman minimizer at that coarse value can be gradient-corrected back to a, and its curl energy is no greater than its Feynman energy.

Solving the scalar minimum gives the precision symbol

$$\mathcal{E}_n = D_n^{-1} - \frac{D_n^{-1} t^+ (t^-)^{\mathsf{T}} D_n^{-1}}{(t^-)^{\mathsf{T}} D_n^{-1} t^+}. \tag{3.lxxxix}$$

Here $D_n = \mathrm{diag}(D_{\mu,n})$. At the real zero momentum the classical value is zero on every constant coarse one-form: its constant fine lift is a/n. We accordingly set $\mathcal{E}_n(0) = 0$. This zero mode is retained, not removed by a mass term. We next prove that this definition is the value of a uniformly holomorphic symbol.

Uniform noncentral alias bounds. Fix a small $\rho > 0$ and allow $|\operatorname{Re} p_\nu| < \pi + \rho$, $|\operatorname{Im} p_\nu| < \rho$. For $m_\nu \neq 0$,

$$|n \sin((p_\nu + 2\pi m_\nu)/(2n))| \geq c(1 + |m_\nu|). \tag{3.xc}$$

To see this, the real part of the sine argument stays in a fixed subinterval of $(-\pi, \pi)$, and its absolute value is at least $c|m_\nu|/n$. On that interval $|\sin x| \geq c|x|$, and $|\sin(x + iy)|^2 = \sin^2 x + \sinh^2 y$. The numerator in eq. 3.lxxxvi is bounded. For $m_\nu = 0$ the ratio is a quotient of two sinc functions on a fixed compact zero-free neighborhood. Hence, uniformly in n,

$$|q_{\nu,m}(p)| \leq \frac{C}{1 + |m_\nu|}. \tag{3.xci}$$

For $m \neq 0$ the denominator in eq. 3.lxxxvi has a uniform positive real part. In fact $\operatorname{Re} \sin^2(x + iy) \geq \sin^2 x - \sinh^2 y$. After multiplication by $4n^2$, the imaginary displacement costs at most $C\rho^2$, whereas the real sum is at least $c|m|^2$. Decrease ρ to obtain

$$\operatorname{Re} s_{n,m}(p) \geq c(1 + |m|^2) \qquad (m \neq 0). \tag{3.xcii}$$

The constants do not grow as the alias set grows.

Write $s_n = s_{n,0}$, $q_\nu = q_{\nu,0}$, $Q_n = \prod_\nu q_\nu^2$, and $f_\mu = Q_n q_\mu^2$. Then

$$D_{\mu,n} = \frac{f_\mu}{s_n} + R_{\mu,n}, \qquad R_{\mu,n} = \sum_{m\neq 0} \frac{f_{\mu,m}}{s_{n,m}}. \tag{3.xciii}$$

Each summand of R is bounded by the absolutely summable majorant

$$\frac{C}{1 + |m|^2} \prod_{\nu=1}^{4} (1 + |m_\nu|)^{-2}. \tag{3.xciv}$$

The extra factor $(1 + |m_\mu|)^{-2}$ may be discarded. Thus R is holomorphic and uniformly bounded on the stated box, independently of n. Cauchy on a smaller box bounds all its fixed-order derivatives

uniformly as well. For $n = 1$ the sum is empty. Every noncentral summand vanishes at $p = 0$, so $R_{\mu,n}(0) = 0$; only boundedness is needed below.

Cancellation of the apparent gauge denominator. Near $p = 0$, uniformly in n, $q_\nu = 1 + O(|p|^2)$, $s_n = O(|p|^2)$, and $f_\mu = 1 + O(|p|^2)$. Define

$$h_\mu = (f_\mu + s_n R_{\mu,n})^{-1}, \qquad H_n = \operatorname{diag}(h_\mu). \tag{3.xcv}$$

On a sufficiently small fixed complex polydisc these are holomorphic and uniformly bounded. The exact filter identity

$$\sum_\mu \frac{t_\mu^+ t_\mu^-}{f_\mu} = \frac{4n^2 \sum_\mu \sin^2(p_\mu/(2n))}{Q_n} = \frac{s_n}{Q_n} \tag{3.xcvi}$$

is essential. It follows directly by canceling the numerator $\sin^2(p_\mu/2)$ against q_μ^2, including removable values. It is not an approximation to a gauge denominator.

Since $h_\mu = f_\mu^{-1} - s_n R_{\mu,n} h_\mu / f_\mu$, eq. 3.xcvi gives

$$\begin{aligned} F_n &:= \sum_\mu t_\mu^+ t_\mu^- h_\mu = s_n J_n, \\ J_n &= Q_n^{-1} - \sum_\mu \frac{t_\mu^+ t_\mu^- R_{\mu,n} h_\mu}{f_\mu}. \end{aligned} \tag{3.xcvii}$$

Here $J_n(0) = 1$ and $|J_n - 1| \le C|p|^2$ uniformly. It is therefore nonzero on a smaller fixed polydisc. On its meromorphic domain $D_n^{-1} = s_n H_n$, and the denominator in eq. 3.lxxxix equals $s_n F_n = s_n^2 J_n$. The actual precision consequently has the holomorphic form

$$\mathcal{E}_n(p) = s_n H_n - \frac{H_n t^+ (t^-)^{\mathsf{T}} H_n}{J_n}. \tag{3.xcviii}$$

This removes the whole complex zero cone of s_n, not merely the value at the real origin. The expression is uniformly bounded there, is $O(|p|^2)$, and gives $\mathcal{E}_n(0) = 0$. It also obeys the exact Ward identity $\mathcal{E}_n t^+ = 0$, by eq. 3.xcvii. For $n = 1$, it reduces to $\lambda(p) I - t^+ (t^-)^{\mathsf{T}}$, the ordinary curl quadratic form. This checks the normalization and phases.

A uniform strip and its Fourier kernels. We establish a complex domain away from zero explicitly. On the real Brillouin cube the central q_ν are positive and bounded above and below uniformly in n. Also $c|p|^2 \le s_n(p) \le C|p|^2$. For real $|p| \ge r > 0$, the central term in eq. 3.xciii and the nonnegative alias terms give

$$c_D \le D_{\mu,n}(p) \le C_r, \qquad (t^-)^{\mathsf{T}} D_n^{-1} t^+ \ge c_r > 0. \tag{3.xcix}$$

The second inequality uses $\sum_\mu |t_\mu^+|^2 \ge c|p|^2$ and the upper bound on D.

On a sufficiently thin complex neighborhood of this real compact set, $\operatorname{Re} s_n \ge cr^2 - C|\operatorname{Im} p|^2$. Thus the central term is holomorphic and bounded there; eq. 3.xc–eq. 3.xciv do the same for the aliases. Cauchy bounds the first derivatives uniformly in n. Shrinking the neighborhood by a fixed amount depending on r, eq. 3.xcix therefore keeps every D_μ and its scalar gauge denominator nonzero. The formula in eq. 3.lxxxix is holomorphic and uniformly bounded on that neighborhood. This is a quantitative perturbation of uniformly separated real denominators.

Choose r inside the origin polydisc of eq. 3.xcviii, then reduce the common width once. The two formulas agree wherever their denominators are nonzero, by their exact algebraic derivation, and hence on their overlaps by continuity. Together they give constants $\eta > 0, M_E < \infty$, independent of n, such that

$$\mathcal{E}_n \text{ is holomorphic and } \sup_{|\operatorname{Im} p_\nu| < \eta} \|\mathcal{E}_n(p)\| \le M_E. \tag{3.c}$$

The symbol is 2π-periodic. In eq. 3.lxxxvii, changing a coarse momentum by 2π reindexes the aliases; an endpoint alias changes its fine frequency by 2π, under which the actual filter and denominator are periodic. The same is true of eq. 3.lxxxix, and its analytic continuation has that periodicity.

Define its infinite-lattice kernel by

$$\mathcal{K}_n(z) = (2\pi)^{-4} \int_{[-\pi,\pi]^4} e^{ip\cdot z} \mathcal{E}_n(p)\, dp. \tag{3.ci}$$

For $0 < \eta' < \eta$, shift the ν-th contour to $\operatorname{Im} p_\nu = \eta' \operatorname{sgn} z_\nu$. Periodicity cancels the vertical faces. The exponential then gives

$$\|\mathcal{K}_n(z)\| \le M_E e^{-\eta'|z|_1}. \tag{3.cii}$$

All diagonal terms are retained in this Fourier definition. The kernel and its weighted absolute row sums are bounded uniformly in k. Its zero-frequency value and Ward identity are those already proved; no contact term is added afterward.

The actual next-step precision and its inverse. Now group the current lattice into the fixed blocks of side L used by the next RG step. For block Bloch momentum P, let $r \in B_L(0)$, $j \in I_L^4$, and $\zeta_j = (P + 2\pi j)/L$. The finite cell transform and its analytic inverse are

$$U(P)_{rj} = L^{-2} e^{i\zeta_j \cdot r}, \qquad V(P)_{jr} = L^{-2} e^{-i\zeta_j \cdot r}. \tag{3.ciii}$$

Finite geometric-series orthogonality proves $VU = UV = 1$. For real P, $V = U^*$. For complex P the displayed inverse, not literal conjugation, is used. Their norms are bounded on a fixed strip, since their extra diagonal factors are $e^{\pm iP\cdot r/L}$ and $|r_\nu|/L < 1/2$. The folded classical precision is

$$\mathcal{E}_n^{\mathrm{cell}}(P) = U(P)\, \mathrm{diag}_j(\mathcal{E}_n(\zeta_j)) V(P), \tag{3.civ}$$

with the identity on component indices understood. It is periodic and holomorphic on a fixed block strip, uniformly in n. Periodicity again follows by the alias permutation.

Let $C(P)$ be the actual flat middle-pivot basis for the plain one-step constraint. Its free restriction is the identity and its pivot block solves the coefficient $L^{-3} I_4$; hence its entries are fixed Laurent polynomials in the block phases. Let G be the internal contour matrix defined in eq. 3.lxxix, with rows (y, x), $x \ne y$. Define $C^\sharp(P) = C(-P)^{\mathsf{T}}$; on real P this is $C(P)^*$. The exact classical free nonpivot precision is

$$\mathsf{A}_n(P) = C^\sharp(P)[\mathcal{E}_n^{\mathrm{cell}}(P) + G^{\mathsf{T}} G] C(P). \tag{3.cv}$$

This is the action pullback plus the actual soft gauge. The Feynman form was used only to compute the gauge-invariant minimum in eq. 3.lxxxi; it has not replaced the soft gauge in eq. 3.cv.

For clarity the uniform real gap used next can be obtained independently of this symbol calculation. Expanding the curl of eq. 3.lxxviii gives an average of n by n fine plaquette sheets. Its nonnegative row weights sum to n^2 and its total column weights to n^{-2}. Weighted Cauchy gives $\|\mathrm{d}_n S_n w\| \le \|\mathrm{d} w\|$, hence $E_n(a) \ge \|\mathrm{d} a\|^2$ in current units. Consequently eq. 3.cv dominates the fixed-cell form $C(P)^*[d_P^* d_P + G^{\mathsf{T}} G] C(P)$. This form has no zero vector: zero curl makes internal path sums independent of the path, so zero G kills every internal bond. A plaquette crossing a block face then makes its crossing values equal tangentially. The plain constraint kills that common face value. The free restriction of C is the identity, so the original free vector is zero. The matrices in this comparison are continuous on the compact block Bloch torus, with fixed dimension and fixed rank. Their least Rayleigh quotient on the unit sphere therefore has a positive minimum $c(L)$. This proves $\mathsf{A}_n(P) \ge c(L) 1$ uniformly in n, including $P = 0$. eq. 3.c, the finite transform and the fixed polynomial matrices in eq. 3.cv give a uniform bound for A_n on a complex strip. Cauchy on a smaller strip bounds its first derivatives by a constant $M_A(L)$. Choose its width so that

$$\|\mathsf{A}_n(P + iY) - \mathsf{A}_n(P)\| \le 4 M_A(L) |Y|_\infty < c(L)/2. \tag{3.cvi}$$

The Neumann series around the real positive matrix then proves

$$\mathsf{A}_n^{-1} \text{ is holomorphic}, \qquad \|\mathsf{A}_n(P + iY)^{-1}\| \le 2/c(L) \tag{3.cvii}$$

on one strip independent of n. This step uses both the proved analytic bounds and the gap.

Contour shifting as in eq. 3.ci–eq. 3.cii now bounds the Fourier coefficients of the block precision and its inverse by $C(L)e^{-c(L)|m|_1}$. The cell has fixed size, so converting its indices back to current nonpivot bonds only changes the constants. We obtain

$$|\mathsf{A}_k^{\mathrm{flat}}(b,b')| + |\mathsf{C}_k^{\mathrm{flat}}(b,b')| \le C_L e^{-\mu_L d(b,b')}, \qquad \mathsf{C}_k^{\mathrm{flat}} = (\mathsf{A}_k^{\mathrm{flat}})^{-1}. \tag{3.cviii}$$

Here $d(b,b')$ is bond distance in current lattice units; using starting-site distance or midpoint distance only changes the fixed constants. The symbols $\mathsf{C}_k^{\mathrm{flat}}$ in this conclusion are covariances; the undecorated pivot map $C(P)$ is a different rectangular matrix. Exponential weighted row and column sums follow by summing the fixed-dimensional lattice shells.

Finite tori, holonomies, and scope. For a periodic lattice the exact quadratic minimization is diagonal on its allowed Fourier momenta. Its symbols are the samples calculated above, with no volume correction. If $K_n(m)$ is any infinite block kernel just obtained and the block period is s_b, discrete Fourier orthogonality and absolute convergence give

$$K_{n,\mathsf{s}_\mathrm{b}}(m) = \sum_{v\in\mathbb{Z}^4} K_n(m+\mathsf{s}_\mathrm{b}v). \tag{3.cix}$$

The image sum preserves an exponential bound in periodic distance, uniformly over the admissible periods. It identifies the infinite-lattice kernel determined by the same symbol, with exponentially small image errors on fixed nonwrapping neighborhoods. It does not assert exact equality of a full torus kernel and an infinite kernel on a lift. The same argument applies to the inverse symbol, since its sampled matrix is the inverse of each sampled positive precision.

For real flat holonomies in the prescribed block axial representative, a unitary gauge constant on each block flattens the connection on the universal cover and preserves the contour gauge norm. The commuting adjoint holonomies split into unitary characters. Each character shifts the allowed block momenta by a real amount; the infinite symbols are unchanged. Equivalently the image sum in eq. 3.cix receives unit-modulus factors. All absolute kernel bounds remain valid, without requiring small global holonomies.

The conclusion is the exponential precision and covariance bound for the actual unweighted classical flat quadratic problem. The auxiliary D_n itself is massless and is not asserted to have an exponential kernel. The gap and decay in eq. 3.cviii concern the next-step constrained nonpivot variables with the soft gauge, not a physical Yang–Mills mass gap. No signed profile, counterterm, nonzero-current, non-Abelian or enlarged complex-decoupling comparison has been proved by this calculation. Those require their actual operators and uniform perturbation estimates.

3.7. **First-step precision at small curvature.** This section concerns one unweighted step on a unit-spacing lattice. It starts with a given real field and the actual nonlinear block average. It proves a gap and exponential covariance bounds for the physical curved-fibre Hessian at a given constrained-critical background. Small plaquettes suffice; a small global potential or small torus holonomies are not required. The argument does not construct the background, iterate the conclusion through lower levels, or control signed profiles and complex decoupling parameters.

A fine current and a coarse multiplier have different types. We keep them distinct throughout. An auxiliary extension with an independently prescribed fine current will be useful in the proof. Its agreement with any separately named off-shell completion is an additional identification, stated precisely at the end.

The actual map and the two currents. Fix odd $L \ge 3$. Positive fine bonds carry Hermitian traceless matrices with colour pairing $\langle X, Y\rangle = \frac{1}{2}\operatorname{tr}(XY)$. Complexification uses this bilinear pairing and its transpose. The ℓ^2 norm on real fields uses the associated Euclidean colour norm. Operator estimates on complex fields use its Hermitian extension. No bare-spacing factor occurs in the exponential.

Use the centered blocks, contour-path multiset and middle pivots of § 3.3. Denote the actual contour mean from y to $x \in B(y)$ by $T_{y,x}(U)$. Thus it solves $\sum_\Gamma \log(U(\Gamma)T_{y,x}^{-1}) = 0$, with the prescribed equal weights. The block bond $c = (y, y')$, $y' = y + Le_\mu$, is

$$\begin{aligned} Z_x(U) &= T_{y,x}(U)U([x, x + Le_\mu])T_{y',x+Le_\mu}(U)^{-1}U[c]^{-1}, \\ \mathcal{M}(U)(c) &= \exp\left\{L^{-4}\sum_{x\in B(y)} \log Z_x(U)\right\} U[c]. \end{aligned} \tag{3.cx}$$

The internal implicit mean and the outer explicit exponential are different operations. The analytic branches are the ones fixed by the local pivot construction. On a torus every relevant double block and its bond neighbourhood must have the embedded rectangular lift used there. Periods divisible by L and exceeding $4L + 4$ are sufficient. Work on the periodic cover whenever a larger local patch is needed.

The unweighted action and actual soft gauge are

$$A(U) = \sum_p \left[1 - \tfrac{1}{2}\,\mathrm{tr}\, U(\partial p)\right], \qquad \mathrm{GF}(U) = \sum_y \sum_{x\in B(y)\setminus\{y\}} \left[1 - \tfrac{1}{2}\,\mathrm{tr}\, T_{y,x}(U)\right]. \tag{3.cxi}$$

These expressions equal their usual real-trace versions on SU(2). Their complex continuations use the trace in eq. 3.cxi, without taking a real part. All internal contour paths avoid every middle crossing pivot. Hence GF depends on no pivot variable. On the infinite lattice these sums specify local interactions: derivatives are taken of their finite differences under compactly supported variations. Only finitely many local terms then change. The coefficient bounds below extend the resulting matrices to ℓ^2; no finite value for the whole background action is assumed.

Let $\mathfrak{X}$ be the positive nonpivot bonds and ι their inclusion into all fine bonds. For a background U, define

$$\begin{aligned} q_U(a) &= \frac{1}{i}\log\left[\mathcal{M}(e^{ia}U)\mathcal{M}(U)^{-1}\right], \\ P_U = Dq_U(0), &\qquad P_U h_U = 1, \qquad C_U = \iota - h_U P_U \iota. \end{aligned} \tag{3.cxii}$$

Here h_U is supported only on the pivot of each coarse bond. The actual fibre chart Φ_U has free restriction u, satisfies $q_U(\Phi_U(u)) = 0$, and obeys

$$\Phi_U(0) = 0, \quad D\Phi_U(0) = C_U, \quad D^2\Phi_U(0)[u, v] = -h_U D^2 q_U(0)[C_U u, C_U v]. \tag{3.cxiii}$$

Indeed differentiating the constraint gives its displayed linear and quadratic identities. The second derivative of the chart is supported on pivots, so applying $h_U P_U$ to it is the identity.

Write $J_A(U)$ for the Wilson gradient in the left exponential coordinates. For an arbitrary fine current J, set $\mu_U(J) = h_U^{\mathsf{T}} J$; this is a coarse row covector. Define the auxiliary matrix by its bilinear form

$$\begin{aligned} \mathscr{K}_U[J](u, v) = {} & D^2 A_U[C_U u, C_U v] + D^2\mathrm{GF}_U[\iota u, \iota v] \\ & - \langle \mu_U(J), D^2 q_U(0)[C_U u, C_U v]\rangle. \end{aligned} \tag{3.cxiv}$$

The equality $D^2\mathrm{GF}[C_U u, C_U v] = D^2\mathrm{GF}[\iota u, \iota v]$ holds because GF has no pivot coordinate. The same fact gives $h_U^{\mathsf{T}} J_{\mathrm{GF}}(U) = 0$ identically, even if the contour means are not the identity.

The chain rule and eq. 3.cxiii now give the exact physical identity

$$\begin{aligned} K_{\mathrm{phys}}(U) &:= D_u^2\{A(e^{i\Phi_U(u)}U) + \mathrm{GF}(e^{i\Phi_U(u)}U)\}_{u=0}, \\ K_{\mathrm{phys}}(U) &= \mathscr{K}_U[J_A(U)], \\ \mathscr{K}_U[J] - K_{\mathrm{phys}}(U) &= \langle J - J_A(U), D^2\Phi_U(0)\rangle. \end{aligned} \tag{3.cxv}$$

No criticality is needed for this coordinate identity. Its Gaussian interpretation uses a given constrained-critical background in the block-axial representative. All internal contour means then

equal one. The GF gradient vanishes and its Hessian is the sum of the squares of the derivatives of the actual contour means. Constrained criticality also gives

$$J_A(U) = P_U^{\mathsf{T}} \mu_U(J_A(U)). \tag{3.cxvi}$$

To see this, the gradient annihilates $\ker P_U$, and P_U is onto by its pivot right inverse. Thus it is $P_U^{\mathsf{T}}\mu$; applying h_U^{T} identifies μ. An independent J is not asserted to satisfy eq. 3.cxvi.

At this first step there is no inner background minimization: the zero-fold averaging and site maps are identities. In a formulation using an intermediate Landau projector, that projector is zero, and the zero-fold constraint has no quadratic part. These facts do not by themselves identify or annihilate a separately defined invariant-Hessian correction such as $\Delta'_\pi[J]$, even after projection. The physical identity above follows directly from the actual chart chain rule, independently of that normal-form check. In canonical Gaussian coordinates $a = gu$, an action coefficient x with $xg^2 = 1$ gives precisely this same unweighted Hessian.

A joint analytic domain and explicit support counts. We record the finite bounds used below. Constants c, C in this section are universal, with their value allowed to change. There are radii

$$r_b = c_b L^{-5}, \qquad r_u = c_u L^{-9} \tag{3.cxvii}$$

with universal positive c_b, c_u, the latter fixed after the former, such that, for $U = e^{iX}$, the actual chart is jointly holomorphic on $\|X\|_\infty < 8r_b$, $\|u\|_\infty < 8r_u$, and

$$\begin{aligned} \|h_U\|_{\infty\to\infty},\ \|h_U\|_{1\to 1} &\le CL^3, \\ \|C_U\|_{\infty\to\infty},\ \|C_U\|_{1\to 1} &\le CL^4, \\ \|\Phi_U(u)\|_\infty &\le CL^4\|u\|_\infty. \end{aligned} \tag{3.cxviii}$$

The notation for ℓ^1 and ℓ^∞ here includes the fixed three-dimensional colour space; changing among its coordinate norms changes only C.

Here are the domain and locality details. Products along a contour of length $O(L)$, the implicit internal mean, and the logarithms in eq. 3.cx are jointly holomorphic for $\|X\|, \|a\| < c/L$. The product and logarithm estimates of the pivot construction give $\|P_U\|_{\infty\to\infty} \le CL$ and a quadratic constraint remainder at most $CL^2\|a\|^2$. A background derivative of P_U, obtained on this larger joint domain by Cauchy's formula, is at most CL^2. Consequently the pivot coefficient differs from $L^{-3}1$ by at most $CL^2\|X\|$. For the first radius in eq. 3.cxvii, its inverse has norm at most CL^3. The pivot matrix is block diagonal over coarse bonds: no other pivot occurs in the support of a given constraint row. This proves the bound for h_U.

A constraint row uses at most CL^4 fine bonds. A fine bond lies in at most eight relevant double blocks. These facts and the same directional Cauchy estimate give the column bound CL for P_U, as well as its row bound. The formula in eq. 3.cxii proves both bounds for C_U. Solving the nonlinear remainder with the pivot inverse has contraction constant at most $CL^3L^2(L^4\|u\|) = CL^9\|u\|$. Taking the second radius in eq. 3.cxvii small secures a contraction on the whole indicated joint domain. Its iterates are holomorphic in both parameters and converge uniformly there on smaller closed polydiscs. Passing their Cauchy integrals to the limit proves joint holomorphy.

For locality, the pivot value $\Phi_U(u)(b_0(c))$ depends only on the background and free variables in its own double block. The component contraction for this pivot does not involve another pivot. All nonpivot values are exactly u. In particular:

(i) A given free coordinate affects its own full bond and at most eight pivot components. Each of these bonds belongs to six plaquettes. Thus at most 54 Wilson plaquette terms can depend on that free coordinate through the chart.

(ii) GF has no pivot. A free coordinate can occur only in the $L^4 - 1$ internal means of its own block. Counting contour-path multiplicities does not increase the number of these terms.

(iii) Each such composed term depends on at most CL^4 scalar coordinates. For a fixed free bond, the union of all possible other free coordinates coupled to it still lies in a fixed number of neighbouring blocks and has size CL^4. This union bound does not multiply the two preceding counts together.

All matrix coefficients are therefore finite range. A double block has ℓ^1 diameter at most $5L$. Two pivot bonds entering one plaquette have starting sites at distance at most two. Thus the union of their chart supports has diameter at most $10L+2 \le 12L$. The safe range $12L$, measured by starting sites of fine bonds, also accommodates the internal contour terms. The same bound applies to the background variables on which a coefficient depends.

Each composed local action or gauge term is bounded by a universal constant on the joint domain above. Indeed all the products have $O(L)$ factors, with X and Φ of size $O(L^{-5})$, and the contour mean remains in its fixed analytic neighbourhood. Cauchy's formula in two free scalar directions bounds its Hessian coefficient by $Cr_u^{-2} \le CL^{18}$. The CL^4 possible terms give CL^{22} per matrix entry, and the CL^4 possible coupled coordinates give the Schur bound CL^{26}. One more background-direction Cauchy estimate costs $r_b^{-1} \le CL^5$. Here and below the Schur norm is the maximum of the absolute row and column sums of colour block norms. We have proved

$$\begin{aligned} \|K_{\mathrm{phys}}(e^{iX})\|_{\mathrm{Sch}} &\le CL^{26}, \\ \|K_{\mathrm{phys}}(e^{iX_1}) - K_{\mathrm{phys}}(e^{iX_0})\|_{\mathrm{Sch}} &\le CL^{31}\|X_1 - X_0\|_\infty. \end{aligned} \tag{3.cxix}$$

on a fixed smaller background domain. Only local terms were estimated; no extensive action bound independent of the volume was used.

For the current term, Cauchy's formula and eq. 3.cxviii give $|\partial_{u_b}\partial_{u_{b'}}\Phi(b_0(c))| \le CL^4/r_u \le CL^{13}$. A fixed free coordinate occurs in at most eight such pivot components and couples to CL^4 others. Hence

$$\|\langle J, D^2\Phi_U(0)\rangle\|_{\mathrm{Sch}} \le CL^{17}\|J\|_\infty. \tag{3.cxx}$$

The corresponding background derivative costs another CL^5. The Wilson gradient near the identity obeys $\|J_A(e^{iX})\|_\infty \le C\|X\|_\infty$, by differentiating the six adjacent plaquette products. Combining eq. 3.cxv, eq. 3.cxix and eq. 3.cxx proves, for $\|J_i\| \le 1$,

$$\begin{aligned} \|\mathscr{K}_{e^{iX}}[J] - K_0\|_{\mathrm{Sch}} &\le CL^{32}(\|X\|_\infty + \|J\|_\infty), \\ \|\mathscr{K}_{e^{iX_1}}[J_1] - \mathscr{K}_{e^{iX_0}}[J_0]\|_{\mathrm{Sch}} &\le CL^{32}(\|X_1 - X_0\|_\infty + \|J_1 - J_0\|_\infty). \end{aligned} \tag{3.cxxi}$$

Here $K_0 = \mathscr{K}_1[0]$ is the actual first flat precision. These are derived coefficient estimates, not assumptions about a matrix perturbation. All counts and domains are independent of the torus volume.

Local frames which preserve the actual soft gauge. Suppose now that U is real and block axial, and $\sup_p \|U(\partial p) - 1\| \le \epsilon$. The relevant symmetry of GF is a unitary gauge transformation constant on each centered block. Its values may vary from block to block. If v is such a transformation and $(V_v a)(b) = \mathrm{Ad}(v(b_-))a(b)$, then

$$\Phi_{U^v}(V_v u) = V_v\Phi_U(u), \qquad \mathscr{K}_{U^v}[V_v J] = V_v\mathscr{K}_U[J]V_v^{-1} \tag{3.cxxii}$$

on free coordinates. In this formula V_v is restricted to the appropriate full or free space. To verify it, internal means transform by conjugation with the block value, so GF is unchanged. The relative coarse logarithm in eq. 3.cxii transforms by that same adjoint action at the coarse bond's starting site. The pivot's starting site belongs to that block. The pivot right inverse and free-identity basis therefore intertwine these actions. Uniqueness of the actual chart proves its first identity, and differentiating the invariant local functions proves the second. The transformations are unitary in the colour norm. No covariance of GF under an arbitrary site gauge is used.

Consider a rectangular patch of diameter $O(LR)$, with a fixed additional margin of complete blocks. A unitary comb gauge g on that patch makes

$$\|U^g(b) - 1\| \le CLR\epsilon. \tag{3.cxxiii}$$

For completeness, compare the two comb paths to the endpoints of a bond. Moving that bond successively past the later coordinate segments expresses the resulting closed transport as a product of at most CLR conjugated elementary plaquettes. Unitarity and the telescoping identity for a product of unitary matrices bound its distance from the identity by the sum of their distances. This proves eq. 3.cxxiii, with no bound on $g - 1$.

Although g need not be block constant, block axiality supplies the missing adjustment. The contour means transform exactly as

$$T_{y,x}(U^g) = g(y)g(x)^{-1}. \tag{3.cxxiv}$$

Every path in such a mean has length $O(L)$. By eq. 3.cxxiii its transport, and therefore its implicit mean, is within $CL^2R\epsilon$ of the identity. This last statement follows directly from the contraction defining the mean: inputs within t of the identity have mean within Ct. Let $v(x) = g(y)$ on $B(y)$. Then $v(x)g(x)^{-1} = T_{y,x}(U^g)$, so eq. 3.cxxiii–eq. 3.cxxiv imply

$$\|U^v(b) - 1\| \le CL^2R\epsilon, \qquad v \text{ is block constant.} \tag{3.cxxv}$$

We can take its logarithm with the same bound. Thus the local frame preserves the actual soft gauge and gives a small potential on the patch. Arbitrary coarse holonomies have been retained outside it.

If a real field is initially given without the axial condition, small plaquettes make the contour-path transports mutually close: the same plaquette sliding uses at most CL^2 plaquettes. The actual implicit means therefore exist. Taking the site gauge $u(x) = T_{y,x}(U)$, $u(y) = 1$, makes all internal means equal to one and leaves the coarse datum unchanged. This supplies the representative used here. It does not assert existence of a constrained-critical orbit.

The gap from a covariant partition of unity. Let $c_0 = c_0(L) > 0$ be the proved flat first-step gap $K_0 \ge c_0$, as in eq. 3.lvii. Inequalities for real symmetric matrices in this section use their Hermitian quadratic forms on the complexified ℓ^2 space. Increase a universal constant once so that $K_L = CL^{40}$ dominates the coefficient, support and partition constants just obtained. Choose

$$\begin{aligned} R \ge 40, \qquad & K_L/R^2 \le c_0/8, \\ CL^2R\epsilon \le r_b/8, \qquad & K_L(R\epsilon + \gamma) \le c_0/8. \end{aligned} \tag{3.cxxvi}$$

Here γ bounds the real fine current J, and it is also at most one. These are explicit smallness requirements in terms of L, the finite flat gap and the already proved chart radii.

Construct a scalar squared partition on the coarse lattice. Let $h(t) = \max(1 - |t|, 0)$, put $h_z(x) = \prod_\nu h(x_\nu/R - z_\nu)$, and divide by $(\sum_z h_z(x)^2)^{1/2}$. At least one factor product is $\ge 2^{-4}$, and at most 2^4 are nonzero. The resulting χ_z satisfy $\sum_z \chi_z^2 = 1$, have support of radius R, and obey

$$\sum_z |\chi_z(x) - \chi_z(x')|^2 \le C|x - x'|_1^2/R^2 \quad \text{if } |x - x'|_1 \le 20. \tag{3.cxxvii}$$

The estimate follows by differentiating the normalized hats along the segment; only a bounded number of them occur there. Evaluate them at the block containing a free bond's starting site.

For a compactly supported free field f, the exact matrix identity and its bound are

$$\begin{aligned} \langle f, \mathscr{K}_U[J]f\rangle &= \sum_z \langle \chi_z f, \mathscr{K}_U[J]\chi_z f\rangle + \mathcal{E}, \\ |\mathcal{E}| &\le (K_L/R^2)\|f\|_2^2. \end{aligned} \tag{3.cxxviii}$$

Indeed $1 - \sum_z \chi_z(b)\chi_z(b') = \frac{1}{2}\sum_z(\chi_z(b) - \chi_z(b'))^2$. The matrix has range $12L$, so the block indices differ by at most a fixed number. Apply eq. 3.cxxvii, the row and column bounds, and

$2|f_b||f_{b'}| \le |f_b|^2 + |f_{b'}|^2$. The localization is on free variables. Its full tangent field is $C_U(\chi_z f)$; it is not replaced by $\chi_z C_U f$.

Use eq. 3.cxxv on a larger patch around each support. The margin contains every background variable of its matrix coefficients. eq. 3.cxxii carries the localized form into that block-constant frame. Extend the small background logarithms by zero outside the larger patch, and the transformed current by zero. The coefficients in the localized form are unchanged, by their strict locality. The near-identity bound in eq. 3.cxxi and the flat gap therefore give

$$\langle \chi_z f, \mathscr{K}_U[J]\chi_z f\rangle \ge \{c_0 - K_L(R\epsilon+\gamma)\}\|\chi_z f\|_2^2. \tag{3.cxxix}$$

The harmless L^2 in eq. 3.cxxv has already been absorbed in $K_L = CL^{40}$. On a double block the same local-frame argument also proves the uniform coefficient bounds and existence of its pivot inverse before eq. 3.cxxviii is used; this involves only the smaller $R = O(1)$ patch and has no dependence on the desired global gap. Thus no matrix bound needed in the IMS error has been assumed. Summing eq. 3.cxxix and using eq. 3.cxxvi–eq. 3.cxxviii proves

$$\mathscr{K}_U[J] \ge \tfrac{1}{2}c_0\, 1. \tag{3.cxxx}$$

This proof takes place on the periodic cover. It also gives the torus inequality without requiring one local frame to descend to the torus. Lift a fixed periodic vector to the cover and restrict it to a box of N^4 period cells. Its squared norm is N^4 times the period norm. Finite range makes its quadratic form equal N^4 times the torus form, up to a boundary error of order N^3, for that fixed vector and period. Divide the cover inequality by N^4 and let N tend to infinity. The constant in eq. 3.cxxx is independent of the period. This also explains why no assumption on noncontractible holonomies entered the proof.

For the physical current, each first variation of one plaquette vanishes when its plaquette transport is the identity. Differentiating its four factors and using unitarity bounds its contribution by $C\|U(\partial p) - 1\|$. There are six adjacent plaquettes, hence

$$\|J_A(U)\|_\infty \le C\epsilon. \tag{3.cxxxi}$$

Consequently a sufficiently small ϵ, depending only on L, satisfies eq. 3.cxxvi with $J = J_A(U)$. eq. 3.cxv and eq. 3.cxxx prove the actual physical first-step gap at every given real block-axial constrained-critical field of this curvature size.

Complex neighbourhood and exponential kernels. The same local frames yield a quantitative complex statement. Fix a real pair satisfying eq. 3.cxxvi, with room in those inequalities, and put $\mathbf{U} = e^{iE}U$, $\mathbf{J} = J + Z$, for complex fine fields. The local unitary gauges preserve $\|E\|_\infty$ and $\|Z\|_\infty$. The logarithm in a small local frame has bounded derivative, so the joint-domain estimate in eq. 3.cxxi, now applied to the background difference, proves

$$\|\mathscr{K}_{\mathbf{U}}[\mathbf{J}] - \mathscr{K}_U[J]\|_{\mathrm{Sch}} \le K_L(\|E\|_\infty + \|Z\|_\infty) \tag{3.cxxxii}$$

provided $\|E\|_\infty \le r_b/16$ and the total current remains below one. In particular require

$$K_L(\|E\|_\infty + \|Z\|_\infty) \le c_0/8. \tag{3.cxxxiii}$$

Schur's inequality bounds the ℓ^2 perturbation by the same quantity. The inverse follows by a Neumann series about the real matrix and has norm at most $4/c_0$. The coefficients are holomorphic local functions, and their uniform Cauchy bounds make that Neumann inverse holomorphic in every admitted finite complex parameter family.

For physical analytic continuation take $\mathbf{J} = J_A(\mathbf{U})$. The adjacent-plaquette formula also gives $\|J_A(e^{iE}U) - J_A(U)\|_\infty \le C\|E\|_\infty$ on the stated unitary-centred complex neighbourhood. Thus a smaller explicit bound $\|E\| \le c_0/(CK_L)$, together with the chart bound, implies eq. 3.cxxxiii. If such a field is a given block-axial complex critical background, its physical Gaussian is the analytic matrix in eq. 3.cxv. Existence of that background is still a separate question.

Write $r_L = 12L$, increase K_L to bound the complex row and column norms by $2K_L$, and choose

$$\tau_L = r_L^{-1} \log\left(1 + c_0/(16K_L)\right) > 0. \tag{3.cxxxiv}$$

For a bounded real function φ which is one-Lipschitz in starting-site distance, multiplication by $e^{\tau_L \varphi}$ changes the matrix by an operator of norm at most

$$2K_L(e^{\tau_L r_L} - 1) \le c_0/8. \tag{3.cxxxv}$$

This follows entry by entry, from finite range, and then from the row and column bounds. The inverse of the conjugated matrix has norm at most $8/c_0$. Take $\varphi(b) = \min\{d(b, b'), N\}$, apply this estimate between coordinate vectors and then let N increase. On the infinite lattice the weights used before this limit are bounded; no unbounded conjugation identity is assumed. We obtain

$$\|\mathscr{K}_{\mathbf{U}}[\mathbf{J}]^{-1}(b, b')\| \le (8/c_0)e^{-\tau_L d(b,b')}. \tag{3.cxxxvi}$$

The same proof on a torus uses its periodic distance. Fixed-matrix Dirichlet compressions retain the real lower bound, coefficient estimates and conjugation bound, so eq. 3.cxxxvi also holds for them. This does not identify a matrix rebuilt from a different local background or a different sequence of regions with that compression. Finite range gives an exponential bound for the precision itself. Summing the kernel bound with the smaller weight $e^{\tau_L d/2}$ gives absolute weighted row and column bounds, since a four-dimensional lattice has at most $C(m+1)^3$ bonds at distance in $[m, m+1)$. All these constants depend only on L and the fixed flat gap, not on volume or global holonomies.

The remaining identification and the exact scope. The physical conclusion is fully determined by the actual chart and the actual Wilson and contour-gauge functionals. An extension to independent-current cores must specify its complete projected current and gauge form. If its isolated one-step constraint subtraction is called $E_U^{(2)}[J]$, the necessary constraint-readout condition for agreement with eq. 3.cxiv is

$$\langle C_U u, E_U^{(2)}[J] C_U v\rangle = \langle h_U^{\mathsf{T}} J, D^2 q_U(0)[C_U u, C_U v]\rangle. \tag{3.cxxxvii}$$

Equivalently, if $q_U^{(2)}$ denotes the homogeneous quadratic part, its diagonal readout is $2\langle h_U^{\mathsf{T}} J, q_U^{(2)}(C_U u)\rangle$. This fixes the factor of two and the pivot-right-inverse composition. The first-step calculation below verifies eq. 3.cxxxvii for the named form and checks its remaining terms on the axial locus. The condition alone does not identify a general all-core completion. Its projected gauge block and every remaining current or gauge-restoration contribution, including a term denoted $\Delta'_\pi[J]$, must also match. The Hessian of the absolute contour gauge used here agrees with the relative-contour gauge Hessian on the axial locus, but need not agree away from it. Agreement at physical critical pairs alone proves none of these off-core identities. We have defined and bounded eq. 3.cxiv explicitly, without assuming the identification being tested.

Thus the actual on-shell first unweighted Gaussian, and its admitted physical analytic continuation, have the proved gap and kernels. The auxiliary independent-current extension has the same bounds under its explicit current ceiling. No assertion about all lower levels, signed layer coefficients, nonzero-current many-level Schur complements, enlarged complex interpolation domains, or the conditional exterior-force law follows from this one-step result.

3.8. **The first-step background and its regular minimum.** We construct a background for one raw, unweighted step. The input is a real coarse connection with sufficiently small plaquettes. Its potential and its noncontractible holonomies need not be small. The output is an actual block-axial fine connection, with the prescribed nonlinear average, which is constrained-critical for the Wilson action and minimizes it within the explicit regular class proved below. The construction gives exponential first responses, product-topology continuity, and compatible local complex continuations. It uses the actual contour soft gauge as an auxiliary function in the construction.

The constants below depend on the fixed odd integer $L \ge 3$, but not on volume. We use the actual average, middle pivots and physical left bond logarithms of § 3.7. On a periodic lattice

we retain its embedded-double-block condition and use the periodic cover for larger patches. The infinite-lattice action is interpreted through finite local variations. No finite total action is assumed.

An exact initial field. For a coarse connection V, define its face lift $U_0(V)$ as follows. A fine bond internal to a centered block has value I. Every positive fine bond crossing from $B(y)$ to $B(y+Le_\mu)$ has value $V(y,\mu)$. The value on a reversed bond is the inverse. Every internal contour transport, and therefore every actual implicit contour mean, is I. Every straight length-L segment used in the average crosses its designated coarse face once and has transport $V(y,\mu)$, as does its reference segment. Consequently

$$T_{y,x}(U_0(V)) = I, \qquad Z_x(U_0(V)) = I, \qquad \mathcal{M}_L U_0(V) = V. \tag{3.cxxxviii}$$

These are exact nonlinear identities. A fine plaquette whose two directions are not both crossing directions is I. If both directions cross, its four factors are precisely the four factors of the corresponding coarse plaquette. In particular, for real V,

$$\sup_p \|U_0(V)(\partial p) - I\| \le \sup_P \|V(\partial P) - I\| =: \epsilon. \tag{3.cxxxix}$$

There is no holonomy restriction in this construction.

Write $\Phi_V := \Phi_{U_0(V)}$ for the actual fibre chart, with identity free restriction. Its free bond set $\mathfrak{X}$ depends only on the fixed block partition. Define

$$U_V(u) = e^{i\Phi_V(u)} U_0(V), \qquad F_V(u) = D_u\{A(U_V(u)) + \mathrm{GF}(U_V(u))\}. \tag{3.cxl}$$

We identify a row derivative with a field using the fixed bilinear colour pairing. On the infinite lattice, a component of F_V is the derivative under its compactly supported free coordinate variation. Only finitely many local terms enter that component. The estimates below give a bounded analytic map on the stated ℓ^∞ ball; eq. 3.cxl does not assign a value to an infinite sum of action terms.

Let $c_0 = c_0(L) > 0$ be the actual flat gap. Fix a physical curvature ceiling $\alpha_L > 0$ so that every real block-axial field of curvature at most α_L, together with its Wilson current, satisfies the smallness conditions of the preceding section with room. At the face lift, the actual GF gradient vanishes. Thus

$$\begin{aligned} F_V(0) &= C^{\mathsf{T}}_{U_0(V)} J_A(U_0(V)), & \|F_V(0)\|_\infty &\le A_L\epsilon, \\ K_V &:= DF_V(0) = K_{\mathrm{phys}}(U_0(V)), & K_V &\ge \tfrac{1}{2}c_0 I, \qquad A_L = C_* L^4. \end{aligned} \tag{3.cxli}$$

Here and below C_* is a sufficiently large fixed universal constant. The gap is legitimate before criticality is established: the exact chain rule eq. 3.cxv and the proof of eq. 3.cxxx require a real block-axial small-curvature field and its small physical current. Criticality was required there only to interpret the resulting matrix as a background Gaussian. No such interpretation is used to obtain eq. 3.cxli.

The bounded-field inverse and the nonlinear estimates. The matrix K_V is real symmetric, has range $12L$, and has uniform absolute row and column bounds. Its ℓ^2 inverse has the actual exponential kernels proved in eq. 3.cxxxvi. If $\tau_L > 0$ is the rate there, put

$$S_4(\tau_L) = \sum_{m\ge 0} C_4(m+1)^3 e^{-\tau_L m}, \qquad B_L = 1 + \frac{8}{c_0} S_4(\tau_L). \tag{3.cxlii}$$

The universal C_4 bounds the number of positive fine bonds in a distance shell; it is valid also for periodic distance. We may enlarge it so $B_L \ge 8/c_0$. Absolute kernel rows define an operator H_V on bounded free fields, with

$$\|H_V\|_{\infty\to\infty} \le B_L, \qquad K_V H_V = H_V K_V = I \quad \text{on } \ell^\infty. \tag{3.cxliii}$$

For clarity, both identities are proved here. Each matrix entry of $K_V H_V$ or $H_V K_V$ equals the identity entry by the ℓ^2 inverse identities. Applying the former to a bounded field involves finitely

many K_V entries in each row and absolute H_V rows, so the sums interchange. For the latter, the absolute double sum is bounded by

$$\sum_j \|H_V(b,j)\| \sum_{b'} \|K_V(j,b')\| \, \|f\|_\infty \le B_L \|K_V\|_{\mathrm{Sch}} \|f\|_\infty .$$

It therefore interchanges as well. This proves eq. 3.cxliii on ℓ^∞, rather than merely extending an ℓ^2 notation to that space.

We need nonlinear estimates for the actual local functions. The joint background and free radii $r_b = c_b L^{-5}$, $r_u = c_u L^{-9}$ of eq. 3.cxvii are retained. In each local real block-constant frame the face lift has small potential. The actual joint chart therefore exists on a fixed multiple of these radii, with uniform local bounds. Its component dependence is the same as in the preceding section. A fixed free coordinate enters at most 54 composed Wilson terms and $L^4 - 1$ actual GF terms, and its coupled free coordinates lie in a fixed number of blocks. Two scalar free Cauchy formulas cost r_u^{-2}, the term count costs CL^4, and the coupled-coordinate count costs CL^4. Hence, on a fixed smaller ball,

$$\begin{gathered} \|DF_V(u)\|_{\mathrm{Sch}} \le M_L, \qquad \|DF_V(u) - K_V\|_{\mathrm{Sch}} \le N_L \|u\|_\infty, \\ M_L = C_* L^{26}, \qquad N_L = C_* L^{35}. \end{gathered} \tag{3.cxliv}$$

To obtain the second estimate, apply one more scalar Cauchy formula in an arbitrary unit supremum free direction. It costs $r_u^{-1} = CL^9$. Integrate that derivative along the free segment from zero to u. No count of all coordinates in the direction is inserted. All these Hessians have range $12L$, and their coefficients depend on background variables within a fixed neighbourhood of the same size. These are derived bounds for the composed actual action and actual contour GF; a bound on their desired matrix perturbation is not an input.

We will also vary the coarse datum. Fix a real V as above, and write

$$\begin{gathered} V_B(c) = e^{iB(c)} V(c), \qquad U_0(V_B) = e^{iE_0(B)} U_0(V), \\ E_0(B)(b) = \begin{cases} B(c), & b \text{ crosses face } c, \\ 0, & b \text{ is internal.} \end{cases} \end{gathered} \tag{3.cxlv}$$

In particular $\|E_0(B)\|_\infty \le \|B\|_\infty$. The real local frames are fixed while B varies. Write $F(B,u) = F_{V_B}(u)$. On $\|B\|_\infty < r_b / C_*$ and the retained free ball, the actual chart and all component functions are jointly holomorphic, and

$$\begin{aligned} &\|F(B,0) - F(0,0)\|_\infty \le Q_L \|B\|_\infty, && Q_L = C_* L^{18}, \\ &\|D_u F(B,u) - K_V\|_{\mathrm{Sch}} \le D_L \|B\|_\infty + N_L \|u\|_\infty, && D_L = C_* L^{31}. \end{aligned} \tag{3.cxlvi}$$

For the first estimate the local scalar Cauchy costs are L^9 for one free derivative and L^5 for one background direction, followed by the L^4 term count. For the second, apply the background Cauchy loss L^5 to the L^{26} Schur estimate and combine with eq. 3.cxliv. The face replication in eq. 3.cxlv has supremum norm one, so no number of crossing bonds is charged to the directional background Cauchy radius. Local real unitary frames preserve all input norms. These estimates are consequently uniform even when the coarse holonomies are large.

Explicit radii and the real fixed point. Enlarge $S_L = C_* L^4$ so that on the retained chart

$$\|\Phi_V(u)\|_\infty \le S_L \|u\|_\infty, \qquad \sup_p \|U_V(u)(\partial p) - I\| \le \epsilon + S_L \|u\|_\infty \tag{3.cxlvii}$$

for real u. The second estimate follows by telescoping four unitary bond factors and using the first. Set

$$\begin{aligned} r_N &= \min\left\{r_u/16,\ (16B_LN_L)^{-1},\ \alpha_L/(16S_L)\right\},\\ \eta_{\mathrm{reg}} &= \min\left\{\alpha_L/4,\ c_*L^{-5},\ r_N/(16C_{\mathrm{cmp}}L^3)\right\},\\ P_L &= 1+2B_LS_LA_L, \qquad \epsilon_* = \min\left\{\alpha_L/16,\ r_N/(16B_LA_L), \eta_{\mathrm{reg}}/(16P_L)\right\}. \end{aligned} \tag{3.cxlviii}$$

Here C_{cmp} is the universal comparison constant proved below, and c_* is small enough for its local logarithm branches. This is a sequential choice: r_N is fixed first, then η_{reg}, then ϵ_*. All are positive and depend only on L.

Suppose $\epsilon \le \epsilon_*$. On the closed bounded-field ball $\|u\|_\infty \le r_N$, let

$$\mathcal{T}_V(u) = u - H_V F_V(u). \tag{3.cxlix}$$

By eq. 3.cxliii–eq. 3.cxliv,

$$\|D\mathcal{T}_V(u)\|_{\infty\to\infty} \le B_LN_Lr_N \le 1/16, \qquad \|\mathcal{T}_V(0)\|_\infty \le B_LA_L\epsilon \le r_N/16. \tag{3.cl}$$

Thus $\mathcal{T}_V$ maps the ball strictly into itself and is a contraction. Its iterates from zero are real and converge to a unique root $u(V)$ in that ball. The two-sided identity in eq. 3.cxliii makes the fixed-point equation equivalent to $F_V(u(V)) = 0$. Moreover

$$\|u(V)\|_\infty \le 2B_LA_L\epsilon, \qquad \|\Phi_V(u(V))\|_\infty \le 2S_LB_LA_L\epsilon. \tag{3.cli}$$

The resulting real field has curvature at most $P_L\epsilon \le \eta_{\mathrm{reg}}/16$. In particular it remains inside the physical NFP curvature domain. No critical point was assumed to start this iteration.

Why the root is a Wilson critical background. We first check the tangent space used by the stationarity equation. On the retained joint domain, the pivot derivative of the actual constraint stays invertible. The chart has identity free restriction. Differentiating its constraint and solving the pivot part therefore shows that its derivative spans the entire tangent kernel of that constraint, at every point in the ball. The component derivative is strictly local. In particular a compactly supported full tangent variation is represented by its compactly supported free restriction; no tangent directions are omitted in eq. 3.cxl.

Let $x \in B(y)\setminus\{y\}$. Apply a site gauge supported at x, with $s_t(x) = e^{itX}$, and identity at every other site. It fixes all coarse centers, so the actual nonlinear average is unchanged. It is an admitted fibre variation for sufficiently small t. The Wilson derivative along it is zero by gauge invariance. Endpoint covariance of the actual contour mean gives

$$T_{y,x}(U^{s_t}) = T_{y,x}(U)e^{-itX}. \tag{3.clii}$$

Every other internal mean is unchanged: any occurrence of x inside a contour cancels between its two adjacent factors. Consequently stationarity of eq. 3.cxl at the root implies

$$0 = \frac{i}{2}\,\mathrm{tr}\left(T_{y,x}(U)X\right) \quad \text{for every traceless Hermitian } X. \tag{3.cliii}$$

The trace pairing then says that $T_{y,x}(U)$ is scalar. Its determinant is one, so it is I or $-I$. The chart keeps all internal bonds, their $O(L)$-length contour transports and their means in the retained neighbourhood of I; the choice $r_N \le r_u/16$ secures this uniformly. The minus sign is excluded. Thus

$$T_{y,x}(U(V)) = I \quad \text{for every internal pair}, \qquad D\mathrm{GF}(U(V)) = 0. \tag{3.cliv}$$

The second identity holds on the full fine-bond space: the trace derivative of an SL(2) curve through I is zero. The root equation is therefore Wilson stationarity along the entire actual fibre. We have constructed

$$\boxed{\mathcal{M}_LU(V) = V, \qquad U(V) \text{ is block axial}, \qquad J_A(U(V)) \perp \ker P_{U(V)}.} \tag{3.clv}$$

All arguments on the infinite lattice used compactly supported free or site variations; they require no value for the background action. Here the perpendicular notation means annihilation of compactly supported tangent fields. The bounded pointwise multiplier identity, which implies no ℓ^2 membership, is proved in eq. 3.clxxi–eq. 3.clxxii. At this actual critical background the physical gap and covariance bounds of the preceding section now have their stated Gaussian interpretation.

Uniqueness and the comparison with the face lift. An axial real Wilson critical field represented by $U_V(u)$ in the closed r_N-ball has zero GF gradient and hence satisfies $F_V(u) = 0$. The contraction proves that it equals $U(V)$. The comparison in eq. 3.cxlviii identifies a geometric uniqueness class without assuming chart membership.

Let W be a real block-axial field with fine plaquette deviation at most η. On one block a unitary comb gauge g, anchored at its center, makes its internal bonds $CL\eta$-close to I. Every transformed internal path has length $O(L)$, so its actual mean is $CL^2\eta$-close to I. But axiality and covariance give that mean as $g(y)g(x)^{-1} = g(x)^{-1}$. Thus the original internal bonds obey

$$\|W(b) - I\| \le CL^2\eta \quad (b \text{ internal}). \tag{3.clvi}$$

For a coarse face c, write $S_x = W([x, x + Le_\mu])$. Coordinate-path swaps express each contour/reference loop in the double block as a product of at most CL^2 conjugated elementary plaquettes. Unitarity makes its deviation at most $CL^2\eta$. Two internal coordinate-order paths differ by the same number of swaps, so their transports differ by that amount. The contraction for the implicit mean, recentered at any one unitary input, shows that every such path transport differs from its actual mean by $CL^2\eta$. Since those means are I, replacing the two contour transports in the closed loop by their means gives

$$\|S_x W[c]^{-1} - I\| \le CL^2\eta. \tag{3.clvii}$$

The actual outer exponential of the arithmetic logarithm mean has the same bound relative to $W[c]$. Hence

$$\|S_x \mathcal{M}_L(W)(c)^{-1} - I\| \le CL^2\eta. \tag{3.clviii}$$

Each S_x contains one crossing bond and at most $L - 1$ internal bonds. Stripping those unitary internal factors with eq. 3.clvi proves the safe bound

$$\sup_b \|W(b) - U_0(\mathcal{M}_L W)(b)\| \le C_{\mathrm{cmp}} L^3 \eta. \tag{3.clix}$$

Enlarge C_{cmp} to give the same estimate for the physical left logarithm of the displayed ratio on its near-identity branch. No global small gauge or small coarse potential was used.

If $\mathcal{M}_L W = V$ and $\eta \le \eta_{\mathrm{reg}}$, that logarithm is within the ordinary local graph uniqueness radius and its free restriction is within $r_N/16$. The actual fibre chart therefore represents W; if W is constrained-critical it equals $U(V)$. For a real field not initially axial, small plaquettes first make its internal contour families mutually close. Their actual means exist, even if centered at a large unitary transport. The site gauge $s(x) = T_{y,x}(W)$, $s(y) = I$, sets every mean to I and preserves the coarse datum. Curvature and constrained criticality are preserved. Applying eq. 3.clix to this representative proves uniqueness of the center-fixing gauge orbit among real regular fields of curvature at most η_{reg}. The constructed field belongs to this same class by eq. 3.cli and the final smallness choice in eq. 3.cxlviii. Two axial representatives in a center-fixing orbit are equal: covariance of their means forces the site gauge itself to be identity.

Complex continuation and first response kernels. Keep the real V fixed. Enlarge a universal constant in $P'_L = C_* + 2B_L S_L Q_L$, and set

$$b_N = \min\left\{ r_b/(16C_*),\ (16B_L D_L)^{-1},\ r_N/(16B_L Q_L), \eta_{\mathrm{reg}}/(16P'_L) \right\}. \tag{3.clx}$$

For $\|B\|_\infty < b_N$, use the same fixed real inverse H_V in

$$\mathcal{T}_B(u) = u - H_V F(B,u).$$

eq. 3.cxlvi–eq. 3.cl give

$$\|D\mathcal{T}_B(u)\|_{\infty\to\infty} \le 1/8, \qquad \|\mathcal{T}_B(0)\|_\infty \le r_N/8. \tag{3.clxi}$$

The contraction is uniform on the complex ball and maps it strictly inside. Its iterates are holomorphic and converge uniformly on smaller closed parameter domains. Thus $u(B)$, and $U(V_B) = e^{i\Phi_{V_B}(u(B))}U_0(V_B)$, are holomorphic in every admitted finite complex parameter family. Reality is preserved when B is real. The root satisfies

$$\|u(B)\|_\infty \le 2B_L(A_L\epsilon + Q_L\|B\|_\infty). \tag{3.clxii}$$

The site variation argument in eq. 3.clii–eq. 3.cliv applies to a complex root as well. The equation pairs with every complexified traceless direction; a scalar mean in $\mathrm{SL}(2,\mathbb{C})$ is $\pm I$, and the retained branch selects I. Hence this is an actual complex block-axial Wilson critical background, rather than a critical point only of $A + \mathrm{GF}$. No independent fine current is introduced.

For completeness we derive response locality from actual finite matrices. At the root put $\mathcal{H}_B = D_u F(B,u(B))$. The preceding estimates give

$$\|\mathcal{H}_B - K_V\|_{\mathrm{Sch}} \le (8B_L)^{-1} \le c_0/64, \qquad \|\mathcal{H}_B\|_{\mathrm{Sch}} \le M_L. \tag{3.clxiii}$$

They also retain range $r_0 = 12L$. Choose

$$\sigma_L = r_0^{-1}\log\left(1 + c_0/(64M_L)\right) > 0. \tag{3.clxiv}$$

Multiplication by $e^{\sigma_L\varphi}$, for a bounded real one-Lipschitz φ, changes $\mathcal{H}_B$ by at most $M_L(e^{\sigma_L r_0}-1) = c_0/64$ in Schur norm. A Neumann argument about $K_V \ge c_0/2$, first for the complex perturbation and then for this conjugation, gives an inverse norm at most $8/c_0$. Bounded weights $\varphi(b) = \min\{d(b,b'),N\}$, followed by $N\to\infty$, give the actual kernel bound

$$\|\mathcal{H}_B^{-1}(b,b')\| \le (8/c_0)e^{-\sigma_L d(b,b')}. \tag{3.clxv}$$

Absolute rows again give both inverse identities on bounded fields. At a real root this matrix is a positive coordinate Hessian. At any root the physical free coordinates centered at that root differ from the original free coordinates by pointwise invertible three-by-three exponential-coordinate Jacobians. Their norms and inverse norms are uniformly bounded on the retained ball. Since the first derivative vanishes, the Hessians are related by ordinary congruence with these pointwise matrices. Thus the physical centered Hessian also has the corresponding inverse kernel bounds.

Define the source derivative by first differentiating the first argument of $F(B,u)$ at fixed u, and only then substituting the root: $\mathcal{R}_B = (\partial_1 F)(B,u(B))$. Thus the total derivative of the root equation is $0 = \mathcal{R}_B + \mathcal{H}_B D_B u$. This partial source derivative is strictly local. A free row sees only a fixed number of coarse faces in its dependence neighbourhood. The Cauchy count giving Q_L bounds each coefficient by CL^{18}, while a coarse face can reach at most CL^4 free coordinates. Therefore

$$\|\mathcal{R}_B\|_{\mathrm{Sch}} \le C_* L^{22}, \qquad D_B u = -\mathcal{H}_B^{-1}\mathcal{R}_B. \tag{3.clxvi}$$

The support distance between a free bond and a contributing coarse face, represented by its pivot, is at most a fixed multiple of L. Combining this fact with eq. 3.clxv gives

$$\|D_{B(c)}u(b)\| \le C_L e^{-\sigma_L d(b,b_0(c))}. \tag{3.clxvii}$$

The derivative $D_u\Phi$ has the same strict locality and absolute row and column bounds CL^4 on the shrunken domain, by one free Cauchy formula. Its direct background derivative is local and bounded by $CL^9\|u\|_\infty$, using a background Cauchy formula and $\Phi_B(0) = 0$. The exponential map

and the direct face lift have bounded local derivatives. Consequently the actual fine-field derivative in left trivialization satisfies

$$\left\| \frac{1}{i}(D_{B(c)}U(V_B)(b))U(V_B)(b)^{-1} \right\| \le C_L e^{-\sigma_L d(b,b_0(c))}. \tag{3.clxviii}$$

The constants in these response bounds are independent of volume and holonomies. The response formulas concern this first-step solution; they are not many-level background derivative estimates.

Interior locality, periodicity and exact scope. There is a useful finite comparison without interpolating between two distant coarse connections. Let V, V' be admitted real coarse fields which agree on a coarse patch, and let u, u' be their constructed free solutions. Both arrays have the same free coordinate labels and lie in the uniform r_N-ball. The function $F_V(u')$ is defined even where the two face lifts differ. Strict locality gives $F_V(u') = F_{V'}(u') = 0$ on every row whose entire coarse dependence neighbourhood lies in the common patch. Call this set of rows I. On the convex free segment define

$$\overline{\mathcal{H}} = \int_0^1 DF_V(u' + t(u - u'))\, dt. \quad \text{Then} \quad \overline{\mathcal{H}}(u - u') = -F_V(u'). \tag{3.clxix}$$

Every integrand is a real symmetric range-$12L$ matrix with the same Schur bound and the same positive gap: it differs from K_V by at most $N_L r_N \le c_0/128$. Its average has those properties as well, so the bounded-conjugation argument gives exponential inverse kernels. The residual in eq. 3.clxix is supported in I^c and has norm at most $2M_L r_N$, by the derivative bound along the same segment. Summing the inverse with the smaller exponential weight gives

$$|u(b) - u'(b)| \le C_L r_N e^{-\sigma_L d(b,I^c)/2}. \tag{3.clxx}$$

The local chart derivative gives the analogous bound for fine fields whose background dependence neighbourhoods are in the common patch; the fixed additional range is absorbed in C_L. No path from V to V' through small-curvature coarse fields has been assumed. This is a deterministic locality statement for these canonical first-step axial representatives.

The face lift, chart and actual GF intertwine every real unitary gauge transformation constant on blocks. The unique fixed point therefore has the corresponding coarse gauge covariance. The same uniqueness proves compatibility with translations preserving the block partition. If the coarse input is periodic, translating the cover root by a period gives another root in the same ball; it is therefore periodic. Conversely a finite-torus root lifts to such a cover root, so the two constructions agree. This uses locality and uniqueness of the bounded-field equation, rather than silently periodizing an ℓ^2 inverse. All local frames and kernel estimates are valid on the cover, and their constants do not depend on the noncontractible holonomies.

Bounded currents and pointwise constrained stationarity. Let $U = U(V)$, and use the actual chart centered at U for this paragraph. Write $P = P_U$, $h = h_U$, $C = C_U = \iota - hP\iota$, and $J = J_A(U)$. Every component of J is bounded by the physical plaquette estimate. The finite-range maps P, h, C, and their transposes, act on bounded fields by finite component sums. In particular the coarse covector $\mu = h^{\mathsf{T}} J$ is pointwise well-defined and obeys

$$\mu(c) = J_c(U)^{-\mathsf{T}} J(b_0(c)), \qquad \|\mu\|_\infty \le CL^3 \|J\|_\infty, \quad J_c(U) = D_{a(b_0(c))} q_{U,c}(0). \tag{3.clxxi}$$

The symbol $J_c(U)$ here is the three-by-three pivot coefficient, whereas $J(b)$ is a fine Wilson current.

For each compactly supported free field v, Cv is a compactly supported tangent field. Wilson stationarity gives $\langle J, Cv \rangle = 0$; testing one free coordinate at a time therefore gives $C^{\mathsf{T}} J = 0$ pointwise. Set $R = J - P^{\mathsf{T}} h^{\mathsf{T}} J$. Its free restriction is exactly $C^{\mathsf{T}} J$, hence zero. On a pivot $b_0(c)$, no other constraint row contains that pivot, and eq. 3.clxxi gives

$$R(b_0(c)) = J(b_0(c)) - J_c(U)^{\mathsf{T}} J_c(U)^{-\mathsf{T}} J(b_0(c)) = 0.$$

Both restrictions vanish. Thus the exact bounded-current statement is

$$\boxed{J_A(U) = P_U^{\mathsf{T}} h_U^{\mathsf{T}} J_A(U) \quad \text{pointwise on fine bonds.}} \tag{3.clxxii}$$

Conversely, this pointwise identity annihilates every compactly supported $a \in \ker P_U$: both a and $P_U a$ have finite support, so transposition is a finite-sum identity and $\langle J_A(U), a\rangle = \langle h_U^{\mathsf{T}} J_A(U), P_U a\rangle = 0$. The multiplier is unique since $Ph = I$. These equivalences are statements about bounded currents and compact variations; their proof does not place $J_A(U)$ or μ in ℓ^2.

Local interactions and bounded-field differentiability. We specify the derivatives used in the iteration, source response and comparison arguments. For a finite-support increment of free variables, each changed pivot is in a fixed neighbouring double block. Only finitely many Wilson and GF terms change, so the relative value of $A + \mathrm{GF}$, its first variation, and its second variation are ordinary finite sums. The b-component of $F(B, u)$ is the derivative under a variation of the single free coordinate b. It is a function of finitely many local free and coarse coordinates. This defines the same component even when u and the background do not have finite support. The row/column estimates previously proved extend its derivative matrices to bounded fields.

Here is a uniform remainder check that proves actual Fréchet differentiability on ℓ^∞. Put

$$\rho_b = c_{\mathrm{loc}} r_b, \qquad \rho_u = r_u/4, \qquad G_L = C_* L^{13}. \tag{3.clxxiii}$$

Here $c_{\mathrm{loc}} > 0$ is a universal constant fixed by the matrix-logarithm and local-frame domain estimates before C_* is chosen. Take C_* large enough that $b_N \le \rho_b/4$ and to cover all derivative constants below. Each component of F is holomorphic and bounded by G_L on the joint local domain of radii $2\rho_b, 2\rho_u$. Indeed one free Cauchy derivative of a bounded local interaction costs CL^9, and at most CL^4 terms enter that component. The estimate is independent of the number of coordinates elsewhere on the lattice. The radii in eq. 3.cxlviii and eq. 3.clx, with its reduced first entry, lie strictly inside half these local radii.

At such an interior point define $\nu = \|\Delta B\|_\infty/\rho_b + \|\Delta u\|_\infty/\rho_u \le 1/4$. For each row apply scalar Cauchy to $t \mapsto F_b(B + t\Delta B, u + t\Delta u)$ on a circle of radius $(2\nu)^{-1}$; the case $\nu = 0$ is immediate. The circle stays in the stated local domain. Summing the scalar Taylor remainder of order at least two, uniformly in the row, gives

$$\begin{aligned}\|F(B + \Delta B, u + \Delta u) - F(B, u) - (\partial_1 F)(B, u)\Delta B - (\partial_2 F)(B, u)\Delta u\|_\infty \\ \le C G_L \nu^2.\end{aligned} \tag{3.clxxiv}$$

The first Taylor coefficient is a linear map of the increments because each component is an ordinary finite-dimensional derivative. Its uniform Cauchy bound makes that map bounded on ℓ^∞. eq. 3.clxxiv is the required uniform Fréchet remainder. Applying the same argument to the derivatives proves their continuity and higher local analytic remainders. It also applies to the chart components, using their uniform bound $S_L\|u\|_\infty$. Consequently the iteration is a genuine bounded-field equation. Its holomorphic iterates converge uniformly; their component Cauchy integrals and uniform remainders pass to the limit. The resulting bounded-field maps are locally holomorphic, as are the finite parameter families already stated. No extensive action estimate or formal derivative of an infinite action value is needed.

The regular minimum and its quantitative strictness. For every real u in the whole closed r_N-ball, eq. 3.cxliv and the radius choice give the Hermitian form bound

$$DF_V(u) \ge (c_0/2 - N_L r_N)\, I \ge c_0/4\, I. \tag{3.clxxv}$$

In fact $N_L r_N \le (16 B_L)^{-1} \le c_0/128$. On a finite torus this proves uniform strict convexity of the actual $A + \mathrm{GF}$ in free coordinates. On the infinite lattice the same quadratic inequality applies to compact variations.

On a finite torus let W be any real fibre field of curvature at most η_{reg}, with $\mathcal{M}_L W = V$. Its canonical gauge fixing, equal to identity at the coarse centers, gives an axial representative W_{ax}. By eq. 3.clix it has actual coordinates u_W in the same ball. Let $u_* = u(V)$ and $d = u_W - u_*$. The full free segment $u_* + sd$, $0 \le s \le 1$, remains in the convex ball. The segment is used for $A + \mathrm{GF}$; axiality is needed at its two endpoints. Since $F_V(u_*) = 0$, Taylor's integral identity and eq. 3.clxxv give

$$\begin{aligned}&[A + \mathrm{GF}](U_V(u_W)) - [A + \mathrm{GF}](U_V(u_*))\\ &\quad = \int_0^1 (1-s)\langle d, DF_V(u_* + sd)d\rangle\, ds \ge (c_0/8)\|d\|_2^2.\end{aligned} \tag{3.clxxvi}$$

Both endpoints are axial, so their actual GF values vanish. Wilson gauge invariance gives $A(W) = A(W_{\mathrm{ax}})$. Therefore

$$\boxed{A(W) - A(U(V)) \ge (c_0/8)\|u_W - u(V)\|_2^2.} \tag{3.clxxvii}$$

Equality forces the canonical axial representatives to coincide, so equality occurs precisely in the constructed center-fixing gauge orbit. The constructed field belongs to this regular class by eq. 3.cxlviii–eq. 3.cli. Hence the construction gives its minimizing orbit among the stated regular fibre fields; no minimum over fields outside that class is claimed.

On the infinite lattice take instead a compact perturbation W of $U(V)$, still real, regular and in the same fibre. Only finitely many blocks can have changed internal means. Its canonical axializing site gauge is therefore identity outside finitely many blocks, because $U(V)$ is already axial. Thus $W_{\mathrm{ax}} - U(V)$, and hence $u_W - u_*$, have finite support. Chart locality makes the entire segment in eq. 3.clxxvi a variation in a fixed finite fine neighbourhood. All relative action values and derivatives in that equation are finite interaction differences. The same Taylor argument proves eq. 3.clxxvii with exactly that meaning of the left-hand side. It does not compare infinite extensive action values.

Dependence on coarse data in the product topology. For a free row b, let D_b be its finite set of coarse face variables on which $F_V(u)_b$ depends. This set is contained in a fixed number of neighbouring coarse blocks, for every admitted u. For a finite coarse patch $\mathcal{P}$, put

$$I_{\mathcal{P}} = \{b : \mathsf{D}_b \subset \mathcal{P}\}, \qquad \delta_{\mathcal{P}} = \sup_{c\in\mathcal{P}} \|V(c) - V'(c)\|, \qquad \delta_L = \min\{1/8, r_b/(8C_*)\}. \tag{3.clxxviii}$$

Suppose V, V' are both admitted real data and $\delta_{\mathcal{P}} \le \delta_L$. Write $u = u(V)$, $u' = u(V')$, and evaluate the latter array in F_V. It is in the common free ball even though the data can differ arbitrarily outside $\mathcal{P}$.

We justify a local source estimate without a patch-volume loss. For $c \in \mathcal{P}$ take the principal left logarithm $B(c) = i^{-1}\log(V'(c)V(c)^{-1})$; it has norm at most $C\delta_{\mathcal{P}}$. Extend it by zero outside the patch. On a row in $I_{\mathcal{P}}$, strict locality identifies the endpoint data with V'. Uniqueness of each actual local pivot graph identifies that endpoint with the chart used for V', independently of data outside its dependence set. Fixed local real frames for V keep the background interpolation $e^{itB}V$ inside the actual joint analytic chart. This interpolation need not stay in the admitted small-curvature class. One background-direction and one free-direction Cauchy formula, with u' held fixed, give

$$\sup_{b\in I_{\mathcal{P}}} |F_V(u')_b - F_{V'}(u')_b| \le Q'_L\delta_{\mathcal{P}}, \qquad Q'_L = C_* L^{18}. \tag{3.clxxix}$$

The count is L^5 for the background radius, L^9 for the free radius and L^4 local terms. The background direction has supremum norm at most $C\delta_{\mathcal{P}}$, so its number of nonzero faces is absent from this estimate.

The same real averaged Hessian as in eq. 3.clxix, with the data V fixed, satisfies

$$\overline{\mathcal{H}}(u - u') = -F_V(u'), \qquad |F_V(u')_b| \le \begin{cases} Q'_L\delta_{\mathcal{P}}, & b \in I_{\mathcal{P}},\\ 2M_L r_N, & b \notin I_{\mathcal{P}}.\end{cases} \tag{3.clxxx}$$

The interior estimate uses $F_{V'}(u') = 0$; the exterior estimate uses $F_V(u) = 0$ and the uniform derivative bound along the free segment. No comparison of the distant coarse data is used there. Define the finite weighted kernel-row constant

$$\mathcal{B}_L = \frac{8}{c_0} \sum_{m \geq 0} C_4 (m+1)^3 e^{-\sigma_L m/2}, \qquad C_{\mathrm{cont},L} = \mathcal{B}_L \max\{Q'_L, 2M_L\}. \tag{3.clxxxi}$$

The conjugation proof applies to $\overline{\mathcal{H}}$ by eq. 3.clxxv. Its exponentially weighted absolute rows, multiplied by the two parts of eq. 3.clxxx, yield

$$|u(b) - u'(b)| \leq C_{\mathrm{cont},L} \delta_{\mathcal{P}} + C_{\mathrm{cont},L} r_N e^{-\sigma_L d(b, I^c_{\mathcal{P}})/2}. \tag{3.clxxxii}$$

If the complement is empty, its distance is infinity and the second term is zero. The estimate contains neither the patch cardinality nor the torus volume. Local chart derivatives give the analogous fine-field estimate, with a fixed additional neighbourhood absorbed in the constant and in the distance margin.

For clarity the admitted infinite-volume real data set is

$$\mathcal{A}_L = \{V \in \mathrm{SU}(2)^{\mathcal{E}_{\mathrm{coarse}}} : \|V(\partial P) - I\| \leq \epsilon_* \text{ for every coarse plaquette } P\}. \tag{3.clxxxiii}$$

The bond set is countable. Each displayed condition is continuous in finitely many product coordinates, so $\mathcal{A}_L$ is closed in the compact metrizable product configuration space. Given a fixed free bond and an error tolerance, first choose a finite patch with distance to its exterior large enough to make the second term of eq. 3.clxxxii small. Then constrain its finitely many face variables so $\delta_{\mathcal{P}}$ makes the first term small. This proves coordinatewise continuity of $V \mapsto u(V)$ on $\mathcal{A}_L$ in its relative product topology. Every fine output component depends continuously on finitely many data and chart coordinates, so $V \mapsto U(V)$ is continuous in the fine product topology. It is consequently Borel. The Borel structures here are those of the two countable product configuration spaces.

Compatibility of the complex germs. For each admitted real V, use the complex neighbourhood with principal coarse coordinates $W = e^{iB}V$, $\|B\|_\infty < b_N$. The fixed-real-base construction gives a root $u_V(W)$; denote its associated fine field by $\mathcal{U}_V(W)$. Its improved bound follows directly from eq. 3.clxi:

$$\|u_V(W)\|_\infty \leq \frac{\|\mathcal{T}_B(0)\|_\infty}{1 - 1/8} \leq r_N/7 < r_N/4. \tag{3.clxxxiv}$$

Consider a common complex datum $W = e^{iB}V = e^{iB'}V'$ in two such neighbourhoods. The face lift $U_0(W)$ is the same exact bond configuration in both presentations. Its internal bonds and their means are I, and its exact average is W. The free coordinates are the principal small left bond logarithms relative to this same lift.

We check that the actual chart is shared. At zero, all closed products in its average are I. For the retained small full chart variables, the internal path transports, the closed products, and the relative coarse products stay in their same near-identity logarithm neighbourhoods. The face values of W and their inverses are uniformly bounded, because W is in a retained complex neighbourhood of a real unitary datum. Internal means use the unique near-identity implicit mean. The closed and relative logarithms use the unique principal branch there. Unitary local frames conjugate these branches; they do not select new ones. It follows that both presentations have the same actual function

$$\begin{aligned} q_W(a) &= i^{-1} \log[\mathcal{M}_L(e^{ia} U_0(W)) W^{-1}], \\ P_W = Dq_W(0), &\qquad R_W(a) = q_W(a) - P_W a. \end{aligned} \tag{3.clxxxv}$$

Here h_W is the inverse of the same diagonal pivot coefficients, inserted at the same pivots. For a fixed free u, either chart satisfies the identical local equation

$$a = C_W u - h_W R_W(a), \qquad a|_{\mathrm{free}} = u. \tag{3.clxxxvi}$$

The existing joint pivot contraction has Lipschitz constant less than one on its retained full-variable neighbourhood. Both chart outputs are in that neighbourhood, since $\|a\|_\infty \le S_L r_N$ and $r_N \le r_u/16$. Its uniqueness therefore proves equality of the two graphs for $\|u\|_\infty \le r_N$, component by component. The resulting equation $F_W(u) = 0$ is identical in the two constructions.

Both roots in eq. 3.clxxxiv are in the entire r_N-ball on which either fixed-real-base map is a contraction. Either inverse H_V or $H_{V'}$ is two-sided on bounded fields, so its fixed points in that ball are exactly the roots of this common equation. Uniqueness at the common complex datum gives

$$u_V(W) = u_{V'}(W), \qquad \mathcal{U}_V(W) = \mathcal{U}_{V'}(W). \tag{3.clxxxvii}$$

The uniform local Fréchet estimates and holomorphic contractions then glue these continuations on overlaps. This uses the common complex datum and the actual pivot-graph uniqueness; it does not assume that the overlap contains an admitted real point or extend the argument to unrelated average maps or logarithm branches.

We have proved existence, a quantitative regular minimizing orbit, bounded pointwise current stationarity, product-topology continuity, compatible complex continuation and exponential first responses for an actual first-step background. The named comparison below checks independent currents on this first-step axial locus. Nothing here constructs a many-level background, treats signed layer coefficients or complex decoupling arrays, or proves the conditional exterior-force, history-class or interacting Gaussian-law assertions.

3.9. **Domains of local substitutions.** The ordinary step uses three coordinate systems at once. A bond logarithm is a group coordinate, a potential is a group coordinate divided by a length, and a Gaussian coordinate is a physical logarithm divided by a coupling. Its analytic domains also have two distinct parts: bounds on a field and bounds on every background obtained from its restricted averages. We fix these conventions and give quantitative admission tests. The tests apply to the nonlinear local maps themselves.

The finite averaging chart, the classical flat comparison, the first-step physical Hessian and the first-step background construction are used in their stated scopes. The last construction includes its regular minimum, product continuity and complex gluing conclusions. The many-level background and response estimates are not conclusions of this section. They occur below as explicitly named domain estimates. Once those estimates hold, all the inclusions, changes of units and Cauchy estimates used here are proved with constants independent of depth and compatible volume.

3.9.1. *Lengths, covectors and quadratic coefficients.* Work in the units of a fixed level. The bare spacing is η, with $0 < \eta \le 1$; a bond configuration is written

$$\mathbf{U}(b) = e^{ia(b)}U(b) = e^{i\eta A'(b)}U(b), \qquad a = \eta A'. \tag{3.clxxxviii}$$

Here U is real. The independent analytic current will be denoted by $\mathbf{J}$. The Wilson gradient is denoted by $J_A(U)$ when its normalization has been specified. These are different variables. The color pairing is $(X, Y) = \frac{1}{2}\operatorname{tr}(XY)$. It is complex bilinear. Operator norms on complex coordinate spaces use the corresponding Hermitian norm, and therefore use adjoints rather than bilinear transposes in positivity arguments.

Suppose that the current density is normalized by

$$DA_W(U)[\eta A] = \eta^4 \sum_b (J_A(U)(b), A(b)). \tag{3.clxxxix}$$

The covector for the raw logarithm a, with counting pairings, is $\jmath_A(U) = \eta^3 J_A(U)$. Indeed substitution of $A = a/\eta$ in eq. 3.clxxxix gives $DA_W(U)[a] = \sum_b (\eta^3 J_A(U)(b), a(b))$. At unit spacing, these two current conventions coincide. The formula in eq. 3.clxxxix also explains the dimension three weight on a current: the action has dimension zero, while a potential has dimension one in four dimensions.

More generally let a linear response H map datum coordinates to field coordinates with positive diagonal pairing matrices W_r, W_f. Its bilinear transpose and its transpose after length normalization are

$$H^{\mathsf{T}} = W_r^{-1} H^{\mathrm{t}} W_f, \qquad P = \mathsf{m}Q, \qquad P^{\mathsf{T}} = Q^{\mathsf{T}}\mathsf{m}^{\mathsf{T}}. \tag{3.cxc}$$

The matrix m multiplies a row by its length ξ_c. This formula is valid for arbitrary specified row weights; no row-volume factor is inferred from the letter Q. To verify it, write $u^{\mathrm{t}} W_f H v = (H^{\mathrm{t}} W_f u)^{\mathrm{t}} v$ and compare with the row pairing. Thus every transpose in a field-current identity must refer to its two declared pairings. Counting row pairings and volume field pairings can be used together, provided eq. 3.cxc is used.

Let h be a right inverse for the raw constraint derivative P. The right inverse for the per-length derivative Q is $h_Q = h\mathsf{m}$. For the corresponding raw and per-length multipliers one obtains

$$Ph = 1, \quad Qh_Q = 1, \qquad \mu = h^{\mathsf{T}} J, \quad \mu_Q = h_Q^{\mathsf{T}} J = \mathsf{m}^{\mathsf{T}} \mu. \tag{3.cxci}$$

If $q_Q = \mathsf{m}^{-1} q$, then $\langle \mu_Q, D^2 q_Q \rangle = \langle \mu, D^2 q \rangle$. Consequently changing a constraint from raw to per-length coordinates changes its multiplier at the same time. It does not change the physical curvature pairing.

For a change of length unit, let the new unit be L^{-n} times the old one. Numerical lengths multiply by L^n. The same configuration and current are represented by

$$\eta_{\mathrm{new}} = L^n \eta_{\mathrm{old}}, \quad A_{\mathrm{new}} = L^{-n} A_{\mathrm{old}}, \quad J_{\mathrm{new}} = L^{-3n} J_{\mathrm{old}}, \quad \nabla_{\mathrm{new}} A_{\mathrm{new}} = L^{-2n} \nabla_{\mathrm{old}} A_{\mathrm{old}}. \tag{3.cxcii}$$

The first identity and $a = \eta A$ prove the second. A difference quotient contains one inverse numerical length, which proves the fourth. The third follows either from eq. 3.clxxxix, or from the dimension three of its covector. In particular $\eta^4 \langle J, A \rangle$ is unchanged. If a bond lies in a layer of local scale ξ, the quantities

$$\xi |A|, \qquad \xi^2 |\nabla_U A|, \qquad \xi^3 |J|, \qquad (\xi/\eta)^2 |\partial U - 1| \tag{3.cxciii}$$

are unchanged as well. These are the quantities that enter a layered regularity test. Applying the same radius to their unweighted numerical coordinates would describe a different domain.

At a step whose fixed reference inverse coupling is t, put $g = \mathsf{t}^{-1/2}$. If y is the Gaussian free coordinate and Φ_U the actual physical fibre chart, the configuration is

$$U_y = e^{i\Phi_U(gy)} U, \qquad |y| < \mathfrak{b}, \qquad \delta = g\mathfrak{b}. \tag{3.cxciv}$$

Thus a physical free-coordinate radius r becomes r/g, before allowances for the norm of the chart and the background response. The chart is applied to gy, not to y.

For a holomorphic scalar functional $F(B)$ of a physical datum, let $F_s(B_s) = F(gB_s)$. The chain rule gives

$$D^2 F_s(0) = g^2 D^2 F(0), \qquad |b(F_s)| \le CM(g/r)^2 \iff |b(F)| \le CMr^{-2}. \tag{3.cxcv}$$

Here the last equivalence means the corresponding bounds under the same linear coefficient readout. It is not an assertion that a general coefficient is saturated by its Cauchy bound. The free-response and spatial-moment sums in that readout have their own fixed constants. In particular a radius proportional to $g(\log g^{-2})^q$ is a growing logarithmic radius in the Gaussian variable. Its physical extraction factor remains $g^{-2}(\log g^{-2})^{-2q}$.

3.9.2. *The actual average and its three linearizations.* The internal transport $T_{y,x}(U)$, $x \in B(y)$, is the mean of the transports along coordinate-order shortest paths from y to x. There is one path for each ordering of the four directions, with multiplicity; there are at most 4! such paths. It is the solution near that family of $\sum_\Gamma \log(U(\Gamma) T_{y,x}^{-1}) = 0$. It is not an arithmetic average of matrices.

With $x' = x + c_+ - c_-$, set

$$W_x(U) = T_{c_-,x}(U)U([x,x'])T_{c_+,x'}(U)^{-1}U[c]^{-1},$$
$$\mathcal{M}(U)(c) = \exp\left(L^{-4}\sum_{x\in B(c_-)}\log W_x(U)\right)U[c]. \tag{3.cxcvi}$$

This formula uses the regular local logarithm. The total measurable average also has its prescribed fallback rules. Those rules make real measure identities meaningful on every configuration. Cauchy estimates below use only the analytic extension of eq. 3.cxcvi, with all physical substitution values remaining in its regular branch.

At the identity let $\overline{a}(y,x)$ be the arithmetic mean of the signed path sums. Define the raw straight and plain derivatives by

$$\begin{aligned}(S_La)(c) &= L^{-4}\sum_{x\in B(c_-)} a([x,x']),\\ (\Sigma_La)(y) &= L^{-4}\sum_{x\in B(y)}\overline{a}(y,x),\\ P_La &= S_La - \mathrm{d}_c\Sigma_La, \qquad (q_L\lambda)(y) = L^{-4}\sum_{x\in B(y)}\lambda(x),\end{aligned} \tag{3.cxcvii}$$

where $(\mathrm{d}_cf)(c) = f(c_+) - f(c_-)$. The sign in eq. 3.cxcvii follows by differentiating the four transports in eq. 3.cxcvi. For a gradient $a = \mathrm{d}\lambda$, every path sum telescopes. Consequently

$$\Sigma_L\mathrm{d}\lambda = q_L\lambda - \lambda|_{\text{centers}}, \qquad S_L\mathrm{d}\lambda = \mathrm{d}_cq_L\lambda, \qquad P_L\mathrm{d}\lambda = \mathrm{d}_c(\lambda|_{\text{centers}}). \tag{3.cxcviii}$$

This proves both gradient identities directly. The scalar site average and restriction to centers have different kernels.

The straightening relative to a real background U_0 removes a block factor. In raw coordinates its one-step definition is

$$\begin{aligned}u_y(a) &= \exp\left(L^{-4}\sum_{x\in B(y)}\log[T_{y,x}(e^{ia}U_0)T_{y,x}(U_0)^{-1}]\right),\\ e^{i\mathcal{Q}^1(U_0,a)(c)}\mathcal{M}(U_0)(c) &= u_{c_-}(a)^{-1}\mathcal{M}(e^{ia}U_0)(c)u_{c_+}(a).\end{aligned} \tag{3.cxcix}$$

For several steps this definition is iterated, including the accumulated node factors. Differentiating at a flat background removes precisely the $\mathrm{d}_c\Sigma_L$ term and gives the straight derivative. For a general background, the resulting derivative is the straightened derivative $Q^\sharp$. Its leading transported straight derivative is a third operator, Q^{st}. The plain derivative Q^{pl}, $Q^\sharp$, and Q^{st} must therefore have separate names.

In physical potential coordinates, the derivative also contains the input length factor. After k straight steps at the identity it is $\eta_kS_L^k$, where $\eta_k = L^{-k}$. Its row sum is one, because the raw straight row sum is L at every step. With covariant difference quotients and the appropriate coarse units, differentiation of gauge covariance gives

$$Q_k^{\mathrm{pl}}(U)D_U\lambda = D_{\mathcal{M}^kU}(\lambda|_{\text{centers}}), \qquad Q_k^\sharp(U)D_U\lambda = D_{\mathcal{M}^kU}Q_k'(U)\lambda. \tag{3.cc}$$

The first formula follows from the exact bi-equivariance of $\mathcal{M}$, including its node endpoints. The second follows from the same calculation after eq. 3.cxcix; its site factor is the derivative of the averaged gauge transformation. A transported straight main term does not satisfy the second identity exactly unless the omitted straightening correction is zero.

There is a quantitative reason to keep these distinctions even at a flat field. For the raw straight map, every fixed fine bond occurs in exactly L of the intervals $[x, x+Le_\mu]$, counted over all block starts. Its unsigned column sum is L^{-3}. Its row sum is L. In contrast choose the first internal bond

from a block center in direction μ. Among the path orderings, at least a fraction $1/4$ start in that direction. There are $(L-1)L^3/2$ endpoints with positive μ-coordinate. Therefore its coefficient in $\Sigma_L a(y)$ is at least

$$L^{-4}\frac{1}{4}\frac{L-1}{2}L^3 = \frac{L-1}{8L} \geq \frac{1}{12} \qquad (L \geq 3). \tag{3.cci}$$

Take an outgoing coarse bond in another direction. Its straight part does not see this fine component, and its plain derivative contains this Σ_L coefficient. Hence the plain column bound is not the straight column bound. Zero displacement in some path directions causes no problem, since the coordinate orders form a multiset. This calculation uses a nonwrapping local lift. Periodic tori large enough for the same double block have the identical calculation.

On curvature quotients the difference in eq. 3.cxcvii is a gradient, so the classical energy comparison can transfer after an exact gradient correction. That quotient statement does not identify the full gauge, current or node-factor operators. In particular a column estimate for one of those operators is an estimate in its declared coordinates, not an estimate for an unnamed map denoted by Q.

3.9.3. *The fibre chart, current subtraction and contour gauges.* On the regular logarithm branch, define

$$q_U(a) = i^{-1}\log[\mathcal{M}(e^{ia}U)\mathcal{M}(U)^{-1}].$$

Put $P_U = Dq_U(0)$. The pivot construction gives a right inverse h_U, supported on the crossing pivots. If ι inserts the free coordinates and leaves pivots zero, set

$$C_U = \iota - h_U P_U \iota, \qquad q_U(\Phi_U(u)) = 0, \qquad \Phi_U(0) = 0, \quad D\Phi_U(0) = C_U. \tag{3.ccii}$$

The chart has identity restriction to the free coordinates; its nonlinear correction is on the pivots. Two differentiations of the constraint give

$$D^2\Phi_U(0)[u,v] = -h_U D^2 q_U(0)[C_U u, C_U v]. \tag{3.cciii}$$

Indeed its image is on the pivots, where P_U has inverse h_U. This also proves the sign without appealing to a convention for a "quadratic part." If $q_U^{(2)}$ is the homogeneous quadratic polynomial, then $D^2 q_U(0)[a,a] = 2q_U^{(2)}(a)$.

Let $\mathscr{A}_U$ denote the raw Wilson Hessian, and let J be a raw fine covector in this paragraph. The explicitly defined auxiliary form and its physical value are

$$\begin{aligned} K_U^{\mathrm{aux}}[J](u,v) &= \langle C_U u, \mathscr{A}_U C_U v\rangle + G_U^{\mathrm{abs}}(u,v) - \langle h_U^{\mathsf{T}} J, D^2 q_U[C_U u, C_U v]\rangle, \\ K_U^{\mathrm{phys}} &= K_U^{\mathrm{aux}}[\jmath_A(U)]. \end{aligned} \tag{3.cciv}$$

Here G_U^{abs} is the Hessian of the absolute contour gauge composed with the chart; pivot avoidance also identifies it with $C_U^{\mathsf{T}}(\mathrm{Hess}\,\mathrm{GF})C_U$. The equality is the ordinary chain rule, since the pivots occur in no internal contour path and hence $h_U^{\mathsf{T}}\jmath_{\mathrm{GF}} = 0$. It does not require the starting field to be a critical point. Criticality is used for the stationary Gaussian interpretation. The proved small-curvature physical gap also applies to the noncritical starting face lift used to construct the first-step background.

For clarity the two contour functionals are

$$\begin{aligned} \mathrm{GF}(V) &= \sum_{y,x\neq y}\left(1 - \tfrac{1}{2}\,\mathrm{tr}\,T_{y,x}(V)\right), \\ \mathrm{GF}_{\mathrm{rel},U}(a) &= \sum_{y,x\neq y}\left(1 - \tfrac{1}{2}\,\mathrm{tr}[T_{y,x}(e^{ia}U)T_{y,x}(U)^{-1}]\right). \end{aligned} \tag{3.ccv}$$

The second has zero first derivative at every U. If $G_U a$ is the first derivative of the relative contour logarithm, its Hessian is $G_U^{\mathsf{T}} G_U$, with the declared color pairings. This follows by expanding $1 - \frac{1}{2}\,\mathrm{tr}\,e^{iX} = \frac{1}{2}|X|^2 + O(|X|^4)$. The first functional has that Hessian only on the axial locus

$T_{y,x}(U) = 1$. For example the second derivative of $1 - \frac{1}{2}\operatorname{tr}(e^{it\sigma_3}e^{i\vartheta\sigma_3})$ is $\cos\vartheta$, whereas the relative expression has second derivative one. Absolute gauge is invariant under block-constant gauges. The relative function is jointly invariant under arbitrary site gauges: the product of its two contour factors transforms by conjugation at y. These are different covariance statements.

The gauge-restoration term in a named propagator requires an additional check. Let Q' be the assigned average of site functions, $\Delta_{\text{site}} = D^{\mathsf{T}}D$, and $G' = (\Delta_{\text{site}} + Q'^{\mathsf{T}}aQ')^{-1}$, with the specified positive site weight a. The real gauge projection R projects onto $\Delta_{\text{site}}\ker Q'$; on the admitted complex domain the same operators use their bilinear analytic formulas. Their existence on that domain is part of the primitive operator requirement. Put $S = 1 - DG'RD^{\mathsf{T}}$. On physical currents its projected Hessian is expressed by

$$\Delta_\pi = S^{\mathsf{T}}\Delta^{\mathrm{W}}S, \qquad \Delta'_\pi = \Delta^{\mathrm{W}} - \Delta_\pi. \tag{3.ccvi}$$

Thus $R = 0$ makes this physical correction zero. For an independent-current completion $\Delta'_\pi[J]$, it is necessary to inspect its actual formula. If it is obtained by expanding eq. 3.ccvi and extending its current factors without removing the factors of R, then it is zero when $R = 0$ for every J: every term of $\Delta^{\mathrm{W}} - (1-T)^{\mathsf{T}}\Delta^{\mathrm{W}}(1-T)$, $T = DG'RD^{\mathsf{T}}$, contains a T. This is a sufficient algebraic criterion, not a conclusion from agreement on the physical graph alone.

Normalize every quadratic matrix by the exponent $-\frac{1}{2}\langle u, Ku\rangle$. At the first step, where the zero-fold average is the identity, the difference between a named completion and eq. 3.cciv has the complete form

$$\begin{aligned}\mathcal{D}_U[J] &= C_U^{\mathsf{T}}(\mathscr{G}_U^{\text{named}} - \mathscr{G}_U^{\text{abs}} - \Delta'_\pi[J])C_U \\ &\quad - C_U^{\mathsf{T}}E_U^{(2)}[J]C_U + \mathcal{E}_U[J], \\ \mathcal{E}_U[J](u,v) &= \langle h_U^{\mathsf{T}}J, D^2q_U[C_Uu, C_Uv]\rangle.\end{aligned} \tag{3.ccvii}$$

The notation for the current readout inside $E^{(2)}$ must first be converted by eq. 3.cxc–eq. 3.cxci. The formula in eq. 3.ccvii is obtained by subtracting the two quadratic forms term by term. Matching just its last line is the constraint-readout condition; it is not the complete comparison. In particular a relative gauge prescription at a seam-free stage must be reconciled with the named matrix used at that stage.

3.9.3.1. Domain estimate I: the named completion. For the actual regular pair on each required region, compute all terms of eq. 3.ccvii with one declared pairing and Hessian normalization. Prove either $\mathcal{D}_U[J] = 0$, or an explicit local coefficient estimate small enough for the available gap. The quantifiers include independent complex J on its own radius, the chosen gauge representatives and all admitted local restrictions. The physical identity in eq. 3.cciv and the first-step physical gap already hold independently of this estimate. The calculation at zero inner depth can be done directly.

3.9.3.2. The named form at the first step. Take the unweighted bare torus with no lower layers, and use bare units. In the lower sequence all bond and site rows are the zero-fold rows $Q = 1$ and $Q' = 1$. The Landau projection R is zero. In the definition of the gauge-restoration term, the gauge read is $\mathsf{V}A = G'RD^{\mathsf{T}}A$. Its vanishing gives $\Delta'_\pi[J] = 0$ directly from the defining quadratic form, for independent J as well as for the physical current. The lower straightened constraint $\mathcal{Q}_0(U;A) = A$ is linear. Its quadratic correction $\Delta^{(2)}$ is therefore zero. With the bare row weight one, the ordered inverse formulas give

$$\mathsf{G}_1^{-1} = \mathscr{A}_U + 1, \qquad \mathsf{H}_1 = 1, \qquad (Q\mathsf{G}_1Q^{\mathsf{T}})^{-1} - 1 = \mathscr{A}_U.$$

These identities are on the domain of the named inverses.

The outer row is still the genuine one-step average. The source's per-length derivative is $L^{-1}Dq_U(0)$, so at a pivot its coefficient is L^{-1} times that of the raw derivative. The pivot operator with coefficient $L^{-1}\kappa_U(c)^{-1}$ is exactly h_U in raw constraint coordinates. The polarized

quadratic coefficient of the raw logarithm is $\frac{1}{2}D^2q_U(0)$. In the bare pairing the lower current read $\mathsf{H}_1^{\mathsf{T}}J$ is J itself, restricted to the bonds of the next step. The named correction pairs twice that polarized coefficient, after h_U, with this current. Consequently

$$\langle C_U u, \mathsf{E}^{(2)}[\mathsf{H}_1^{\mathsf{T}}J]C_U v\rangle = \langle h_U^{\mathsf{T}}J, D^2q_U(0)[C_U u, C_U v]\rangle.$$

The named gauge term is the relative contour Hessian in eq. 3.ccv. On the axial locus the base contour values equal one, so the relative and absolute functionals agree there as functions of the perturbation. With the common free chart, all terms of the named form therefore agree with eq. 3.cciv on this first-step locus for independent admitted currents. Away from that locus the calculation gives the named relative completion, with the absolute-to-relative difference explicitly displayed in eq. 3.ccvii.

3.9.4. *Triples, simple bounds and hereditary cores.* Write $\eta_j = L^{-j}$ in level-j units. A core is initially a domain of triples $(U, A', \mathbf{J})$, with U real and $\mathbf{U} = e^{i\eta_j A'}U$. For fixed U, analyticity means holomorphy in $(A', \mathbf{J})$. On a single layer its simple conditions at radii (b_0, b_1) are

$$\begin{gathered}|\partial U - 1|,\ |\partial \mathbf{U} - 1| < b_0\eta_j^2, \qquad |A'|,\ |\nabla_U A'| < b_1, \qquad |\mathbf{J}| < b_0,\\ U = e^{i\eta_j A} \text{ in real gauges on the specified } O(LM) \text{ cubes}, \qquad |A|, |\nabla A| < C_g M b_0.\end{gathered} \tag{3.ccviii}$$

A convention with LM instead of M in the last constant is absorbed in $C_g(L)$, not in a level-dependent radius. On a layered domain the inequalities are written in the dimensionless quantities eq. 3.cxciii, with the assigned radii of that layer.

For every subdomain Z of level $p \le j$, form each of the two assigned eroded towers. The first uses its prescribed cube size and outer-unit gap, the second its prescribed minimal determining size and inner-unit gap. If $\mathbf{B}'$ is the determining set of a truncated tower, its configuration is the background continued from the real datum, evaluated at

$$B_Z = \frac{1}{i}\log\left[M_{\mathbf{B}'}(e^{i\eta_j A'}U)M_{\mathbf{B}'}(U)^{-1}\right]. \tag{3.ccix}$$

This definition keeps the real base U. Existence of a continuation from one base does not by itself identify it with a continuation from another base representing the same complex pair.

Let $Z^{\ominus 2}$ mean removal of the prescribed two cube layers. The hereditary clauses, for every truncation $n \le p$ of both rules, are existence and the bounds

$$\begin{aligned}&|\partial U_n(Z;\mathbf{U}) - 1| < b_0 L^{-(j-p)}\eta_p^2,\\ &|J_A(U_n(Z;\mathbf{U}))| < b_0 L^{-(j-p)}L^{2(n-p)} \qquad \text{on } Z^{\ominus 2}.\end{aligned} \tag{3.ccx}$$

The current in the second line is formed in level-n units. The same clauses are imposed on the real factor U. This current is not the independent argument $\mathbf{J}$ of an activity. The two kinds of current enter different tests.

We denote the resulting hereditary core by $\mathcal{C}_j(X; b_0, b_1)$. A local function descends from triples to pairs only when its actual definition gives the same value on two admitted splittings of that pair. In collar expressions this requirement may belong to a specified difference of terms rather than each term. Restriction to a smaller set is permitted only with its required collars and determining neighborhoods. In particular it is not an operation that discards some of the quantifiers in eq. 3.ccx.

The linear regular-pair class has a related but different convention. On a layer of scale ξ it asks for curvature $\alpha_0\eta^2\xi^{-2}$, imaginary potential and first difference $\alpha_1\xi^{-1}, \alpha_1\xi^{-2}$, independent current $\gamma_0\xi^{-3}$, and real gauges on $O(M_1\xi)$ cubes with $\xi|A|, \xi^2|\nabla A| \le \alpha_0$. If those cubes fit into the core's gauge cubes, the simple part of eq. 3.ccviii enters this linear class whenever

$$b_0 \le \min\{\alpha_0, \gamma_0\}, \qquad b_1 \le \alpha_1, \qquad C_g M b_0 \le \alpha_0. \tag{3.ccxi}$$

These inequalities follow by substitution in the four tests. The last one is essential: the linear class's gauge bound is α_0 on the entire cube, not $M\alpha_0$. The required containment of gauge cubes, and

their nonwrapping torus lift, are geometric conditions that must be checked before this inclusion is used.

3.9.5. *Quantitative room inside a core.* Here is a precise meaning of spending a fraction of a core. Divide each left side of eq. 3.ccviii and eq. 3.ccx by its stated radius and scale factor. Include the corresponding real-gauge bounds and the datum-radius tests for each atomic continuation used in eq. 3.ccix. Call the resulting nonnegative tests N_β. A central core of fraction ϑ means $N_\beta \le \vartheta < 1$ for every test, on the same declared atomic domains. At fixed finite world there are finitely many tests, although their number need not have a useful bound independent of depth.

Margin lemma. Suppose a proposed substitution p_z has all its atomic maps defined on a joint parameter domain and

$$N_\beta(p_0) \le \vartheta, \qquad |N_\beta(p_z) - N_\beta(p_0)| \le \epsilon \quad \text{for every } \beta, \qquad \vartheta + \epsilon < 1. \tag{3.ccxii}$$

Then the substitution belongs to the core throughout that domain. This is immediate for each test, and the same bound holds after taking their supremum. No factor counting the tests occurs. The hard part of an application is proving the uniform test difference, including every normalized tower test. Simple-condition bounds alone are not that proof.

Near the identity a useful inclusion follows from a precise tower estimate. Put $\|v\|_1 = \max(\|A'\|_\infty, \|\nabla A'\|_\infty, \|\mathbf{J}\|_\infty)$. The plaquette expansion gives

$$|\partial e^{i\eta A'} - 1| \le C\eta^2(\|\nabla A'\|_\infty + \|A'\|_\infty^2). \tag{3.ccxiii}$$

To prove it, the terms linear in the four exponentials add to the discrete curl times $i\eta^2$. The remaining series has at least two factors $\eta A'$ and is bounded by $C\eta^2\|A'\|_\infty^2$ on a fixed small chart. This proof is uniform as $\eta \downarrow 0$. A supremum bound on A' without its difference quotient would instead allow a linear term of order $\eta\|A'\|_\infty$.

3.9.5.1. Domain estimate II: uniform atomic towers. Cor. 3.130 proves that simple bounds at sufficiently small radii (e_0, e_1) give every continued tower in eq. 3.ccix, for both erosion rules and every truncation. The tests in eq. 3.ccx, divided by their displayed length and scale factors, are at most $K_T(e_0 + e_1^2)$. The constant is independent of j, p, n, Z, compatible volume and the real base. The common complex ball and the physical-current estimate are proved in Lem. 3.127 and Prop. 3.129.

Consequently there is $c > 0$ such that

$$\|v\|_1 < c\min\{b_0, b_1, 1\} \quad \Longrightarrow \quad (1, A', \mathbf{J}) \in \mathcal{C}_j(X; b_0, b_1). \tag{3.ccxiv}$$

For a proof choose $e_0 = \min\{b_0/(4K_T), a_T/4\}$ and $e_1 = \min\{b_1/2, \sqrt{b_0/(4K_T)}, a_T/4\}$. Then $e_0 + e_1 < a_T$, as required by Cor. 3.130. The right side of eq. 3.ccxiii divided by η^2, as well as $|\mathbf{J}|$, is less than e_0 when c is small. The potential tests are less than e_1. The real field is the identity, so its gauge tests vanish. Finally $K_T(e_0 + e_1^2) \le b_0/2$, which proves every tower clause. This argument also proves a fixed central-core margin by reducing c.

If a continued background pair $p(B)$, on the physical datum ball $\|B\|_\infty < r_B$, satisfies $\|p(B) - (1,0)\|_1 \le C_B\|B\|_\infty$, eq. 3.ccxiv proves admission on

$$\|B\|_\infty < \min\{r_B/2,\ c\min(b_0, b_1, 1)/(2C_B)\}. \tag{3.ccxv}$$

The radius is in the physical datum. In a Gaussian datum it is divided by g. Thus the background estimate and the tower estimate supply a near-zero ball directly; a further radius loss is not inferred just because the physical radius runs with the coupling.

For two local holomorphic representatives, equality on a real open subset of a common connected datum domain proves equality throughout that domain. One proof expands at a real interior point: every real partial derivative of their difference vanishes, hence every complex Taylor coefficient vanishes. Analytic continuation along overlapping balls in the connected domain finishes the proof. This applies to the first-step background's admitted common complex charts. It applies to functions of independent (A', J) only when the real agreement is open in both variables. Equality just at

$J = J_A(U)$ is not such an agreement; the holomorphic function $J - J_A(U)$ already demonstrates the distinction.

3.9.6. *Absolute and running systems of radii.* Set $f_q(t) = t^{-1/2}(\log t)^q$. The two running field radii have the form $\alpha_{i,j} = C_i f_q(\theta_j)$, $i = 0, 1$, while $\delta_j = C_\delta \theta_j^{-1/2}(\log \theta_j)^{p_0}$, with $q > p_0$. The constants C_i are fixed after the geometric parameters. They are not changed when a complex source is introduced. For a step of depth k, a system $\mathfrak{a}$ is admissible when

$$\begin{gathered} C_s M a_{0,j} < a_{1,j}, \qquad a_{1,j}^2 \le C_s a_{0,j}, \\ a_{i,j} \le \bar a_i := (1 + c_o) a_{i,k+1} \le C_o \sqrt{k + 2 - j}\, a_{i,j}, \\ s_{\mathfrak{a}} := \delta_k / a_{0,k+1} \le s_*, \qquad \bar a_0 + \bar a_1 \le a_*. \end{gathered} \tag{3.ccxvi}$$

The first two conditions govern the shape of the core; the next line compares every input radius with the output radius. The last line gives fluctuation room and an absolute ceiling. An output radius larger than an input radius is permitted; its ratio must be recorded in estimates.

The absolute system has entries $a_{i,j} = \alpha_i$ for $j \le k$ and $a_{i,k+1} = \alpha_i/(1 + c_o)$. Its output radii are $\bar a_i = \alpha_i$. The running system has

$$a_{i,j} = \min\{\alpha_{i,j-1}, \alpha_{i,j}\} \quad (1 \le j \le k), \qquad a_{i,k+1} = \alpha_{i,k}, \qquad \varrho_j = \max_i \frac{\bar a_i}{a_{i,j}}. \tag{3.ccxvii}$$

If a level-zero entry is needed, set $a_{i,0} = \alpha_{i,0}$; there is no negative-index radius. For $k = 0$ the old-member list is empty and its output entry is $a_{i,1} = \alpha_{i,0}$. The adjacent minimum admits the same old member at the two adjacent steps. It is not replaced by a radius chosen after that member is read.

Radii lemma. Suppose the real frame satisfies

$$\theta_j \ge T, \qquad -c_5 \le \theta_i - \theta_j \le B(j - i) \quad (i \le j). \tag{3.ccxviii}$$

Choose $C_1 > C_s M C_0$. For sufficiently large T, the absolute system with sufficiently small fixed α_i, and the running system below it, satisfy eq. 3.ccxvi. Moreover

$$\varrho_j \le C\sqrt{k + 2 - j}, \qquad s_{\mathfrak{a}} \le C(\log \theta_k)^{p_0 - q}. \tag{3.ccxix}$$

For the proof, $(\log f_q)'(t) = (-\frac{1}{2} + q/\log t)/t$, so f_q is decreasing above e^{2q}. Its logarithmic derivative has absolute value at most $1/t$ there. Thus bounded displacements of t change $f_q(t)$ by $1 + O(T^{-1})$, uniformly for $t \ge T$. The lower inequality in eq. 3.ccxviii then proves $a_{i,j} \le (1 + c_o)\alpha_{i,k}$, after increasing T. The adjacent minimum is at least $C_i f_q(\theta_j + B)$. For $u \ge \theta_k$, $f_q(\theta_k)/f_q(u) \le \sqrt{u/\theta_k}$; for $\theta_k - c_5 \le u < \theta_k$ its ratio is uniformly bounded. Since $\theta_j + B \le \theta_k + B(k + 1 - j)$, this proves the first bound in eq. 3.ccxix.

All entries of the running system are a common scalar times C_i. Its first shape condition follows from the choice of C_1/C_0. Its second follows from $a_{1,j}^2/a_{0,j} = (C_1^2/C_0)\min f_q(\theta) \to 0$ uniformly as $T \to \infty$. The remaining ceiling follows the same way, and division of δ_k by $\alpha_{0,k}$ proves the second bound in eq. 3.ccxix. For the absolute system choose the fixed α_i with the same shape, then increase T until the running system lies below it and $\delta_k/a_{0,k+1}$ is small. Every choice is independent of k.

There are two useful radius ratios for an old member. Its general unmarked bound may use $\max\{1, \delta_k/\alpha_j\}$. A homogeneous near-field Taylor bound uses the actual ratio $\rho_j = \delta_k/\alpha_j$, which can be less than one. With $a = k - j$, $\sigma_a = L^{-a}$, the frame bounds imply

$$\frac{C_{\mathrm{ax}} \delta_k \sigma_a}{r_{B,j}} \le C s_{\mathfrak{a}} \sqrt{a + 2}\, L^{-a}, \qquad \text{provided } \alpha_j / r_{B,j} \le C. \tag{3.ccxx}$$

The supremum of $\sqrt{a + 2}L^{-a}$ is finite: it is bounded by $\sum_{a \ge 0}(a + 2)L^{-a}$. Consequently a single small choice of s_* puts the central axial rows in a half datum disc at every age. The remote rows have no such age gain. Their admission uses the fixed absolute whole-datum ceiling eq. 4.xxx for

the actual window maps. For a different datum chart this inclusion must be verified separately; the displayed radius ratio does not imply it.

The corresponding quadratic extraction weights obey the exact identity

$$w_{n,j} = (\alpha_n/\alpha_j)^2, \qquad \alpha_n^{-2} w_{n,j} = \alpha_j^{-2}. \tag{3.ccxxi}$$

This identifies where the physical readout is paid. For example, if $r_j \le C\theta_j^{-p}$, $p > 2$, and the stronger frame bound $\theta_j \ge \theta_n + \lambda(n-j) - c_5$ holds, then

$$\alpha_n^{-2} \sum_{j \le n} w_{n,j} r_j \le C\theta_n^{2-p} (\log \theta_n)^{-2q}. \tag{3.ccxxii}$$

Indeed the left side is bounded by $C \sum_{a \ge 0} (\theta_n + ca)^{1-p} (\log(\theta_n + ca))^{-2q}$, with bounded changes of the lower floor absorbed in C. Pull out $(\log \theta_n)^{-2q}$ and compare the decreasing power with its integral. The integral is a constant times θ_n^{2-p}. Thus summing ages and extracting a quadratic coefficient are two specified operations, not two additional copies of the same radius loss.

3.9.7. *Admission on a joint parameter domain.* Several distinct parameters occur in a local expression. A fine decoupling parameter s_Δ varies on $|s_\Delta| < R$, $R = e^{\bar\kappa} > 1$. A multiplier ν amplifies an actual response. A reference ratio $\tau = x/\mathtt{t}$ lies in a fixed disc $|\tau - 1| < c_\tau$. Physical sources vary the exponent members on their ordinary source domain. An auxiliary potential parameter can have a larger domain. The real frame θ, numerical cutoffs, Gaussian scaling, reference operations and geometry are frozen before any of these source derivatives are taken.

One cannot choose these domains independently by checking one real parameter at a time. A useful exact calculus is the following. Consider a finite ordered collection of atomic holomorphic maps F_v, each already defined on the ball $\|d - d_v^0\| < r_v$. The input d_v of a later map is a specified holomorphic expression in the external parameters and earlier outputs. Suppose normalized displacements satisfy majorants

$$u_v \le e_v + \sum_{w<v} A_{vw} u_w, \qquad A_{vw} \ge 0, \qquad u_v = \|d_v - d_v^0\|/r_v. \tag{3.ccxxiii}$$

These inequalities must be verified on the proposed joint domain, using primitive derivative estimates inside the atomic balls. If the recursively computed right sides are at most $\vartheta < 1$, then every composition is holomorphic there. This follows by induction: the previous compositions exist, their values put the next input in its already assigned ball, and composition of holomorphic maps is holomorphic. There is no step of continuing an unknown map past its domain.

Writing A for the strictly lower triangular matrix, the exact finite bound is

$$u \le (1 + A + \cdots + A^{N-1}) e. \tag{3.ccxxiv}$$

Each matrix product counts ordered paths through the dependency graph. If its row norm is at most $\zeta < 1$, then $\sup u_v \le \sup e_v/(1-\zeta)$, independently of the number of maps. Alternatively actual scale weights can bound the path sum even when the unweighted row norm is not less than one. This bound must be proved. For example the scalar recursion $d_v = d_{v-1} + z$ has input Nz at its last node; an individual bound $|z| < r$ supplies no depth-independent admission disc.

For a localized expression at old level $j \le k$, the actual substitution is of the form

$$p_{j,Y}(s, \nu; B) = \rho_X p \mathbin{\dot+} \nu\, \mathfrak{h}_Y(s; B), \qquad |s_\Delta| < e^{\bar\kappa}. \tag{3.ccxxv}$$

The operation $\dot+$ changes both the potential and current by the specified nonlinear local response; ρ_X is the restriction appropriate to that term. It is not addition only to its potential component. For an inner window the background is first rewritten on the assigned box. Its datum is the actual nonlinear average

$$M_{\mathbf{B}_j}\left(e^{i\eta_k(t + t_\square \zeta_\square)\mathbf{H}_k(B')} U_+\right), \qquad 0 \le t \le 1, \tag{3.ccxxvi}$$

with its declared continuation in $t_{\square}$. The background of this datum is inserted before the bracket interpolation. This is where the pointed marginal cancellation acts. Its datum is not obtained by replacing $M_{\mathbf{B}_j}$ by its linearization.

3.9.7.1. Domain estimate III: the full local substitution. For each inner, outer and removed origin, each allowed localization domain Y, all its restricted towers and the entire joint polydisc in eq. 3.ccxxv, prove admission to the core of the term being evaluated. In the normalized tests of eq. 3.ccxii, a sufficient quantitative bound is

$$\sup_{\beta} |N_{\beta}(p_{j,Y}(s,\nu;B)) - N_{\beta}(\rho_X p)| \le C_R e^{C_R\bar{\kappa}} |\nu|\, \delta_k L^{-(k-j)}/a_{0,j}. \tag{3.ccxxvii}$$

The domain includes every admitted external complex pair, all real free fields on their prescribed window box and every auxiliary parameter of the expression. Atomic datum distances must satisfy their own radii as in eq. 3.ccxxiii. If the actual bound has a further geometric loss, that loss must be included in the right side before choosing the parameters.

The numerical consequence of eq. 3.ccxxvii is complete. On a central core of fraction ϑ, choose

$$\rho_{j,k} = c_R e^{-C_R\bar{\kappa}} \frac{a_{0,j}}{\delta_k L^{-(k-j)}}. \tag{3.ccxxviii}$$

For $|\nu| < \rho_{j,k}$, a sufficiently small c_R spends less than half the initial margin. eq. 3.ccxvii–eq. 3.ccxix give

$$\rho_{j,k}^{-1} \le C e^{C_R\bar{\kappa}} s_{\mathfrak{a}} \sqrt{k+2-j}\, L^{-(k-j)}. \tag{3.ccxxix}$$

Hence one small, depth-independent choice of s_* makes every $\rho_{j,k} > 2$, so $\nu = 1$ is an interior point. The gain $\rho_{j,k}^{-1}$ is obtained by a Schwarz estimate after admission; it is not a device to create admission. The scale factor in eq. 3.ccxxviii is what prevents a bound growing with the number of old levels.

3.9.8. *Cauchy estimates and the count of parameters.* Let F be holomorphic and bounded by M_F on a supremum ball of radius r. For two arbitrary directions u, v, apply Cauchy to $F(zu/\|u\|_\infty + wv/\|v\|_\infty)$ on $|z|, |w| < r/3$. It proves

$$|D^2F(0)[u,v]| \le 9M_F r^{-2} \|u\|_\infty \|v\|_\infty. \tag{3.ccxxx}$$

The same proof on a smaller centered ball works uniformly away from the origin. It has no dimension factor. If instead only entrywise Hessian bounds $|\partial_i\partial_j F| \le M_2$ are known for m coordinates, the elementary bound on the Euclidean operator norm is mM_2. A better bound needs information about the full scalar supremum or the sum of the local entries. In a sum of local energies, the global scalar supremum usually grows with volume; eq. 3.ccxxx does not turn that extensive bound into a volume-independent local one.

For independent decoupling coordinates the calculation is different. If $F(s,\nu)$ is bounded by M_F on $|s_\Delta| < R$, $|\nu| < \rho$ with $\rho > 1$, and $F(s,0)$ is subtracted, Schwarz followed by coordinate Cauchy gives

$$\left| \int_{[0,1]^K} \partial_K [F(s+1_N,1) - F(s+1_N,0)]\, ds \right| \le \frac{2M_F}{\rho} (R-1)^{-|K|}. \tag{3.ccxxxi}$$

Here K, N are disjoint sets of coordinates and ∂_K differentiates each coordinate in K once. A circle of radius arbitrarily close to $R-1$ fits at every real center in $[0,1]$. Successive one-variable Cauchy formulae prove eq. 3.ccxxxi, and the limit in the radii is harmless. There is no $|K|!$, because no coordinate is differentiated repeatedly. By contrast, m derivatives in one coordinate produce $m! r^{-m}$. With $R = e^{\bar{\kappa}}$ and $\bar{\kappa} \ge 1$,

$$(R-1)^{-|K|} \le e^{-(\bar{\kappa}-1)|K|}. \tag{3.ccxxxii}$$

This follows from $1 - e^{-\bar{\kappa}} \ge e^{-1}$.

If local domains of tree length between m and $m+1$, rooted at a fixed cube, number at most $C_D e^{\kappa_D m}$, then every fixed polynomial multiplicity is summable with a strict rate surplus:

$$\sum_{m\ge 0}(m+1)^A e^{-(\kappa-\kappa_D)m}<\infty \qquad (\kappa>\kappa_D). \tag{3.ccxxxiii}$$

For completeness, put $h=(\kappa-\kappa_D)/2$. The continuous function $(t+1)^A e^{-ht}$ is bounded on $[0,\infty)$, so the series is bounded by a constant times $\sum e^{-hm}$. Using eq. 3.ccxxxii in a rooted bracket expansion requires the geometric comparison between its number of parameter cubes and its output tree length. It also requires the actual rooting identity: a component disjoint from the term's base contributes zero. Analyticity by itself does not give this identity.

For a family with potential norm ε, one spare finite potential slot of size w_* admits an auxiliary parameter on $|z|<w_*/\varepsilon$. If the uninserted local logarithm has norm at most C_* on that slot, Cauchy proves

$$\|DE[V]v\|_{\mathrm{out}}\le (2C_*/w_*)\|v\|_{\mathrm{pot}}. \tag{3.ccxxxiv}$$

There is no dependence on the number of field coordinates or the total volume in this estimate when the local majorant has no such dependence. For two directions of norms $\varepsilon_1,\varepsilon_2$, use $|z_i|<w_*/(4\varepsilon_i)$. The sum of the two potentials fits in half the slot, and

$$\|D^2E[V](v_1,v_2)\|_{\mathrm{out}}\le 16C_*w_*^{-2}\varepsilon_1\varepsilon_2. \tag{3.ccxxxv}$$

For n unrelated simultaneous directions the analogous sum-budget disc has radius proportional to $w_*/(n\varepsilon_i)$ in each coordinate. Reusing the two-direction radii for arbitrary n would exceed the slot. This count concerns potential allowance, not the distinct-cube calculation in eq. 3.ccxxxi.

The auxiliary slot need not be an enlarged physical source domain for histories. Suppose the actual source curve has $V(w)=V(0)+wv+O(w^2)$ in potential norm on its ordinary fixed disc. The norm Taylor expansion of the holomorphic local map gives $\partial_w E(V(w))|_0=DE[V(0)]v$. Its quadratic remainder is bounded by $C_*\|V(w)-V(0)\|_{\mathrm{pot}}^2/w_*^2$, by one-variable Cauchy on the line through that difference. Thus the large auxiliary disc computes the actual first jet, even if the nonlinear physical curve is defined only on its smaller source disc.

3.9.9. *Support, Schur norms, and finite coordinate counts.* For a matrix of color blocks, normalize the input and output coordinates by their declared positive weights. Write $B=D_oAD_i^{-1}$ for the normalized matrix and put

$$R_B=\sup_i\sum_j\|B_{ij}\|, \qquad C_B=\sup_j\sum_i\|B_{ij}\|. \tag{3.ccxxxvi}$$

Then $\|B\|_{2\to2}\le\sqrt{R_BC_B}$. To prove this, set $b_{ij}=\|B_{ij}\|$. For finitely supported vectors, $\|(Bx)_i\|^2\le(\sum_j b_{ij})(\sum_j b_{ij}\|x_j\|^2)$. Sum over i, use the column bound, and then complete. This also proves the assertion on a countable lattice. A row estimate alone is not the required Schur estimate. For example the matrix with a single nonzero column containing m ones has row sum one and norm $\sqrt{m}$.

Suppose one scalar local energy has modulus at most M_0 on a joint coordinate domain with free radius h_u and background radius h_b. Suppose at most T such energies contribute to any fixed row and at most N columns couple to that row, with the same bounds for columns. Cauchy, first in two free directions and then in a background direction, proves

$$\|K\|_{\mathrm{Schur}}\le CNTM_0h_u^{-2}, \qquad \|K(U')-K(U)\|_{\mathrm{Schur}}\le CNTM_0h_u^{-2}h_b^{-1}\|U'-U\|. \tag{3.ccxxxvii}$$

The backgrounds lie in a smaller common analytic chart, and the segment between their coordinate values stays there. The first bound counts the terms in an entry, then entries in a row. The second integrates the third derivative along that segment. This proof specifies where coordinate counts enter; they are not powers of the number of parameters in eq. 3.ccxxxi.

For the actual first-step chart, the verified finite geometry gives

$$h_u = cL^{-9}, \quad h_b = c'L^{-5}, \quad T, N \le CL^4. \tag{3.ccxxxviii}$$

A free coordinate changes its own bond and a fixed number of nearby crossing pivots. Wilson terms have fixed plaquette incidence, and a gauge block contains at most $L^4 - 1$ internal contour rows. Thus the number of scalar terms affecting one row and the number of coupled free coordinates are each CL^4, not their product before taking the row sum. With $M_0 \le C$, eq. 3.ccxxxvii gives CL^{26} and $CL^{31}\|U' - U\|$. Also $\|\Phi_U(u)\|_\infty \le CL^4\|u\|_\infty$ on its free ball implies, by two-direction Cauchy, $\|D^2\Phi_U(0)[e_i, e_j]\| \le CL^{13}$. Only a fixed number of pivot outputs occur for a given row. After the CL^4 column count, the independent-current part is bounded by $CL^{17}\|J\|_\infty$. These are local first-step estimates. They provide no hidden bound on a many-level window chart with a number of coordinates growing with its side.

The actual constraint basis must also be used when localizing fields. For a free-coordinate cutoff χ, the tangent field is $C_U(\chi u)$. It need not equal $\chi C_U u$, since pivot values depend on neighboring free coordinates. A quadratic partition argument on free variables therefore produces the commutator of the actual compressed free-coordinate matrix. It is not obtained by clipping the fine constraint rows. If $H_0 \ge c_0$ and a derived local coefficient estimate gives $\|H - H_0\| \le \varepsilon < c_0$, then

$$\mathrm{Re}(u, Hu)_{\mathrm{H}} \ge (c_0 - \varepsilon)\|u\|^2, \qquad \|H^{-1}\| \le (c_0 - \varepsilon)^{-1}. \tag{3.ccxxxix}$$

The inverse bound follows from the Neumann series with H_0^{-1}. A compression of this same matrix inherits the form inequality. An operator rebuilt with different block means or boundary constraints requires its own coefficient comparison; it is not that compression.

3.9.9.1. Domain estimate IV: coordinate counts across scales. On the actual run window of side parameter r, determine its free coordinate set, its constraint inverse and its joint background domain. Prove explicitly the bounds replacing h_u, h_b, T, N in eq. 3.ccxxxvii, including their dependence on r, L, M, the region and the local layer. Polynomial losses in r are allowed. The normalization matrices D_i, D_o, the compatible boundary rows and the nonwrapping lift are part of this estimate. The finite one-step constants in eq. 3.ccxxxviii are not evidence that these window constants are independent of r.

3.9.10. *Gauge changes, pivots and the real coarea factor.* Real unitary changes of local gauge preserve all the norm tests that are written covariantly. A complex change has a cost. If $K = \sup_x \|g(x)\|\|g(x)^{-1}\|$, then $\|\operatorname{Ad}(g(x))X\| \le K\|X\|$. For the actual average, $W_x(U^g) = g(c_-)W_x(U)g(c_-)^{-1}$. Its logarithm has the same covariance as long as both points belong to the regular analytic branch. The internal mean has the analogous bi-equivariance, since its defining logarithmic equation is conjugated at its initial endpoint. Therefore

$$\max_x \|W_x(U) - 1\| < r_{\log}/(2K) \quad \Longrightarrow \quad \max_x \|W_x(U^g) - 1\| < r_{\log}/2. \tag{3.ccxl}$$

This requires a smaller analytic domain; it does not imply that a complex gauge orbit saturates the original core. It also avoids multiplying a condition number separately at every bond of a closed path: covariance reduces that product to one conjugation. A real flat holonomy need not be close to one for this calculation, since the closed comparison transports are the arguments of the logarithms.

At a flat block-axial reference, the crossing pivot appears once in each of L longitudinal segments and in no internal contour path. Its raw constraint derivative is $L^{-3}\operatorname{Ad}(V_c)$, with the actual prefix transport V_c. No other pivot occurs in that constraint's support, under the nonwrapping double-block geometry. Thus

$$J_c := \partial_{a_{p(c)}} q_U(c) = L^{-3}\operatorname{Ad}(V_c), \qquad \det_{\mathbb{R}^3} J_c = L^{-9} \quad \text{at a real flat reference.} \tag{3.ccxli}$$

The determinant of a real adjoint transport is one: conjugation preserves the color metric and is connected to the identity in SU(2). For the per-length pivot matrix $\mathsf{m}_c = J_c/L$, $\det J_c = L^3 \det \mathsf{m}_c$. These two determinants cannot be interchanged in a coarea factor.

Let $\sigma_H(a)d^3a$ be Haar measure in its regular exponential chart. In the same chart $\delta_G(e^{iq}) = \delta_{\mathbb{R}^3}(q)/\sigma_H(0)$. Integrating one real pivot from a constrained integral therefore leaves

$$\frac{\sigma_H(a_{p(c)})}{\sigma_H(0)\,|\det \partial_{a_{p(c)}} q_U(c)|}. \tag{3.ccxlii}$$

At the flat reference this is L^9. The remaining free bonds still carry their Haar densities, and $a_b = g y_b$ contributes g^{3N_f} for N_f free bonds. The positivity and absolute determinant in eq. 3.ccxlii belong to real coarea. On a connected small real chart its oriented determinant stays positive. The analytic factor used later is its holomorphic determinant inverse, times the continued Haar density, on the specified complex chart where the determinant is nonzero. One does not analytically continue an absolute value.

3.9.11. *Finite potentials, cutoffs and renewed pointing.* The local potential norm used by the ordinary finite integral is

$$\|\mathbf{V}\|_\lambda = \sup_{Y,P,B} \frac{e^{\lambda d(Y)}|V(Y;P,B)|}{Q_Y(B)}, \qquad Q_Y(B) = 1 + M^{-4}\sum_{b\subset Y}|B_b|^2. \tag{3.ccxliii}$$

The supremum uses its specified complex local cores and field box. The coordinate B in this paragraph is the Gaussian variable of eq. 3.cxciv. It is neither the physical datum of eq. 3.cxcv nor the pivot basis C_U. An origin tag distinguishes several potential members with the same geometric carrier. The tag changes neither $d(Y)$ nor the geometric support, but its norm is charged in the potential allowance.

Use nested boxes $\mathcal{B}_0 \subset \mathcal{B}_1$ with bounds $\mathfrak{b}$ and $(1+\epsilon_b)\mathfrak{b}$, $\mathfrak{b} \geq 1$. Potentials to be differentiated are holomorphic on the larger box; the finite slot majorant accepts the resulting potentials on the smaller box. The real cutoff is kept on that smaller box. For $t \in [0,1]$, a coordinate Cauchy circle at tB of radius

$$r_{b,a} = c_b(1 + |B_b^a|), \qquad c_b < \epsilon_b/4, \tag{3.ccxliv}$$

fits in the larger box after reducing the fixed constant if needed. The Euclidean color norm differs from the coordinate supremum by a fixed factor. On that circle Q_Y is at most $C_b Q_Y(B)$, because the changed squared coordinate is at most $C(|B_b^a|^2 + 1)$. Consequently

$$|B_b^a \partial_{b,a} v(Y;tB)| \leq C_b \|\mathbf{v}\|_\lambda e^{-\lambda d(Y)} Q_Y(B). \tag{3.ccxlv}$$

This estimate is uniform in $\mathfrak{b}$. A fixed circle of radius proportional to $\mathfrak{b}$, estimated with the quadratic weight at its largest point, would give an unnecessary $\mathfrak{b}^2$ when the original coordinate is small. The formula in eq. 3.ccxliv retains the quadratic norm of the actual field.

An older beta-source member follows the path $v(tB)$. The intrinsic action and gauge-fixing remainders, which vanish through order two, instead have the normalization $t^{-2}V(tB)$. This distinction also has a direct analytic check. If $V(tB) = \sum_{m\geq 3} t^m V_m(B)$ is bounded on a fixed larger t-disc $|t| < 1 + \epsilon_t$, then

$$\int_0^1 \left| \frac{d}{dt}\{t^{-2}V(tB)\} \right| dt \leq \sum_{m\geq 3} |V_m(B)| \leq C_{\epsilon_t} \sup_{|z|<1+\epsilon_t} |V(zB)|. \tag{3.ccxlvi}$$

The first inequality integrates $(m-2)t^{m-3}$, whose integral is one. Cauchy bounds the final series geometrically. Applying t^{-2} to a general older source with a linear or quadratic part would not give this integrability. The actual bond-indexed split of the three interpolation legs must still be used: a bound on their total does not bound the integral of the absolute values of an arbitrarily chosen split.

3.9.11.1. Domain estimate V: the actual root slot. For each of the three assigned interpolation legs, prove the integrated potential norm of its actual bond-root density, on $\mathcal{B}_0$, uniformly in the external core, carrier and interpolation time. The larger box $\mathcal{B}_1$ must provide the coordinate circles in eq. 3.ccxliv. Intrinsic legs use their actual third-order cancellation; older source legs use eq. 3.ccxlv. This is the precise root input to renewed pointing, not a replacement of that pointing by an Euler split.

There is a simple exact interpretation of the connected term. On a complete physical pair let the fixed reference integral be

$$\Xi(z) = \int \chi(B) e^{V(B)+zv(B)}\, d\mu(B). \tag{3.ccxlvii}$$

The reference Gaussian and cutoffs have no z-derivative. Wherever the local expansion supplies its nonzero denominator,

$$\frac{d}{dz}\langle a_z\rangle_z\Big|_0 = \langle \dot a_0\rangle_0 + \langle a_0 v\rangle_0 - \langle a_0\rangle_0\langle v\rangle_0. \tag{3.ccxlviii}$$

This follows by differentiating numerator and denominator, with the same normalizer. The double-direction estimate in eq. 3.ccxxxv, union filing and the rooted cluster bound estimate this root-plus-source term on the actual local cores. On a general independent-current core the localized logarithmic terms are still defined and differentiated by their local finite formulas. They need not be marginals of one global Ξ; eq. 3.ccxlviii is the physical sum interpretation, not an off-graph identity inferred from holomorphy.

The number of scalar Gaussian coordinates in a local set is

$$N(Z) = 3\#\{\text{free bonds in } Z\}$$

and is of order $(LM)^4 N_c(Z)$ when N_c counts coarse cubes. Thus a Gaussian majorant $e^{CuN(Z)}$ equals a bound of the form $e^{C'(LM)^4 uN_c(Z)}$. The dimension factor is counted once. Neither holomorphy of an integrand nor smallness of u alone gives domination: the real reference precision, the fixed integration sets and the available Gaussian quadratic reserve must be specified.

3.9.12. *The real weight, the reference Gaussian and domination.* The reference inverse coupling θ and the real action weight x have different roles. Put $\tau = x/\theta$. In Gaussian coordinates the actual quadratic form consists of τ times the physical action Hessian and the gauge Hessian at the reference weight. Write these two free-coordinate matrices as K_A, K_G. Then

$$K_\tau = \tau K_A + K_G, \qquad K = K_A + K_G, \qquad e^{-\frac12 B^{\mathsf T} K_\tau B} = e^{-\frac\tau2 B^{\mathsf T} K B} e^{\frac{\tau-1}{2} B^{\mathsf T} K_G B}. \tag{3.ccxlix}$$

Thus using the normalized Gaussian with covariance $\tau^{-1}K^{-1}$ is a presentation choice with a compensating free potential. It does not multiply the actual gauge weight by τ. Its normalizing determinant contributes the factor $\tau^{-N/2}$ for N real scalar coordinates. The logarithm is chosen continuously from $\tau = 1$. Physical sources are not inserted in x in this presentation; their Wilson terms occur as potential members. Consequently neither this determinant nor g has a physical-source derivative.

Here is the finite domination calculation with all its premises. Let A_0 be a real positive precision on N coordinates, $A_0 \ge m_0$. Suppose the actual complex symmetric matrix satisfies

$$\|A_0^{-1/2}(A - A_0)A_0^{-1/2}\| \le \epsilon, \qquad \rho \ge 0, \qquad \epsilon + 2\rho/m_0 < \tfrac12. \tag{3.ccl}$$

If a measurable integrand has modulus at most $F_0 e^{\rho|B|^2}$, then the coherently normalized complex Gaussian gives

$$\left|\int F(B)\, d\mu_A(B)\right| \le F_0 \left(\frac{1+\epsilon}{1-\epsilon-2\rho/m_0}\right)^{N/2} \le F_0 e^{C(\epsilon+\rho/m_0)N}. \tag{3.ccli}$$

Indeed the determinant ratio $|\det A|/\det A_0$ is at most $(1+\epsilon)^N$, while $\operatorname{Re} A - 2\rho I \ge (1-\epsilon-2\rho/m_0)A_0$. Integrating that real Gaussian proves the first bound. The logarithms of numerator

and denominator prove the second. The same computation works with an integrand restricted to a fixed Borel set. On smaller parameter polydiscs its right side is an integrable bound independent of the parameters. If the densities and integrands are holomorphic there, dominated Cauchy formulae or Morera's theorem prove holomorphy of the integral.

The hypothesis on parameter-independent sets is substantive. A moving sharp cutoff is not covered by the preceding proof. It must either be frozen, as it is for the ordinary source construction, or be transformed by an explicitly controlled change of variables, including its boundary and Jacobian. Likewise holomorphy of a normalized integral uses the coherent determinant branch and its nonvanishing matrix domain.

There is an explicit coefficient route to eq. 3.ccl. If the actual entries of $A - A_0$ satisfy row and column sums at most ϵm_0, eq. 3.ccxxxvi gives eq. 3.ccl. For a ratio perturbation in eq. 3.ccxlix, the additional relative norm is at most

$$|\tau - 1|\,\|K^{-1/2} K_A K^{-1/2}\|. \tag{3.cclii}$$

At a flat reference $0 \le K_A \le K$, so this factor is at most $|\tau - 1|$. Away from that reference its bound follows from the actual local action coefficients and the proved gap, not from the name of the coupling ratio. Here K is the real reference precision; an additional complex-pair perturbation is tested by eq. 3.ccl. Thus the allowed τ-disc is chosen after these constants and the unused quadratic potential reserve.

3.9.12.1. Domain estimate VI: primitive Gaussian and potential room. For every local conditioned matrix used by the assigned decoupling, derive the normalized entry sums needed for eq. 3.ccl, on its enlarged parameter discs and its external core. Determine the scalar coordinate count, the reference precision and the total positive quadratic growth of the admitted potentials. Verify that the sum leaves the strict inequality in eq. 3.ccl, with the small per-cube cost required by the ordinary polymer criterion. This is one matrix/coefficient and potential-budget estimate. Once it holds, eq. 3.ccli, the spare-slot derivatives and domination of parameter integrals are conclusions. It is not necessary to identify all these local matrices with marginals of one Gaussian at a general independent-current pair.

3.9.13. *The site-frozen complex source box.* The ordinary complex data allow each site to carry its own Euclidean member. Such a member consists of a pointed local family, its infinite companion and its own scalar coefficient, with covariance of the pointed total under the required site symmetries. Members chosen at different sites need not be related. For a label $\mathcal{S}$, let $h_z^{(j)}$ be its fixed nonnegative tents, with $\sum_z h_z^{(j)} = 1$, and let $0 \le \varphi_j \le 1$ be the nested profiles. Write b_j for the real unsourced increments. Define

$$\begin{aligned} c_{\mathcal{S}}(p) &= u(p) + \sum_{j \le k} \varphi_j(p) \sum_z h_z^{(j)}(p)[e_j(z) - b_j], \\ c_{j,\mathcal{S}}(p) &= \varphi_j(p) \sum_z h_z^{(j)}(p) e_j(z), \\ x_k(p) &= \beta - \sum_{j \le k} b_j \varphi_j(p). \end{aligned} \tag{3.ccliii}$$

Each site uses the coefficient $e_j(z)$ of its own full Euclidean member, even though the exponent reads just that member's terms pointed at z. A defect does not inherit this symmetry by being placed at that site.

The exact cancellation of the scalar action weights is

$$-A(x_k - c_{\mathcal{S}}, U) - \sum_{j \le k} A(c_{j,\mathcal{S}}, U) = -A(\beta - u, U). \tag{3.ccliv}$$

Expand eq. 3.ccliii, use $\sum_z h_z^{(j)} = 1$, and use linearity of the Wilson action in its weight. This proves the identity label by label. It does not depend on the number of sites. It also shows why replacing an own counterterm by a coefficient from another member changes the presentation.

The scalar part of the box is measured by

$$\mathsf{u} = \|u\|_\infty + \sum_{j\le k} \sup_z |e_j(z) - b_j|. \qquad \|c_{\mathcal{S}}\|_\infty \le \mathsf{u}. \tag{3.cclv}$$

The inequality uses only the tents and $0 \le \varphi_j \le 1$. For ordered profiles, $x_k(p)$ is a convex combination of $\beta, x_1, \dots, x_k$: its coefficients are $1-\varphi_1, \varphi_1-\varphi_2, \dots, \varphi_k$. Thus on real field integrals $\mathrm{Re}(x_k(p) - c_{\mathcal{S}}(p)) \ge \min_i x_i - \mathsf{u}$. A fixed scalar box $\mathsf{u} \le \bar{c}$ preserves a positive Wilson coefficient when the real floor exceeds $\bar{c}$. This is a weight calculation; it is not a positivity assertion for arbitrary complex local activities.

Let $d_j(X)$ be the localization tree length and $d_j^\natural(X)$ the hull length with the specified standing islands exempted. The remaining coordinates of the ordinary box have sizes

$$\begin{aligned} \mathsf{g}_j &= \sup_{z_0,X,z,P} e^{\kappa d_j(X)} |G_{z_0}^{(j)}(X,P,z)|, \quad \mathsf{a}_j = \sup_{X,z,P} e^{\kappa d_j(X)} |D^{(j)}(X,P,z)|, \\ \mathsf{r}_j &= \sup_{X,P} e^{\kappa d_j(X)} |H^{(j)}(X,P)|, \qquad \mathsf{h} = \sup \frac{|B_{\mathcal{S}}^{(j)}(X)|}{\bar{B}_{\mathcal{S}}^{(j)}(X)}, \qquad \mathsf{f} = \sup_\omega \frac{|\Psi_\omega|}{n(\omega)}. \end{aligned} \tag{3.cclvi}$$

The external P ranges over the prescribed hereditary core. The boundary denominator is its actual unsourced majorant, proportional to $e^{-\kappa d_j^\natural}$. If $\Psi_\omega = \Psi_\omega^\circ + \sum_f \psi_f(P|_{R_f})$, a separate oscillation size is

$$\mathsf{f}_\Phi = \sup_{\omega,R} \frac{\sum_{f:R_f=R} \mathrm{osc}_P\, \psi_f}{(\log\theta_i)^{2p_0} e^{-\kappa d_i^\natural(R)}}. \tag{3.cclvii}$$

Amplitude and oscillation are different coordinates: a constant exponent has zero oscillation and may have arbitrarily large amplitude.

At input or output index $m \in \{k, k+1\}$, the actual box bounds are

$$\begin{gathered} \mathsf{u} \le \bar{c}, \quad \mathsf{g}_j \le E_0 + 1, \quad \mathsf{a}_j \le L^{-(m-j)}, \quad \mathsf{r}_j \le C\theta_j^{-\kappa_0/2}, \\ \mathsf{h} \le C, \qquad \mathsf{f} \le \bar{f}, \qquad \mathsf{f}_\Phi \le C c_\times(\bar{c}). \end{gathered} \tag{3.cclviii}$$

The label spaces, tests, real backgrounds, reference operations, measures and all numerical Gaussian constants are the real ones. The complex variables are exponent members and their own coefficients. This is why local functions can be differentiated without differentiating a sharp test or an adaptively chosen threshold.

For a physical source w, the site's member is the one for the constant source $\zeta = w(p_z)$. The defect is $E^{(j),w}(X,P,z) - E^{(j),w(p_z)}(X,P,z)$, not an independent Euclidean member. A localization that sees only w within a domain of diameter D gives the elementary difference bound $\sup|w - w(p_z)| \le D\ \mathrm{Lip}\, w$. Cauchy in this localized source direction then gives the source-gradient gain when its actual coefficient norm is known. The spatial inequality supplies the gain in $\mathrm{Lip}\, w$; it does not supply a missing α_j^2 in the coefficient norm.

The fixed scalar ceiling in eq. 3.cclviii also explains the two source discs. The potential uA has size $O(\alpha_j^2\|u\|_\infty)$ on a small-field chart, and therefore fits an enlarged auxiliary finite slot. The same $\|u\|_\infty$ occurs without this factor in eq. 3.cclv. It can also occur repeatedly in a history exponent. Hence finite-slot admission cannot enlarge the full source box by α_j^{-2}. The first-jet calculation in eq. 3.ccxxxiv remains valid.

There is an exact elementary reserve calculation for history amplitudes. Write $n(\omega) = \sum_j n_j(\omega)$, including each swallowed history exactly once, and $v(\omega) = \sum_j \log\theta_j\, n_j(\omega)$. If $\log\theta_j \ge 2\bar{f}$, then

$$|\exp\Psi_\omega| \le e^{\bar{f} n(\omega)} \le e^{v(\omega)/2}. \tag{3.cclix}$$

It can spend half of a previously established $e^{-v(\omega)}$ reserve, while keeping the remaining half. The retained inner Wilson factor and component rarity must still be present in the original mass estimate. The formula in eq. 3.cclix does not manufacture that estimate.

3.9.13.1. Domain estimate VII: source incidence and excess exponents. For one actual step or one large-field component, list every use of a given complex member, its own coefficient and its scalar anchor. Prove the aggregate site bound and the bounds in eq. 3.cclvi–eq. 3.cclviii after formation, using a single unused action reserve. For a component mass the supremum over its admitted external pair is placed inside its stored-variable integral. For drop-outs it is over the actual fibre of stored variables and recorded tests, not a product set containing an unrelated flat field. These specified incidence and fibre estimates are the remaining source-domain calculation; independent one-factor disc checks do not give the joint box.

3.9.14. *Large run windows and old activities.* The actual free-coordinate window may have $m_I \le C(r+D)^4$ scalar coordinates. A useful larger analytic chart is constructed in physical coordinates and then divided by g_k; it is not obtained by continuing the cutoff indicator. Suppose the actual physical pivot map on this window and every atomic background composition have radius at least

$$h_W \ge c\,\alpha_k r^{-A_c}, \qquad R_y = h_W/g_k, \tag{3.cclx}$$

and their normalized displacements obey the admitted graph bounds in eq. 3.ccxxiii–eq. 3.ccxxiv. This defines a precise chart target, including the polynomial loss A_c. It is not a uniform one-block constant. For old level i, the output displacement appearing in that graph has the scale ratio $L^{-(k-i)}\alpha_k/\alpha_i$; by eq. 3.ccxix its supremum is bounded. Amplified window directions use the same estimate with their actual multiplier, not a separate analytic continuation argument for each real direction.

If the cutoff is $\mathfrak{b}_k \asymp (\log\theta_k)^{p_0}$ and $r \le C(\log\theta_k)^{p_r}$, then the cutoff and two fixed-fraction coordinate circles fit in eq. 3.cclx whenever

$$q > p_0 + A_c p_r, \qquad \theta_k \ge T_*. \tag{3.cclxi}$$

Indeed $R_y \ge c(\log\theta_k)^{q-A_c p_r}$, so $\mathfrak{b}_k/R_y \to 0$. A finite increase of T_* gives any prescribed strict fractional room. If the complete old exponent has scalar supremum at most Cr^{A_0} on this larger chart, its directional Hessian is bounded by eq. 3.ccxxx; an entrywise and row-count proof can instead yield a bound of the form

$$\|\operatorname{Hess}_{y_I} P_{\mathrm{old}}\| \le C r^{A_{\mathrm{tot}}} (\log\theta_k)^{-2q}. \tag{3.cclxii}$$

Here A_{tot} must include the two losses $2A_c$, the actual amplitude and coordinate-count losses, and any response losses. For $r \le C(\log\theta_k)^{p_r}$, this tends to zero if $2q > A_{\mathrm{tot}} p_r$. If the free precision has a fixed gap m_*, increasing T_* makes the bound less than $m_*/4$.

3.9.14.1. Domain estimate VIII: the actual window chart and exponent. Prove eq. 3.cclx for the actual constrained window, exterior coordinates and gauge quotient; prove the graph bounds for all local substitutions; and derive its complete old-exponent amplitude or localized entry bounds before using eq. 3.cclxii. The count m_I, the old-age summation and the normalization of each old activity are part of this estimate. The localized old-activity theorem supplies the Hessian implication from these primitive data and the pointed remainder. It does not identify a conditional exterior law.

For the near, nonwrapping part there is a sharper estimate. Let a regular source derivative born at level j have norm $A_j \le C\alpha_j^2 s_j$, and put $\rho_j = \delta_n/\alpha_j$, $a = n-j$. The actual pointed window theorem, after its fine-site count, gives

$$C A_j \left(\rho_j^2 L^{-\alpha_H a} + \rho_j^3 L^{-2a}\right). \tag{3.cclxiii}$$

The needed hypothesis is a bound $C\delta_n$ on the complete background-plus-fluctuation field used in the near Taylor estimate. A bound only on its increment does not give it. Under that hypothesis, eq. 3.ccxx admits the central half-disc at every age, even when $\rho_j < 1$; the remote datum uses the

separate absolute ceiling eq. 4.xxx. On the complete homogeneous window class, eq. 4.cxlv and the full-profile calculation preceding eq. 4.clxxx supply the proportional $C\delta_n$ remote-datum bound as well. For a class without that bound its response is retained as a separate tail. The frame gives $A_j/\alpha_j^2 \le Cs_n$ and $\rho_j \le Cs_n\sqrt{a+2}$. Therefore the sum of eq. 3.cclxiii is at most $C\delta_n^2 s_n$, by geometric summation. A defect with an additional factor $h_j \operatorname{Lip} w$ sums the same way since $h_j = h_n L^{-a}$. A field-independent remote or winding term has no such homogeneous radius factor and is assigned its own decaying class.

The exterior-force estimate is a separate bounded target. In the assigned conditional coordinates I, O, it must control

$$Q^{\mathrm{sc}}y, \quad Q^e_{IO}y_O(e), \quad (Q^e_{II} - Q^{e_0}_{II})y, \quad \nabla_I(P_e - P_{e_0}), \qquad Q^{\mathrm{sc}} = Q_{IO}Q_{OO}^{-1}Q_{OI}. \tag{3.cclxiv}$$

For example the third term needs the actual bound $|((Q^e_{II} - Q^{e_0}_{II})y)_b| \le C\mathfrak{b}\, e^{-c\,d(b,O)}$, uniformly over the admitted exterior data and the real window; the fourth needs the corresponding exponential derivative bound without an uncontrolled exterior factor. They require control of the actual exterior field and conditional exponent. Neither eq. 3.cclxii nor decay of one covariance proves them.

3.9.15. *Carriers, world floors and the source norm.* A world is a torus with physical side ℓ and cutoff K. Its numerical side at level j is $\mathfrak{s}_j = \ell L^{K-j}$. A comparison of local formulas requires one injective rectangular lift containing the whole bond/path neighborhood being compared. A separate lift for each endpoint is not enough. In particular the pivot determinant calculation requires the support of the relevant constraint to contain no other crossing pivot. That support, including its contour paths, is what is lifted.

For the actual finite average the determining neighborhood grows by a fixed number of blocks at each scale. If R_j is its radius in bare numerical units after j steps, the elementary support recursion is

$$R_{j+1} \le R_j + C_L L^{j+1}\eta, \qquad L^{-k}\eta^{-1}R_k \le C_L \sum_{a=0}^{k-1} L^{-a} \le \frac{C_L}{1 - L^{-1}}. \tag{3.cclxv}$$

Every internal path lies in its assigned block and every straight segment in the assigned double block, which proves the first inequality. Composing supports proves the recursion; the displayed geometric sum proves the depth-independent radius in final units. The differentiated map has the same determining neighborhood. Taking a local plaquette or current adds its explicit finite range.

This proof concerns the average, not the full nonlinear minimizing background. The latter has inverse tails. A localized walk term has its own finite surroundings; the complete inverse is an absolutely convergent sum of such terms. Carrier identities for a localized substitution use its decoupling and rooting rule. They cannot be deduced by applying eq. 3.cclxv to an unlocalized inverse. For instance a scale-dependent collar of width e_j contributes $\sum_{j\le k} e_j L^{j-k}$ in final units. If e_j is bounded, this is a geometric sum. The weaker relation $e_j \le Le_{j+1}$ alone does not give a depth-independent sum: $e_j = L^{k-j}$ makes every summand one. Thus changes of localization size must be checked in the actual carrier construction.

The nonwrapping conditions have three separate uses. The double blocks of an average and the cubes of local gauges must be shorter than half the torus. A gauge cube enlarged by its comparison collar must still have that property. Finally each tower is formed only to a depth at which its prescribed inner cube size fits in half the torus. If the largest required numerical size in the relevant level is D_j, the test is

$$2D_j < \ell L^{K-j}. \tag{3.cclxvi}$$

This condition is unchanged by moving the lifted patch around the torus. It asserts no smallness of holonomy around a noncontractible cycle. The first-step curved physical gap handles arbitrary real holonomies by its local gauge and partition argument; it is not obtained by choosing one globally small potential.

3.9.15.1. Domain estimate IX: compatible carriers and floors. For each average, tower, conditioned inverse term and inner, outer or removed substitution, give its actual determining neighborhood and collars. Prove that its required lifts satisfy eq. 3.cclxvi, and that each restriction or transport carries all its defining rows and parameter cubes. For full inverses, give the separately summed boundary/image tail. This finite-list geometric estimate must accompany the analytic estimate III; replacing a region operator by a clipped average does not preserve its determining neighborhood.

Let $h_j = L^{j-K}$ be the physical spacing of level j, and let f be a Lipschitz test on the physical torus. Use

$$\|f\|_{\sharp,j} = \max\{\|f\|_\infty, c_M h_j \operatorname{Lip} f\}, \qquad c_M \geq C_{\mathrm{geo}} M. \tag{3.cclxvii}$$

The constant c_M contains the fixed block-size factor. If a domain of tree length $d_j(X)$ sees plaquettes within physical distance $C_{\mathrm{geo}} M h_j(d_j(X)+1)$ of its anchor, then

$$|f(p) - f(p_z)| \leq C_{\mathrm{geo}} M h_j (d_j(X)+1) \operatorname{Lip} f \leq (d_j(X)+1)\|f\|_{\sharp,j}. \tag{3.cclxviii}$$

This follows from the Lipschitz definition and the diameter of a connected tree of cubes. The polynomial $d_j(X)+1$ is absorbed by the strict entropy surplus in eq. 3.ccxxxiii. Moreover $\|f\|_{\sharp,j} \leq \|f\|_{\sharp,n}$ for $j \leq n$, and $h_j/h_n = L^{-(n-j)}$. These are exactly the scale factors of a source-gradient defect in a later window. No second block factor is removed from eq. 3.cclxviii; M/c_M, rather than M, is the fixed ratio being bounded.

3.9.16. *Tubes of frozen couplings and real admission.* The frozen reference choices are formed from a real frame θ. Let the real recursion have weights $x_j^\natural = \beta - \sum_{i\leq j} b_i$, deviations $z_j = \theta_j - x_j^\natural$, and nonincreasing tube radii t_j. The actual tube requires $t_j(\log \theta_{j+1})^{C_t} \leq c_t \theta_{j+1}$. Room $2r$ means $|z_j| + 2r \leq t_j$ at every intermediate level. It is a simultaneous condition, not just a condition at the endpoint.

Suppose the constant-source coefficients are holomorphic on $|\zeta| < 2r$, and their difference quotients have bounds d_i with $\sum_i d_i \leq B_0$. Their exact running shift is

$$\zeta_j(\zeta) = \zeta + \sum_{i\leq j} [b_i(\zeta) - b_i(0)], \qquad |\zeta_j(\zeta)| \leq (1+B_0)|\zeta|. \tag{3.cclxix}$$

Thus $|\zeta| < r/(1+B_0)$ leaves room r inside every tube. The estimate is just the triangle inequality for the displayed recursion and is independent of the number of levels. The substantive input is the summable quotient bound on its actual disc, including the marked bare-disc forcing if that is how the bound is obtained.

A constant source may be read either in the fixed source presentation of eq. 3.ccliii, or as an alternative frozen-weight presentation. In the former, it remains absent from the Gaussian structures; in the latter, the compensating presentation identity in eq. 3.ccxlix must be used with the new weights. Equality of the finite integrals includes all these normalizing and interaction factors. It is not justified by changing τ in only the Gaussian determinant.

Real admission also matters when comparing two holomorphic presentations. On a connected complex overlap that contains a real open set where both are admitted and represent the same bare integral, the real identity extends holomorphically. The proof is the Taylor argument following eq. 3.ccxv. Geometric overlap of two complex discs without a common admitted real set gives no such conclusion for the actual presentations. Endpoint bracketing and slope bounds on a canonical admitted interval can therefore be used for tuning on that interval; broader calibration gluing requires its own real-admission estimate.

3.9.16.1. Domain estimate X: the actual coupling tube and overlap. Prove the coefficient quotient bounds used in eq. 3.cclxix on the declared frozen discs, preservation of the intermediate tube with its prescribed slack, and the actual real admission of any overlap on which gluing is claimed. The objects are the unchanged frozen choices and the actual constant-source coefficients. This estimate

is separate from the many-level field core: a bound on a physical field radius does not give a bound on an analytic coupling disc.

3.9.17. *A simultaneous choice of the remaining small parameters.* The elementary choice problems can now be separated from their model estimates. First determine the polynomial degrees and their dependencies. The logarithmic exponents are chosen before geometric parameters when the actual construction requires that order. The fixed block size, its finite-map constants, the propagator rates, tower and collar sizes, remaining analytic radii and localization sizes are then chosen in their declared order; the weak-coupling floor is last. For the numerical calculation below these geometric data and a strict entropy surplus have already been fixed. Choose the enlarged decoupling radius $e^{\bar\kappa}$ so that the remaining rate in eq. 3.ccxxxii, after geometric and entropy charges, is still positive. Choose the shape constants C_0, C_1 and the absolute ceiling to satisfy eq. 3.ccxi and eq. 3.ccxvi. The quantities $L, M, \bar\kappa$ are then fixed; a constant such as $e^{C_R\bar\kappa}$ is not allowed to depend on the depth.

The analytic logarithmic exponent q has to satisfy every required finite lower bound, including

$$q > p_0, \qquad q > p_0 + A_c p_r, \qquad 2q > A_{\mathrm{tot}} p_r. \tag{3.cclxx}$$

Any additional power of the window radius or history reserve used by the actual estimates must be added before that exponent is chosen. The elementary feasibility conclusion assumes that the displayed polynomial degrees do not themselves increase with the new choice of q. When q must be chosen before later geometry, these degree bounds must also be uniform over the later admitted choices, or a simultaneous feasibility list must be solved in the required order. Fixed-geometry logarithmic smallness alone does not prove that earlier choice. If the degrees do depend on q, the resulting simultaneous inequalities must first be solved with that dependence; increasing q alone is no proof of feasibility. For finitely many conditions $C_\nu(\log T)^{-b_\nu} < \epsilon_\nu$, with $b_\nu > 0$, a single sufficiently large T satisfies them all: take $\log T > \max_\nu (C_\nu/\epsilon_\nu)^{1/b_\nu}$. The conditions $CMf_q(T) < c$ hold after a further increase, since every power of $\log T$ is $o(T^{1/2})$. This proves simultaneous smallness of the radius ceilings, $s_{\mathfrak{a}}$, the factors in eq. 3.ccxxix, the Gaussian ratio perturbation and every explicitly listed logarithmic loss. It is a finite feasibility calculation after the exponents of the actual estimates have been obtained.

Finally fix the source scalar ceiling and excess-exponent ceiling, and increase the real floor so that $\log T \geq 2\bar f$ and the Wilson weights in eq. 3.cclv remain positive on the required real integrals. The spare potential allowance is chosen inside the already established Gaussian/polymer reserve; the nested field boxes spend their fixed fractional slack once. None of these choices alters an earlier real cutoff or reference operation under a source derivative.

At this point the algebraic domain reductions are closed. Domain estimates I–X specify what remains to be proved for the actual many-level operators, towers, substitutions, roots, Gaussian matrices, source arrays and run windows. They have explicit objects, radii and uniformities. The finite chart and physical background results realize only their stated first-step chart, background, gap and radius instances. Independent-current normal-form matching, actual integrated roots, complete local Gaussian budgets and source/history estimates remain separate wherever they have not been supplied, even at a first step. At further levels the action is the actual composed action $A(U_k(V))$, with its constraint and current terms. Reusing the numerical first-step constants without the corresponding many-level estimate would not be an induction.

3.10. **A relative-gauge current extension at the first step.** An independent-current operator is not determined by its values on the physical current graph. We therefore give a concrete alternative definition at one step and prove what it supplies. Its complete nonlinear action, quadratic form, gauge covariance, real gap and complex inverse are specified. At a constrained-critical axial background it has the actual physical action as its value, throughout the admitted fibre chart. Agreement with any other current completion requires a separate identification. Using it at later scales requires the further consistency and closure checks stated below.

The raw fibre and the relative contour functional. Use fine lattice spacing one in this section. Currents are raw covectors for the bond logarithms with the counting pairing. The conversion to a potential or a different length unit is the domain section's conversion, including its dual cell weights. For the actual one-step group average put

$$q_U(a) = \frac{1}{i}\log[\mathcal{M}(e^{ia}U)\mathcal{M}(U)^{-1}], \qquad P_U = Dq_U(0). \tag{3.cclxxi}$$

All logarithms and contour means use their admitted regular branches. The geometry is the embedded double-block geometry of the pivot chart, on the infinite lattice or a compatible torus. In particular no second crossing pivot enters a row.

Let h_U be the pivot right inverse, let ι insert free coordinates with zero pivots, and set

$$C_U = \iota - h_U P_U \iota, \qquad q_U(\Phi_U(u)) = 0, \qquad \Phi_U(0) = 0, \qquad D\Phi_U(0) = C_U. \tag{3.cclxxii}$$

The free restriction of $\Phi_U(u)$ is exactly u. The quantitative chart gives a joint background and free-variable neighbourhood, with free radius $r_u = cL^{-9}$ and background radius $r_b = c'L^{-5}$ after its specified fixed shrinkages. Two differentiations give

$$D^2\Phi_U(0)[u,v] = -h_U D^2 q_U(0)[C_U u, C_U v]. \tag{3.cclxxiii}$$

The second derivative has only pivot components, so the right inverse on those components proves the identity and its sign.

Write $f_U(a) = A_W(e^{ia}U)$ and let $j_U = Df_U(0)$ be its raw gradient. On a finite torus these are ordinary finite-dimensional functions. On the infinite lattice every scalar action difference below is first evaluated for finitely supported free variations. The locally finite decomposition and its derivatives then define the kernels. No extensive scalar action is assigned a finite supremum on all bounded fields.

For every internal contour row define its relative logarithm by

$$\ell_{U;y,x}(a) = \frac{1}{i}\log[T_{y,x}(e^{ia}U)T_{y,x}(U)^{-1}], \qquad G_U a = (D\ell_{U;y,x}(0)a)_{y,x\neq y}. \tag{3.cclxxiv}$$

The relative gauge function is

$$\mathcal{G}_U(a) = \sum_{y,x\neq y}\left(1 - \tfrac{1}{2}\operatorname{tr}[T_{y,x}(e^{ia}U)T_{y,x}(U)^{-1}]\right). \tag{3.cclxxv}$$

It has value and first derivative zero at $a = 0$. Since $1 - \frac{1}{2}\operatorname{tr} e^{iX} = \frac{1}{2}|X|^2 + O(|X|^4)$, its Hessian is $G_U^{\mathsf{T}}G_U$. Here G_U acts on full bond variations; on free coordinates the contour differential is $G_U C_U$. This distinction fixes the placement of both copies of C_U.

A stationary extension for every independent current. For a declared independent raw current J define

$$\begin{aligned} S_U^A[J](u) &= f_U(\Phi_U(u)) - f_U(0) - \langle j_U, \Phi_U(u)\rangle \\ &\quad + \langle J, \Phi_U(u) - C_U u\rangle, \\ S_U^{\mathrm{rel}}[J](u) &= S_U^A[J](u) + \mathcal{G}_U(\Phi_U(u)). \end{aligned} \tag{3.cclxxvi}$$

The pairings are complex bilinear. These formulas are definitions on the actual pivot chart, rather than an extension by agreement on a lower-dimensional graph.

Every term in the first derivative cancels: $Df_U(0)C_U = j_U C_U$, the next term subtracts it, and $D(\Phi_U - C_U u)(0) = 0$. The relative gauge also has zero first derivative. Thus

$$S_U^{\mathrm{rel}}[J](0) = 0, \qquad DS_U^{\mathrm{rel}}[J](0) = 0 \quad \text{for every admitted } (U,J). \tag{3.cclxxvii}$$

The cancellation uses the actual j_U in the subtraction. Replacing it by J there would give a different linear term.

Put $\mathscr{A}_U = D^2 f_U(0)$. The chain rule and eq. 3.cclxxiii give

$$\begin{aligned} K_U^A[J](u,v) &= \langle C_U u, \mathscr{A}_U C_U v\rangle - \langle h_U^{\mathsf{T}} J, D^2 q_U(0)[C_U u, C_U v]\rangle, \\ K_U^{\mathrm{rel}}[J] &= K_U^A[J] + (G_U C_U)^{\mathsf{T}}(G_U C_U). \end{aligned} \tag{3.cclxxviii}$$

Indeed the $j_U D^2\Phi_U$ term from the first composition is cancelled by $-\langle j_U, \Phi_U\rangle$. The J term supplies $\langle J, D^2\Phi_U\rangle$. There is no constraint-curvature term from the relative gauge because its full-bond first derivative is zero. All matrices are normalized as Hessians, with quadratic exponent $-\frac{1}{2}\langle u, Ku\rangle$.

For a fixed reference inverse coupling $\theta = g^{-2}$ and physical action weight x put $\tau = x/\theta$. The gauge part keeps its reference weight. Consequently the corresponding free precision is

$$K_{U,\tau}^{\mathrm{rel}}[J] = \tau K_U^A[J] + (G_U C_U)^{\mathsf{T}}(G_U C_U). \tag{3.cclxxix}$$

The factor τ has not multiplied the gauge block. This is the actual distinction needed in a complex-weight comparison at a frozen frame.

Exact physical agreement and the noncritical linear term. If U is constrained-critical, C_U parametrizes its fibre tangent and therefore

$$C_U^{\mathsf{T}} j_U = 0. \tag{3.cclxxx}$$

At the physical current $J = j_U$, eq. 3.cclxxvi then gives, for every free u in the chart,

$$S_U^A[j_U](u) = A_W(e^{i\Phi_U(u)}U) - A_W(U). \tag{3.cclxxxi}$$

This is an equality of the whole action difference. It is stronger than equality of Hessians.

If U is also contour-axial, $T_{y,x}(U) = 1$. Hence $\mathcal{G}_U(a) = \mathrm{GF}(e^{ia}U)$ identically on the chart, and

$$\begin{aligned} g^{-2}\{\tau S_U^A[j_U](gy) + \mathcal{G}_U(\Phi_U(gy))\} = x\{A_W(e^{i\Phi_U(gy)}U) - A_W(U)\} \\ + \theta\,\mathrm{GF}(e^{i\Phi_U(gy)}U). \end{aligned} \tag{3.cclxxxii}$$

Thus the extension produces the actual weighted constrained action and the reference gauge weight at this physical background.

For a noncritical U the exact identity instead has

$$S_U^A[j_U](u) = A_W(e^{i\Phi_U(u)}U) - A_W(U) - \langle C_U^{\mathsf{T}} j_U, u\rangle. \tag{3.cclxxxiii}$$

The missing physical linear force must be restored. It has zero Hessian, so at $J = j_U$ the quadratic comparison is still the physical chain-rule comparison. But its contribution after Gaussian rescaling is of order g^{-1} unless that tangent force vanishes. No coupling-independent holomorphic potential claim for the whole noncritical physical action follows from eq. 3.cclxxvii.

Gauge covariance from the actual graph. For a site gauge s the left logarithm transforms as $a^s(b) = \mathrm{Ad}(s(b_-))a(b)$. Denote this full-bond linear map by $\mathcal{U}_s$ and its free restriction by $\mathcal{U}_s^f$. The actual average is bi-equivariant. On common regular branches this gives

$$q_{U^s}(\mathcal{U}_s a) = \mathcal{U}_s^{\mathrm{coarse}} q_U(a). \tag{3.cclxxxiv}$$

Free restriction and pivot insertion are stable under this bondwise transformation. The vector $\mathcal{U}_s\Phi_U(u)$ solves the transformed constraint and has free restriction $\mathcal{U}_s^f u$. Uniqueness of the pivot graph proves

$$\Phi_{U^s}(\mathcal{U}_s^f u) = \mathcal{U}_s\Phi_U(u), \qquad C_{U^s}\mathcal{U}_s^f = \mathcal{U}_s C_U. \tag{3.cclxxxv}$$

For complex gauges this assertion is made only on the common admitted graph branch. It does not say that a complex orbit saturates a core.

Wilson gauge invariance gives $j_{U^s} = \mathcal{U}_s j_U$ under the invariant bilinear colour pairing. The product in eq. 3.cclxxv is conjugated at its contour's initial node. Combining these facts proves

$$S_{U^s}^{\mathrm{rel}}[\mathcal{U}_s J](\mathcal{U}_s^f u) = S_U^{\mathrm{rel}}[J](u). \tag{3.cclxxxvi}$$

The same holds separately for the action and gauge parts, and hence for every fixed τ in eq. 3.cclxxix. In an orthonormal colour basis $\mathcal{U}_s^f$ is bilinearly orthogonal even for admitted complex gauges. For real unitary gauges it is also unitary in the Hermitian Hilbert norm. Therefore

$$K^{\mathrm{rel}}_{U^s,\tau}[\mathcal{U}_s J] = \mathcal{U}_s^f K^{\mathrm{rel}}_{U,\tau}[J](\mathcal{U}_s^f)^{-1}. \tag{3.cclxxxvii}$$

This proves matrix covariance directly. It does not use an integral change by a complex gauge through a sharp real cutoff.

Axialization and the independent-current real gap. For a real regular field, define within each block $s(y) = 1$ at its centre and $s(x) = T_{y,x}(U)$. The internal contour means are unitary. Their bi-equivariance gives

$$T_{y,x}(U^s) = 1, \qquad \mathcal{M}(U^s) = \mathcal{M}(U). \tag{3.cclxxxviii}$$

The second equality uses $s = 1$ at the coarse centres. The regular logarithm branches remain the same: after this transformation all path transports are near identity by the small-plaquette comparison, and uniqueness of the internal mean identifies the transformed mean. This is the finite averaging chart's real gauge-covariance construction.

Plaquette norms and the norm of the transformed current are unchanged. The gauge is periodic on a compatible torus and is defined on the full cover as well. No noncontractible holonomy is made small.

Let $c_0(L)$ be the proved flat gap. Choose R, ϵ, γ as in the first-step gap theorem, in particular

$$R \geq 40, \quad K_L/R^2 \leq c_0/8, \quad CL^2 R\epsilon \leq r_b/8, \quad K_L(R\epsilon+\gamma) \leq c_0/8, \quad K_L = CL^{40}, \quad \gamma \leq 1. \tag{3.cclxxxix}$$

Suppose all fine plaquettes have size at most ϵ and the real raw current has norm at most γ. At the axialized field the relative and absolute contour Hessians coincide. The formula in eq. 3.cclxxviii is then exactly the explicit axial auxiliary form of the first-step gap theorem. That theorem gives $K^{\mathrm{rel}}_{U^s}[\mathcal{U}_s J] \geq c_0/2$. Unitary conjugation in eq. 3.cclxxxvii proves

$$K^{\mathrm{rel}}_U[J] \geq c_0/2 \tag{3.ccxc}$$

for every such real regular U, without assuming that U was axial or critical. The inequality uses the Hermitian quadratic form of the real symmetric matrix on its complexification. The current is the declared raw current of this one-step problem.

This transfer is possible because the relative gauge is jointly site-gauge covariant. Applying it to an arbitrary absolute-gauge operator off the axial locus would not be valid.

The full half-disc with the gauge weight retained. There is a stronger weight statement than a small operator-norm neighbourhood of $\tau = 1$. Choose the universal constant in K_L in eq. 3.cclxxxix to control the action and gauge blocks separately as well as their sum. The same free-coordinate partition proof gives

$$K^A_U[J] \geq -K_L\{R^{-2} + R\epsilon + \gamma\} \geq -c_0/4. \tag{3.ccxci}$$

Here the flat action block is nonnegative: it is $C_0^{\mathsf{T}} \mathscr{A}_{\mathbf{1}} C_0$, the compression of the free Wilson curl form. In each localized patch the action block differs from it by at most $K_L(R\epsilon+\gamma)$, by the same actual chart coefficient comparison used for the complete form. Localizing the action block on free variables costs at most K_L/R^2. Summing the squared partition therefore proves eq. 3.ccxci. No positive gap for the action block alone has been assumed. Real gauge covariance transfers this statement from the axial representative just as before.

Write $K = K^A_U[J] + K^G_U$, where $K^G_U = (G_U C_U)^{\mathsf{T}}(G_U C_U) \geq 0$. eq. 3.ccxc and eq. 3.ccxci imply

$$B = K^{-1/2} K^A_U[J] K^{-1/2}, \qquad -\tfrac{1}{2} I \leq B \leq I. \tag{3.ccxcii}$$

The upper bound follows from $K_U^G \geq 0$. The lower bound uses $K^{-1} \leq 2/c_0$. In particular B is a bounded self-adjoint operator with norm at most one, and

$$K_{U,\tau}^{\mathrm{rel}}[J] = K^{1/2}[I + (\tau - 1)B]K^{1/2}. \tag{3.ccxciii}$$

For $|\tau - 1| \leq 1/2$ this proves $\mathrm{Re}(v, K_{U,\tau}^{\mathrm{rel}}[J]v)_{\mathrm{H}} \geq \frac{1}{2}(v, Kv)_{\mathrm{H}} \geq (c_0/4)\|v\|_2^2$ and inverse norm at most $4/c_0$. The inverse is holomorphic on $|\tau - 1| < 1$ by the Neumann series for its middle factor. The gauge block has stayed at its original weight.

In finite dimension let $\beta_a \in [-1/2, 1]$ be the eigenvalues of B. Then $\det K_\tau = \det K \prod_a [1 + (\tau - 1)\beta_a]$. Every factor has positive real part on that disc. Its logarithm continued from one defines the coherent Gaussian determinant branch. This is a matrix normalizer statement, not a zero-free theorem for an interacting partition function with cutoffs.

One also obtains a useful absolute bound. For N real coordinates, $0 \leq \rho < 1/4$, and $|F(y)| \leq F_0 e^{\rho(y,Ky)}$,

$$\left| \int F \, d\mu_{K_\tau} \right| \leq F_0 \left(\frac{3/2}{1/2 - 2\rho} \right)^{N/2}, \qquad |\tau - 1| \leq 1/2. \tag{3.ccxciv}$$

The determinant modulus is at most $(3/2)^N \det K$, and $\mathrm{Re}\, K_\tau - 2\rho K \geq (1/2 - 2\rho)K$. Integrating this real Gaussian proves the inequality. Its cost is exponential in the actual number of coordinates. A component mass estimate must pay that cost from its stated reserve; it has not become a volume-independent scalar bound.

A complex neighbourhood and exponentially local inverse. The matrix has the fixed finite range of the actual one-step chart. Relative contour factors add no new geometric range: both factors use the same internal paths. On the joint chart their analytic values and inverses are bounded in a local unitary frame. The local Cauchy estimates and coordinate counts give

$$\|K_{e^{iE}U,\tau}^{\mathrm{rel}}[J + Z] - K_U^{\mathrm{rel}}[J]\|_{\mathrm{Sch}} \leq \widehat{K}_L(\|E\|_\infty + \|Z\|_\infty + |\tau - 1|), \qquad \widehat{K}_L = C' L^{40}. \tag{3.ccxcv}$$

Here use $\|E\|_\infty \leq r_b/16$, retained chart room and total current at most one. To justify the same safe power, each scalar relative contour term is bounded on the same free radius cL^{-9} and background radius $c'L^{-5}$. At most CL^4 terms affect one row and at most CL^4 columns couple to it. Its free Hessian costs CL^{26} and one background difference CL^{31}. The current curvature term has the previously counted CL^{17} current cost. The action block in the τ derivative has a bounded row sum of this same safe order. Increasing C' gives eq. 3.ccxcv, independently of volume.

If the right side is at most $c_0/8$, the Neumann series about eq. 3.ccxc gives inverse norm at most $4/c_0$. Finite range and its uniform row and column sums also give a local exponential inverse. For clarity let d be the fine lattice distance between free coordinates and let ψ be any bounded one-Lipschitz function. For small $m > 0$,

$$\|e^{m\psi} K e^{-m\psi} - K\|_{\mathrm{Sch}} \leq C_L(e^{mr_0} - 1), \qquad r_0 \leq 12L. \tag{3.ccxcvi}$$

This follows entry by entry from the range bound. Choose $m = m(L) > 0$ so this perturbation is at most $c_0/8$. The conjugated complex matrix is still invertible by comparison with the same real matrix. Apply its inverse bound with $\psi(b) = \min\{d(b, b'), N\}$ and let N increase. One obtains

$$\|(K^{-1})_{bb'}\| \leq (4/c_0)e^{-md(b,b')}. \tag{3.ccxcvii}$$

The distance is periodic distance on a torus. Counting its shells in the four-dimensional cover shows that row and column sums of this kernel are bounded uniformly in compatible volume. Consequently it is a two-sided inverse on bounded fields as well. The left identity uses the finite range of K; the right identity follows by absolute summation using that row bound. This also proves uniqueness of a bounded solution.

The half-disc has a uniform complex-field version as well. Bound the action-block and gauge-block differences separately by the same local Cauchy estimates. Since $|\tau| \leq 3/2$, their sum has norm at

most $C_L(\|E\|_\infty + \|Z\|_\infty)$, uniformly on $|\tau - 1| \le 1/2$. Make this norm at most $c_0/16$. Comparison with the inverse in eq. 3.ccxciii gives the inverse for the complex pair. For the weighted conjugation choose $m(L) > 0$ so its additional row/column cost is at most $c_0/16$. The total perturbation of the same real-pair half-disc operator is then at most $c_0/8$. Its inverse norm and kernel satisfy

$$\|K^{\mathrm{rel}}_{\mathbf{U},\tau}[\mathbf{J}]^{-1}\| \le 8/c_0, \qquad \|(K^{\mathrm{rel}}_{\mathbf{U},\tau}[\mathbf{J}]^{-1})_{bb'}\| \le (8/c_0)e^{-m(L)d(b,b')}. \tag{3.ccxcviii}$$

This argument is uniform in τ on the full closed half-disc. The smaller near-one comparison in eq. 3.ccxcv is a sufficient alternative; it is not needed to restrict τ in this stronger version.

Local intrinsic remainders and an admitted coupling disc. There is a locally finite decomposition of eq. 3.cclxxvi in which each scalar term has value and derivative zero at zero. For every Wilson plaquette take its action difference minus its own raw gradient paired with Φ_U. For every bond take $\langle J_b, (\Phi_U - C_U u)_b\rangle$. Add each individual relative contour term. The plaquette gradient terms sum to j_U, so this is exactly eq. 3.cclxxvi.

Each term depends on a fixed neighbourhood of its plaquette, bond or contour. On the common free ball of a fixed fraction of r_u its holomorphic supremum is bounded by a constant M_L. The unitary local frames and the actual chart give this bound uniformly in the real regular base, with the retained complex perturbation and current ceilings. Subtract half its local Hessian and denote the result by $R_\alpha(u)$. It vanishes through degree two. One-variable Cauchy on the line through u gives

$$|R_\alpha(u)| \le 2M_L(\|u\|_\infty/r)^3, \qquad \|u\|_\infty \le r/2, \tag{3.ccxcix}$$

for a fixed smaller radius $r = r(L) > 0$. Indeed the Taylor coefficients of order n are bounded by $M_L r^{-n}$ and the sum from $n = 3$ is geometric.

Let the fixed Gaussian field box have $\|y\|_\infty \le b$, $b \ge 1$. For an auxiliary coupling q with $|q|b \le r/2$, the singularity at zero in the following expression is removable:

$$q^{-2}R_\alpha(qy), \qquad |q^{-2}R_\alpha(qy)| \le 2M_L|q|b^3/r^3. \tag{3.ccc}$$

The gauge and action parts may have the separate fixed coefficients $1, \tau$ of eq. 3.cclxxix. All constants are uniform for τ on its retained disc.

The actual Haar and pivot-coarea factors also give local analytic potentials. Factor their value at $u = 0$ and take the holomorphic logarithm of the ratio on a smaller common chart. Each factor and its inverse are bounded there by the quantitative pivot inverse and Haar chart. Cauchy bounds its logarithmic derivative on a half ball; integration along the radial segment proves $|\log(J_\alpha(u)/J_\alpha(0))| \le C_L\|u\|_\infty/r$. This does not analytically continue an absolute value: the real coarea orientation is positive, and the complex factor is its coherent determinant inverse.

Group these fixed-range terms into their actual local carriers at a fixed block size M. Only $C_{L,M}$ terms enter a carrier or a rooted carrier sum. The potential weight $Q_Y(y) \ge 1$ and the bounded tree length of these carriers then give

$$\|V_{q,\tau}\|_\lambda \le C_{L,M,\lambda}|q|b^3/r^3. \tag{3.ccci}$$

This is a potential-norm estimate, independent of the number of carriers. For any fixed allowed potential budget w_* one can therefore take an admitted disc $|q| < c_{L,M,\lambda,w_*}b^{-3}$, also shrunk to ensure $|q|b < r/2$. This is an actual lower bound on an admissible radius for these first-step intrinsic and measure potentials. It is not just an upper restriction on a radius that has not been constructed.

The finite integral and the factors that remain outside. Here I denotes the constrained integral with this specified soft gauge weight and regular field box. Its identification with a regular part of the original Wilson measure uses the actual gauge-fixing identity and its prefactor; neither is created by the pivot change of variables.

At a physical critical axial pair, let $\mathcal{J}_U(u)$ be the whole real Haar/coarea density in the free chart and let N be the number of real free coordinates. On its fixed Gaussian box the exact integral is

$$I = e^{-xA_W(U)} g^N \mathcal{J}_U(0)(2\pi)^{N/2}(\det K^{\mathrm{rel}}_{U,\tau}[j_U])^{-1/2} \cdot \int \chi(y) e^{V_{g,\tau}(y)} d\mu_{K^{\mathrm{rel}}_{U,\tau}[j_U]}(y). \tag{3.cccii}$$

This follows from eq. 3.cclxxxii, the exact chart coarea factor and subtraction of its quadratic exponent. The nonconstant potential consists of the negative intrinsic remainders divided by g^2 and the logarithm of $\mathcal{J}_U(gy)/\mathcal{J}_U(0)$. The Gaussian determinant uses its coherent branch from the real positive matrix.

The prefactor is independent of the integrated field y, but generally depends on the coarse datum U and on the specified current and weight. It is not automatically a numerical vacuum constant. Its field-dependent part still needs the assigned localization; its value at the reference pair is counted once in the scalar normalization. The powers of g have been factored explicitly before introducing the auxiliary analytic coupling q in eq. 3.ccc.

The fixed box may be chosen as a product of colour-norm balls, so real site gauges preserve it. Complex gauge covariance of matrices, already proved in eq. 3.cclxxxvii, is not by itself a contour-deformation theorem for a sharp real integral. Such an integral's local holomorphic gauge identity follows on an admitted connected continuation from its real gauge identity; arbitrary full-core orbit descent requires the additional domain comparison.

We have supplied an explicit consistent first-step extension, the physical action identity, its real gap, complex inverse, and the intrinsic potential radius. The enlarged decoupling matrices, integrated bond-root bounds, all-substitution core admission, localization of the prefactor, and the many-level effective action and history operations remain separate. If this extension is used beyond the first step, each of them must use the same definition and prove its physical sum identity. It is not legitimate to import estimates for a differently defined current completion without the complete comparison. Conversely, the named-completion comparison need not be imposed in addition when the entire alternate construction has actually been rebuilt from eq. 3.cclxxvi.

3.11. **Constrained backgrounds at several scales.** A background is a regular critical orbit of the fine Wilson action with its assigned block averages, not a new independent coarse action. Its construction has three separate ingredients. The determining rows and their residual gauge group are fixed geometrically. The critical equations are then solved on a slice by a coupled field and multiplier argument. Finally a local regularity improvement identifies the solution among all regular orbits and gives the bounds needed for restriction and analytic continuation.

This section develops the geometric and nonlinear construction using the actual finite averaging map. Its proper-region inverse and local coefficient estimates are proved subsequently; their application to all sufficiently small regular mixed data is completed in Prop. 3.124. The construction includes arbitrary regular competitors, the action-boundary current, and the outward node factors. The physical constrained Hessian agrees with an independently defined current operator only when their complete projected forms agree.

The six background statements concern the regular critical orbit, local regularity, complex continuation, response, hereditary complex domains, and restriction with boundary comparison. A proved reduction to an explicitly stated primitive estimate is distinguished from a proof of that estimate.

3.11.1. *Determining rows and the geometry of a seam.* Fix an odd integer $L \geq 3$ and a depth k. Work in level-k units, so the bare spacing and intermediate spacings are

$$\eta = L^{-k}, \qquad \xi_j = L^{j-k}, \qquad 0 \leq j \leq k. \tag{3.ccciii}$$

The regions $\Omega_0 \supset \cdots \supset \Omega_k$ are unions of the assigned aligned cubes of side $\mathfrak{M}\xi_j$, where $\mathfrak{M}$ is an odd power of L. Set $\Omega_{k+1} = \varnothing$. Half-open cells specify boundary membership. The separation condition is

$$\operatorname{dist}_\infty(\Omega_j^c, \Omega_{j+1}) > \rho\xi_j, \qquad \rho \geq C_{\text{geom}} L. \tag{3.ccciv}$$

The number C_{geom} is chosen large enough for the fixed one-step path neighborhoods and collars used below. This condition does not require a region to be connected or simply connected.

Because all cubes are aligned and their sizes are powers of L, each Ω_j is a union of the blocks $B^j(y)$ of side ξ_j, and each Ω_{j+1} is also a union of those blocks. A top is a site $y \in \mathbb{T}^{(j)} \cap (\Omega_j \setminus \Omega_{j+1})$; its pillar is $B^j(y)$. These pillars partition Ω_0. To prove this, take a bare cell and the largest j for which it lies in Ω_j. Its level-j block is contained in Ω_j, while Ω_{j+1}, being a union of level-j blocks, contains none of that block. Its center is therefore a top of level j. Two such blocks at one level are disjoint. Blocks at different levels are nested if they meet, which is incompatible with the corresponding disjoint layers. This proves existence and uniqueness of its pillar.

For a bare bond or plaquette e, let $\mathsf{L}(e)$ be the largest top scale attached to its corners. The numerical action and regularity tests use

$$A_{\Omega_0}(U) = \sum_{p \subset \Omega_0} \left(1 - \tfrac{1}{2} \operatorname{tr} \partial U(p)\right), \qquad \eta^{-2}\mathsf{L}(p)^2 |\partial U(p) - 1|, \quad \mathsf{L}(b)^3 |J_A(U)(b)|. \tag{3.cccv}$$

Only inner plaquettes contribute to this action. Its boundary current therefore need not contain all six plaquettes of a bond. The current is its actual derivative with the length and pairing normalization of § 3.9.

The determining bonds of level j are

$$\Gamma_j = \left\{ c \subset \Omega_0 : \begin{array}{l} c \text{ is a level-}j \text{ bond, } c \text{ touches } \Omega_j, \\ c \text{ has no endpoint in } \Omega_{j+1} \end{array} \right\},$$
$$\mathbf{B} = \bigcup_{j=0}^{k} \Gamma_j. \tag{3.cccvi}$$

No inward row is kept. A row whose two endpoints lie in Ω_j is interior. An outward row has one endpoint outside Ω_j. Every endpoint is a top, possibly of the preceding level.

Here is the precise local geometry behind the last assertion. Let $c = (y, x) \in \Gamma_j$, $j \geq 1$, with $y \in \Omega_j$ and $x \notin \Omega_j$. Their distance is $\xi_j = L\xi_{j-1}$. By eq. 3.ccciv, neither endpoint nor its fixed double-block neighborhood can leave Ω_{j-1}. The endpoint x consequently belongs to $\Omega_{j-1} \setminus \Omega_j$, and it is a site of $\mathbb{T}^{(j-1)}$. It is a top of level $j-1$, even when it also happens to be a site of a coarser lattice. Its centered level-j block is entirely outside Ω_j, because that region is a union of level-j blocks. The separation puts this block entirely in Ω_{j-1}. Hence every level-$(j-1)$ bond internal to that block is a prescribed interior row of Γ_{j-1}.

The same argument shows why a row's double block reads no third layer. Each endpoint block misses Ω_{j+1}, by the no-inward condition and block alignment, and the neighborhood is inside Ω_{j-1} by separation. A one-step seam calculation therefore contains the levels $j-1, j$, whose length ratio is the fixed number L. It does not contain a product of ratios over all earlier levels. Larger constructions must explicitly preserve these determining neighborhoods; the assertion is not true for an arbitrary enlarged box at a seam.

The datum and residual group are

$$M_{\mathbf{B}}(U) = (\mathcal{M}^j U|_{\Gamma_j})_{j=0}^k, \qquad \mathcal{F}(\mathbf{V}) = \{U : M_{\mathbf{B}}(U) = \mathbf{V}\},$$
$$\mathcal{G}_{\text{res}} = \{g : g(y) = 1 \text{ at every node}\}. \tag{3.cccvii}$$

Exact gauge covariance of the iterated average proves that this group preserves the fibre. Its definition involves all nodes, not only the centers of the last lattice.

3.11.1.1. Test loops and the missing inward rows. At an ordinary coarse plaquette the datum loop uses V_j. Where the loop crosses into the preceding layer it uses the actual one-step averages of V_{j-1} on those edges. These are the mixed test loops. Their values transform by conjugation at their starting node; their distance from one is invariant under real unitary gauges. This is the local compatibility information that a regular datum supplies. It is not a bound on all individual $V_j(c) - 1$.

If inward rows are retained, their endpoint in Ω_{j+1} becomes an additional seam node. There is then a genuine distinction between fixing all nodes and imposing a full block-axial gauge in the inner block. The following example is exact. Take an inner top y and an additional seam node $x \neq y$ in its block. Choose a site gauge with $g(y) = 1$ and $g(x) \neq 1$, as close to one as desired, and set $U = 1^g$. All plaquettes and the action current are zero. All closed datum tests are also one. But

$$T_{y,x}(\mathcal{M}^j U) = g(y)g(x)^{-1} \neq 1. \tag{3.cccviii}$$

Every residual transformation fixing both nodes leaves this transport unchanged. Thus this pure-gauge orbit cannot be made fully block axial there. The example does not obstruct an axial gauge *outside* the nodes; that gauge is proved next. It explains why a step that requires a full inner block-axial representative omits the inward rows, or else states its exceptional-node gauge explicitly.

With two kept inward edges meeting the same seam node, compatibility also records their relative frames. In an adapted real datum frame one can write these as products of a coarse edge, the internal fine contour transport and the kept inward edge. The product of one such route with the inverse of another is a closed two-scale loop. It is a datum test independent of the fine representative. Omitting these tests while retaining the edges changes the regular-datum class; elementary plaquettes in each separate layer do not record their relative frame.

3.11.2. *An exact representative outside the nodes.* The residual orbit has a canonical comb representative independently of any elliptic equation. A comb is the fixed coordinate-order path inside a block. The only properties needed here are locality, bi-equivariance and the identity transport at a zero-length path. The construction works as well with an admitted mean transport having those properties.

For a nonnode x, let $n(x)$ be its largest lattice index: $x \in \mathbb{T}^{(n)} \setminus \mathbb{T}^{(n+1)}$. Its parent $z(x)$ is the center of its level-$(n+1)$ block. Its ascent terminates at its pillar top. We seek a residual gauge such that, for every such site,

$$(\mathcal{M}^{n(x)}U)(\Gamma_{z(x),x}) = 1. \tag{3.cccix}$$

Process the indices in descending order. At index n, leave the gauge one at all nodes and at $\mathbb{T}^{(n+1)}$. At a nonnode of exact index n, assign it the current transport $(\mathcal{M}^n U)(\Gamma_{z(x),x})$. Extend this gauge by one at the sites not being processed. Bi-equivariance makes that transport one. Gauge covariance of $\mathcal{M}^m$, $m > n$, sees only values at $\mathbb{T}^{(m)}$, which have not changed. Thus previously imposed conditions remain true. After finitely many stages every condition in eq. 3.cccix holds, and every prescribed node value has stayed one.

Uniqueness is equally direct. Suppose two representatives in one residual orbit satisfy eq. 3.cccix, and let h take one to the other. It is one at the tops. Descending an ascent, if $h(z) = 1$, covariance of a transport already equal to one gives

$$1 = h(z)\,1\,h(x)^{-1}, \qquad h(x) = 1. \tag{3.cccx}$$

Every nonnode is reached, so $h = 1$. The representative is therefore a function of the orbit. On real configurations the construction is Borel: the total average is Borel, the comb transports are finite products, and all inversions and multiplications are continuous group operations. On an admitted regular complex chart it is holomorphic, since there the assigned averages are holomorphic.

This argument gives no depth-independent bound for the derivative of the gauge. A real pure gauge may have arbitrary values at fine sites while fixing the tops. Norm bounds on a slice require

the separate estimates below. Likewise a complex representative is used only when its values remain in the admitted analytic branches and its condition numbers have the required bounds. The Borel orbit construction alone does not establish that admission.

For a sequence of depth $k+1$ with no inward rows, an inner level-$(k+1)$ block has no node except its center. Indeed every lower-level site of the block lies in Ω_{k+1}, so cannot be a top of a preceding layer, and alignment supplies no other coarse center in that block. A residual gauge can consequently set all its level-k internal contour variables to one while fixing the datum. This is the exact node-counting fact used in the definition of the next step's physical background.

3.11.3. *The reduced datum has an explicit local inverse.* Fix a real reference field U_0 whose used averages lie on the regular branches of the actual finite mean. For an interior row the reduced datum is $b(B)(c) = B(c)$. On an outward row oriented toward its outer endpoint z, it is

$$e^{ib(B)(c)} = e^{iB(c)} Z_c(B_{\mathrm{int}}), \qquad Z_c(B_{\mathrm{int}}) = \mathrm{Ad}(V_0(c))\, v_z(B_{\mathrm{int}}). \tag{3.cccxi}$$

The factor v_z is the actual one-step block factor made from the interior data in the finer block centered at z. The geometry following eq. 3.cccvi proves that these are prescribed interior rows, not another set of unknown outward rows. For the reverse orientation use the inverse group identity.

There is therefore a direct inverse. Recover $B_{\mathrm{int}} = b_{\mathrm{int}}$, then set

$$B(c) = \frac{1}{i} \log \left(e^{ib(c)} Z_c(b_{\mathrm{int}})^{-1} \right) \quad \text{on outward rows.} \tag{3.cccxii}$$

All logarithms are on the common small datum chart. Conjugation by the real $V_0(c)$ has norm one; it imposes no smallness of that coarse edge or of a global holonomy. The finite mean construction gives a radius $r_0(L) > 0$ on its admitted local reference class. On a fixed smaller ball, its block factors and their first two derivatives are bounded by constants depending on that finite construction. Thus eq. 3.cccxi–eq. 3.cccxii are admitted on balls $\|B\|_\infty < r_0/C_L$, respectively $\|b\|_\infty < r_0/C_L'$, and satisfy

$$\|b(B)\|_\infty \le C_L \|B\|_\infty, \qquad \|b^{-1}(b)\|_\infty \le C_L' \|b\|_\infty. \tag{3.cccxiii}$$

The uniform statement is over local reference patches on which that same finite chart and its radius are admitted. Establishing those patches for a multilevel background is part of its regular-domain estimate; it is not inferred just from the existence of U_0.

It is useful to see exactly why the inverse does not contain a long product of triangular matrices. Define the right logarithmic differential $\mathcal{E}_X(H) = (1/i)(d/dt) e^{i(X+tH)}|_{t=0} e^{-iX}$. Differentiating eq. 3.cccxi gives the outward diagonal $D_c = \mathcal{E}_{b(c)}^{-1} \mathcal{E}_{B(c)}$, not the identity in general. Let D be this block diagonal matrix, with identity on interior rows, and let T contain all derivatives of block factors. Its only nonzero blocks have interior columns and outward rows. Consequently

$$Db = D + T, \qquad TD^{-1}T = 0, \qquad (Db)^{-1} = D^{-1} - D^{-1}TD^{-1}. \tag{3.cccxiv}$$

Multiplying the last two matrices verifies both inverse identities. This nilpotence is a property of the actual reduced datum. An arbitrary lower triangular coupling between successive levels would not have it.

For the row count, one outward factor reads the $O(L^4)$ interior data of its single finer block. For the column count, an interior bond belongs to one assigned finer block, and that block can be the outer endpoint block of at most eight coarse incident rows. Thus both row and column counts are bounded at fixed L, independently of the number of layers. After inserting the actual cell weights and amplitudes, an interaction changes scale only from $j-1$ to j; its weight ratios are fixed powers of L. eq. 3.cccxiii–eq. 3.cccxiv therefore also give two-sided weighted Schur bounds in those declared norms. Higher derivatives follow from the same finite group formula and its fixed datum disc.

This local datum calculation is different from constructing a right inverse of all the field constraint rows. The latter must also lift fields and control their energy and gauge slice at a seam. That

primitive linear task is retained in the precision section. The exact derivative Db, including its nonidentity outward diagonal, is the datum forcing in the response equations.

3.11.4. *Real reconstruction on one block.* The next estimates are finite group calculations. They concern real unitary fields on a rectangular lift of one or two blocks. They do not require those fields to be close to one on every bond. Let $\varpi(U) = \sup_p |\partial U(p) - 1|$ on that neighborhood.

A coordinate-order path can be changed to another such path by interchanging adjacent steps in different directions and canceling backtracks. Each interchange inserts one plaquette, conjugated by the transport of its preceding path. On a box of side $O(L)$, the number of interchanges is bounded in terms of L, and more specifically at most a dimensional constant times L^2 for the fixed path families used here. Thus a contractible comparison loop γ in this family is a product of transported plaquette factors and

$$|U(\gamma) - 1| \le C_L \varpi(U). \tag{3.cccxv}$$

Indeed for unitary matrices $|AB - 1| \le |A - 1| + |B - 1|$, and conjugation by a unitary transport preserves the norm. Inducting over the inserted factors proves eq. 3.cccxv. The constant is not multiplied by the size of an individual open transport. This is why arbitrary real holonomies cause no loss in the local argument.

Fix the comb from the block center. The relative transports of the coordinate-order path family differ from that comb by eq. 3.cccxv. The local mean lemma, on its fixed regular radius, then implies

$$|T_{y,x}(U) - U(\Gamma_{y,x})| \le C_L \varpi(U). \tag{3.cccxvi}$$

To see that the mean lemma applies without a small open transport, multiply every member on the right by the inverse of the comb transport. The resulting family is near one. The implicit logarithmic mean has a uniformly bounded derivative on a smaller fixed ball, by its finite-dimensional inverse construction. Its value therefore differs from one by $C_L \varpi(U)$. Right equivariance restores the original transport and proves eq. 3.cccxvi.

For a fine bond b, let y_-, y_+ be the centers of its endpoint blocks and use the same center when both endpoints lie in one block. Define its transported value by

$$\widetilde{U}(b) = T_{y_-,b_-}(U)\, U(b)\, T_{y_+,b_+}(U)^{-1}. \tag{3.cccxvii}$$

If the centers coincide, this is a comparison loop, so it is within $C_L \varpi(U)$ of one. Otherwise the centers are joined by a coarse bond c. Replace the means by combs using eq. 3.cccxvi. The resulting open route and the central straight route from y_- to y_+ differ by a loop of the type in eq. 3.cccxv. The closed comparison transports in the definition of $\mathcal{M}(U)(c)$ satisfy the same bound. The finite exponential and logarithm estimate consequently gives

$$|\widetilde{U}(b) - \mathcal{M}(U)(c)| \le C_L \varpi(U) \quad (y_- \ne y_+). \tag{3.cccxviii}$$

All paths used are in the fixed double block. The regularity threshold makes the closed logarithms well defined; the final coarse bond itself may be far from one.

For two such fields U, U_0, put $d_T(x) = |T_{y,x}(U) - T_{y,x}(U_0)|$, using the endpoint's block center. Combining eq. 3.cccxvii–eq. 3.cccxviii and using unitarity gives

$$\begin{aligned} |U(b) - U_0(b)| \le{}& |\mathcal{M}(U)(c) - \mathcal{M}(U_0)(c)| + d_T(b_-) + d_T(b_+) \\ &+ C_L\{\varpi(U) + \varpi(U_0)\}. \end{aligned} \tag{3.cccxix}$$

For a bond internal to one block, omit the coarse-bond difference. The coefficient of the coarse difference is exactly one, since it is multiplied only by unitary transports. In a comparison where the contour means agree the two d_T terms vanish. If only the combs agree, eq. 3.cccxvi absorbs them into the curvature error.

An iteration with this coefficient is qualitatively different from an iteration with an unspecified constant in front of the coarse error. If a bond is in a pillar of height j, and the regularity at intermediate index $n < j$ is $\varpi_n \le \varepsilon L^{2(n-j)}$, eq. 3.cccxix yields, along an aligned descent,

$$e_n \le e_{n+1} + C_L \varepsilon L^{2(n-j)}, \qquad e_n \le e_j + \frac{C_L \varepsilon}{L^2 - 1}. \tag{3.cccxx}$$

The second inequality is obtained by summing the first. An uncontrolled endpoint contour defect would have to be added at each step; it cannot be omitted. For the preliminary gauge on a separated real sequence, let $W_n = \mathcal{M}^n U$ and $W_{0,n} = \mathcal{M}^n U_0$. Begin with $g_k = 1$ and descend. Set $g_n = 1$ on the tops Λ_n of that layer. On the block of an interior next-level center y, set

$$g_n(x) = W_{0,n}(y, x)^{-1} g_{n+1}(y) W_n(y, x).$$

These blocks and the layer tops partition the level-n sites of Ω_n. Since the contour from y to itself is one, the formula extends g_{n+1} and gives a single gauge on the bare sites. Covariance of the mean then makes the two contour values equal in every such block. The interior and outward determining bonds have both endpoints at tops, so their original datum mismatch is unchanged.

At an inward bond orient it towards the seam node. Its corridor belongs to the outward bond one level above, whose outer endpoint block lies wholly in Λ_n. The inward end uses the aligned contour. At the outer end each contour reads at most $2(L-1)$ interior bonds of the recorded block. With a mismatch at most α_1 on the proper determining rows, telescoping along the path and replacing the mean by the path costs at most $2(L-1)\alpha_1 + C_L\alpha_0$. Here α_0 bounds the regularity radius and the double block lies in Ω_n. Including the outward bond one level above gives the inward bound $(2L-1)\alpha_1 + C_L\alpha_0$. This applies whether the inward row is retained or omitted. For a bond with both ends in a deeper layer, the endpoint blocks follow the same largest common layer as the bond, by alignment. Its double-block curvature at level n is bounded by $C\alpha_0 L^{2(n-j)}$ when j is that largest layer. Applying eq. 3.cccxx from the proper or inward bound at j then gives a uniform bound $C_L(\alpha_0 + \alpha_1)$ at every carried link.

The estimate in eq. 3.cccxx is a bound on raw relative group elements. It does not divide those differences by the fine spacing and does not prove a bound on a first difference quotient. The elliptic slice estimate used later is precisely what improves this preliminary closeness to the natural physical norm.

3.11.4.1. The sharp linear curvature factor. A rough application of eq. 3.cccxv to each coarse edge gives $C_L\varpi$, which is not enough for a uniform iteration in physical units. The leading coefficient can be computed exactly. On the same finite rectangular patch take a comb tree gauge. Each remaining bond is a comparison loop with the tree, hence is within $C_L\varpi$ of one. For small ϖ write it as e^{ia_b} with $\|a\|_\infty \le C_L\varpi$. Taylor expansion of the finite products gives

$$|\mathrm{d}a(p)| \le \varpi + C_L\varpi^2, \qquad \log \partial\mathcal{M}(e^{ia})(p')/i = \mathrm{d}_c(P_L a)(p') + O(C_L\varpi^2). \tag{3.cccxxi}$$

The first linear term is the discrete curl; every other product term has at least two a's. The same is true of the finite implicit mean and logarithm on their fixed chart. These statements are estimates for a fixed number of coordinates depending on L, so the quadratic constants are finite and independent of depth.

The flat identity $P_L = S_L - \mathrm{d}_c\Sigma_L$ implies $\mathrm{d}_c P_L = \mathrm{d}_c S_L$. For a $\mu\nu$ coarse plaquette, direct telescoping of the straight sums gives the exact flux formula

$$(\mathrm{d}_c S_L a)_{\mu\nu}(y) = L^{-4} \sum_{x \in B(y)} \sum_{r,s=0}^{L-1} (\mathrm{d}a)_{\mu\nu}(x + re_\mu + se_\nu). \tag{3.cccxxii}$$

For example the difference of the two ν-edge sums separated by Le_μ telescopes in the μ direction; the other two edge sums telescope in ν with the opposite sign. Their combination is the displayed sheet curl. There are L^4L^2 terms with weight L^{-4}, so its supremum norm is at most $L^2\|\mathrm{d}a\|_\infty$.

Finally the exponential changes a small coarse logarithmic curvature into its group value with a quadratic error. Together with eq. 3.cccxxi this proves the real one-step estimate

$$\varpi(\mathcal{M}U) \le L^2\varpi(U) + C_L\varpi(U)^2. \tag{3.cccxxiii}$$

The tree gauge was local and unitary, so the conclusion holds in the original frame.

For a homogeneous regular patch let $\varpi(U) \le \varepsilon L^{-2k}$. Suppose all determining neighborhoods stay in that patch. Put $v_n = L^{2(k-n)}\varpi(\mathcal{M}^n U)$. eq. 3.cccxxiii gives

$$v_{n+1} \le v_n + C_L L^{-2(k-n)-2} v_n^2. \tag{3.cccxxiv}$$

The coefficients in this nonlinear recursion have a sum bounded independently of k. Choose ε small enough that four times this sum times ε is less than one. Inductively, if $v_q \le 2\varepsilon$ up to n, summing the recursion gives $v_{n+1} < 2\varepsilon$. Thus

$$|\partial\mathcal{M}^n U - 1| \le 2\varepsilon L^{2(n-k)} \quad (0 \le n \le k). \tag{3.cccxxv}$$

The same induction establishes admission to every one-step regular mean branch, by reducing ε below its fixed threshold. On a proper region it is used only at points whose full determining neighborhood remains in the region.

Across a seam the comparison uses the finer of the two adjacent length scales. A curvature measured in the coarser scale can therefore lose a fixed factor L^2. The geometry of eq. 3.cccvi permits that local loss and no chain of unexamined intermediate layers in one row. Proving an entire tower or joined-region statement still requires its determining neighborhoods to have the advertised alignment and collars. The formula in eq. 3.cccxxv is the averaging estimate; it does not solve a constrained variational problem.

3.11.5. *A domain specified before the unknown background.* An inverse estimate cannot be used to define its own range of application. We therefore first specify a class of possible reference fields without referring to the unknown solution. On each fixed determining patch use a real unitary local gauge and ask that its elementary plaquettes satisfy the bound in eq. 3.cccv, with a small specified constant ϵ_0. The bound is a test of the given field. Its coarse tests are obtained from the actual averages. For real homogeneous subpatches eq. 3.cccxxv proves admission to their regular branches. At a seam the preceding two-scale neighborhood is tested, and its finite averaging factors are tested in the same regular chart. The latter tests are explicit finite group inequalities, not assertions about the critical field.

Let $\mathcal{R}_{\mathrm{lin}}(\epsilon_0, \gamma_0)$ consist of such real fields and independent currents with

$$\sup_{p\subset\Omega_0} \eta^{-2}\mathsf{L}(p)^2|\partial U(p) - 1| < \epsilon_0, \qquad \sup_b \mathsf{L}(b)^3|J(b)| < \gamma_0. \tag{3.cccxxvi}$$

Include the actual finite-chart and row-rank inequalities needed by the chosen slice, and name their radii. These conditions can be checked on (U, J) before stationarity is imposed. For a physical trial field the current used in a physical curved-fibre Hessian is $J_A(U)$. A separately prescribed J in eq. 3.cccxxvi is not set equal to it. The two domains may coincide on a physical submanifold while their off-submanifold completions differ.

Complex fields are introduced relative to one such real reference by $U' = e^{i\eta A'}U$. Their domain records, separately, bounds on the physical logarithm and on every actual finite averaging or gauge formula used:

$$\|\mathsf{L}A'\|_\infty < r_A, \qquad \|\mathsf{L}^2 D_U A'\|_\infty < r_D, \qquad \|\mathsf{L}^3 J'\|_\infty < r_J, \qquad \mathcal{Q}_\beta(A', J') < r_\beta. \tag{3.cccxxvii}$$

Here $\mathcal{Q}_\beta$ ranges over a declared finite list of local readouts and atomic branch tests, including the outward datum factors, slice maps, current readouts and inverses actually used. The tests are normalized by length and scale, not by their target radii. The separate inequalities and their margins are essential: a point satisfying the curvature inequality need not satisfy a complex logarithm or multiplier inequality.

The linearized operator has to be defined on this primitive domain. If its definition uses a nonlinear background at a smaller scale, that background must already have been constructed in the induction, with its own admitted domain and margins. It cannot use the background presently being solved for. The induction is a directed finite list: an action or readout at level j reads only completed levels below j, and its new constraint rows are the specified level-j rows. This is a condition on the actual construction, not on notation.

There are two useful consequences of this arrangement. A primitive matrix theorem on eq. 3.cccxxvi–eq. 3.cccxxvii can be applied at a noncritical trial field. Also the complex inverse can be continued on an entire admitted ball by the two-sided Schur argument, rather than being asserted only along the eventual solution. Both consequences are needed in a first-exit proof of admission.
3.11.5.1. A regular section and what it must prove. A regular datum is defined by its elementary and two-scale test loops. Before the variational construction one needs a configuration realizing those data sufficiently accurately, or exactly, in the primitive domain. There are four concrete tasks in such a construction.

First, on the finite coarse patches, choose local unitary frames from the datum transports. Their transition matrices must obey the actual node cocycle. Products around contractible test loops are small, while noncontractible holonomies are retained as unitary transition matrices. Replacing them by the identity would change the fibre.

Second, extend the local coarse connection through a block with smooth fields on its free coordinates. The required estimates are on the physical potential, its first differences and its current or covariant Laplacian, at that block's scale. A raw face-supported lift need not have these estimates. For instance a jump in its plaquette field on a coarse face can produce a fine current of order η^{-1} times that jump.

Third, evaluate the *actual* finite mean of this trial field. The discrepancy from the datum is a named local function $\mathfrak{e}(B)$, not the discrepancy of a linear surrogate. The finite chart gives its derivative and quadratic remainder. The linear row right inverse must map this discrepancy into the same potential and current norms.

Fourth, the local corrections must agree on overlaps and leave previously frozen rows unchanged. At a seam this includes the outward factor in eq. 3.cccxi and its interior dependence, not merely the interior average.

The nonlinear correction in the third task is elementary once its linear and finite coefficient estimates have been proved. In declared field and datum norms let

$$\begin{aligned} q(A) &= Q_0 A + N_q(A), \qquad Q_0 E = 1, \qquad \|Eb\|_X \le C_E \|b\|_Y, \\ \|N_q(A) - N_q(A')\|_Y &\le C_q(\|A\|_X + \|A'\|_X)\|A - A'\|_X. \end{aligned} \tag{3.cccxxviii}$$

All maps are the actual constraint and its actual derivative. Writing $A = Eu$ reduces $q(A) = b$ to

$$u = b - N_q(Eu). \tag{3.cccxxix}$$

On $\|u\|_Y \le 2\|b\|_Y$ the right side is a self-map and has Lipschitz constant at most $4C_qC_E^2\|b\|_Y$. If that number is less than one half, successive substitution converges geometrically, uniformly in the finite lattice. The resulting correction is at most $2C_E\|b\|_Y$ in X. For complex data, uniform convergence on a smaller open ball makes it holomorphic: each iterate is holomorphic, and applying continuous linear functionals and Cauchy's integral formula proves holomorphy of the limit.

This proves the constraint correction from eq. 3.cccxxviii. It does not prove the scale-uniform right-inverse estimate, the smoothed trial estimate, or the overlap cocycle just listed. Those are bounded geometric and operator tasks for the actual map. The target is that their constants are independent of depth, volume, region shape and real holonomy, for the fixed allowed local geometry. A proof for only one block realizes the corresponding first-step instance.

3.11.6. *The actual critical equations.* Use fixed reference coordinates $U(A) = e^{i\eta A}U_0$, with the prescribed slice imposed. Write the constraint in the coordinates just specified as $q(A) = b(B)$, and

set $F(A) = A_{\Omega_0}(U(A))$. Here q is the chosen actual plain constraint, or the straightened constraint with the accompanying node factors and reduced datum identified below. These choices have different derivatives; every use of a linear inverse specifies which is used. All transposes below are bilinear cell-weighted transposes. For real positivity the pairing is Hermitian instead. In particular a change from raw bond logarithms to physical potentials also changes the dual current weights.

Let $J_A(U)$ be the physical left-variation current:

$$\frac{d}{dt} A_{\Omega_0}(e^{i\eta t h} U)\Big|_{t=0} = \eta^4 \sum_b (J_A(U)(b), h(b)). \tag{3.cccxxx}$$

For the reference-coordinate derivative this gives

$$DF(A)[h] = \eta^4 \sum_b (J_A(U(A))(b), \mathcal{E}_{\eta A(b)} h(b)). \tag{3.cccxxxi}$$

Indeed $(d/dt)e^{i\eta(A+th)}|_0 = i\eta \mathcal{E}_{\eta A}(h) e^{i\eta A}$. Thus the reference covector at nonzero A includes a right-logarithmic differential. Dropping this factor from a second derivative changes its current terms.

The coupled critical equations are

$$DF(A) - Dq(A)^\sharp \omega = 0, \qquad q(A) = b(B). \tag{3.cccxxxii}$$

Here ω is a coarse covector in the normalization dual to q. For raw constraints $q = mQ$, one has $\omega_Q = m^\sharp \omega$. The scalar $\langle \omega, D^2 q \rangle = \langle \omega_Q, D^2 Q \rangle$ is unchanged.

These equations are equivalent to constrained criticality when Dq is onto on the chosen slice. One direction follows by testing eq. 3.cccxxxii on $\ker Dq$. Conversely choose any right inverse E_A and suppose $DF(A)$ annihilates that kernel. Since $h - E_A Dq\, h \in \ker Dq$,

$$DF(A)[h] = DF(A)[E_A Dq\, h] = \langle E_A^\sharp DF(A), Dq\, h \rangle. \tag{3.cccxxxiii}$$

This proves the assertion and the uniqueness of the multiplier: if $Dq^\sharp \omega = 0$, testing on $E_A v$ gives $\langle \omega, v \rangle = 0$ for every v. Surjectivity and its quantitative bound are therefore genuine parts of the background theorem.

The Lagrangian Hessian is

$$K(A, \omega) = D^2 F(A) - \langle \omega, D^2 q(A) \rangle. \tag{3.cccxxxiv}$$

It is its restriction to tangent fields, not $D^2 F$ alone, that controls the critical fibre. This follows either by differentiating the multiplier equation or directly from a curve $q(A(t)) = b$: $Dq\, \ddot{A} = -D^2 q[\dot{A}, \dot{A}]$ and hence

$$\frac{d^2}{dt^2} F(A(t))\big|_0 = \langle \dot{A}, K(A, \omega) \dot{A} \rangle \quad \text{at a critical point.} \tag{3.cccxxxv}$$

At a noncritical point the same fibre coordinate has an additional term involving its acceleration and DF. For the exact pivot chart Φ, differentiating $q(\Phi(u)) = q(0)$ gives $D^2\Phi = -h\, D^2 q[D\Phi, D\Phi]$. Consequently the Hessian of $F \circ \Phi$ is the projected action Hessian minus the contraction with $h^\sharp DF$, with its correct physical current and chart differentials. This identity follows from the finite chart differentiation. The first-step positivity actually proved by the finite precision results is for $D^2[(F + \mathrm{GF}_{\mathrm{actual}}) \circ \Phi]$ at an admitted real block-axial trial background, under the stated first-step radius and current ceilings. The actual soft gauge term and its identification are retained; at the physical current this is the corresponding action-plus-gauge fibre Hessian. A positive action-only Hessian on a separately chosen slice would require its own slice estimate and is not imported from that result. Criticality is needed to identify the multiplier interpretation in eq. 3.cccxxxiv, not for the stated action-plus-gauge trial-field estimate.

3.11.6.1. Absolute and relative soft gauges. The internal transport is a mean of coordinate-order paths. The absolute gauge term is

$$\mathrm{GF}_{\mathrm{abs}}(U) = \sum_{y,x} \left(1 - \tfrac{1}{2} \operatorname{tr} T_{y,x}(U)\right). \tag{3.cccxxxvi}$$

Its full Hessian is the one in a physical first-step calculation on an axial field. If a construction instead uses the relative gauge with reference U,

$$\mathrm{GF}_{\mathrm{rel},U}(a) = \sum_{y,x} \left(1 - \tfrac{1}{2} \operatorname{tr}[T_{y,x}(e^{ia}U) T_{y,x}(U)^{-1}]\right), \tag{3.cccxxxvii}$$

its gradient at $a = 0$ vanishes for every background. If $G_U a$ is the right-logarithmic first derivative of its transport, its quadratic form is the corresponding positive sum of squares, $G_U^\sharp G_U$, with the actual trace normalization. The second transport derivative has zero contribution because it is paired with the derivative of the scalar function at the identity.

The absolute Hessian has the same form only where $T_{y,x}(U) = 1$. For example along $T(t) = e^{i(\theta+t)\sigma_3}$ the absolute second derivative of $1-\cos(\theta+t)$ is $\cos\theta$, whereas the relative second derivative is one. They differ at arbitrarily small nonzero θ. Both absolute and relative terms are actual finite formulas; one cannot select between them by positivity alone.

The relative expression is covariant under a joint site gauge of its reference and variable field: both transports transform bi-equivariantly, and their product transforms by conjugation at the center. The absolute expression has the corresponding invariance only when the endpoint and center gauge values agree, or when the prescribed gauge convention otherwise makes its transport a closed quantity. At a seam, removing bonds from a determining set can make the relative convention the appropriate one. A retained boundary datum may instead require the absolute convention. The local row definition must decide which formula is present.

Thus an independent-current precision theorem must compare its entire projected form with the physical or prescribed auxiliary one. Write $\mathcal{J} = DF$ for the physical comparison, and let $\mathcal{J}$ be the declared independent fine covector, after the same dual-coordinate conversion, for an auxiliary comparison:

$$C^\sharp[\Delta_{\mathrm{named}}(U,J) - D^2F(U) + \langle h^\sharp \mathcal{J}, D^2 q\rangle - K_{\mathrm{gauge,actual}}(U,J)]C = 0, \tag{3.cccxxxviii}$$

after every term has been expressed in the same raw or physical coordinates. Equivalently the difference may be estimated with an explicit error and charged to the gap. The displayed subtraction is schematic only in its *name*: each named term must have its literal local definition, including every projected extra-current term. The comparison is an equality of fully typed bilinear forms. Constraint-curvature matching alone checks only one summand. Zero-fold averaging maps do not imply that a separate projected correction $\Delta'_\pi[J]$ vanishes. The precision section retains this complete matching task.

3.11.7. *The action induced on the coarse datum.* Suppose the critical solution of eq. 3.cccxxxii has been constructed on an open real datum ball and admits differentiation there. The induced action is $S(B) = F(A(B))$. Let $Q = Dq(A)$, and let T denote the energetic tangent lift: $QT = 1$, while KTv annihilates $\ker Q$. The response equations give

$$\dot{A} = T\, Db\, \dot{B}, \qquad \dot{\omega} = \mathcal{M}\, Db\, \dot{B}, \qquad KT = Q^\sharp \mathcal{M}. \tag{3.cccxxxix}$$

The letter $\mathcal{M}$ here denotes the multiplier response, not the group averaging map. It is determined by these equations and is symmetric in the real bilinear pairing. Indeed $\langle v, \mathcal{M} w\rangle = \langle Tv, KTw\rangle$ by $QT = 1$.

Differentiating S and using eq. 3.cccxxxii proves

$$\begin{aligned} DS(B)[v] &= \langle \omega, Db\, v\rangle, \\ D^2S(B)[v,w] &= \langle Db\, v, \mathcal{M}\, Db\, w\rangle + \langle \omega, D^2b[v,w]\rangle. \end{aligned} \tag{3.cccxl}$$

In particular an outward seam has the second term even when its interior datum coordinates are linear. An argument using only $\mathcal{M}$ would lose this actual datum-curvature term. There is no such term in a chart where the datum itself is the constraint coordinate; converting that chart back to B restores it.

There is also an exact formula from an admitted soft completion. Let a be the coarse gauge or penalty matrix in that completion and assume

$$G = (K + Q^\sharp a Q)^{-1}, \qquad W = QGQ^\sharp \quad \text{are defined, with } W \text{ invertible.} \tag{3.cccxli}$$

Set $H = GQ^\sharp W^{-1}$. Then $QH = 1$, and

$$KH = Q^\sharp(W^{-1} - a), \qquad H = T, \qquad \mathcal{M} = W^{-1} - a. \tag{3.cccxlii}$$

The first identity follows by multiplying $(K + Q^\sharp a Q)G = 1$ by $Q^\sharp W^{-1}$. It proves the energetic property of H. Uniqueness follows from invertibility of the constrained tangent operator: the difference of two energetic lifts lies in $\ker Q$ and is orthogonal under K to that kernel. This proves eq. 3.cccxlii.

These are algebraic identities on the admitted domain. They supply no bound for W^{-1}, no positivity for a completion not actually present, and no identification of an independent-current operator. Once those primitive facts have been proved, however, the coarse readout and its correct subtraction are forced by eq. 3.cccxl–eq. 3.cccxlii. On the next scale the action is this S, that is the original fine Wilson action evaluated at its constrained critical background. It must not be replaced by the bare Wilson formula on the coarse variables.

3.11.8. *Straightening and the named current completion.* Plain, straight and straightened averages must remain distinct. Write $q_n^{\mathrm{st}}(A)$ for the nonlinear straightened raw constraint at level n. Its defining node factors satisfy

$$\mathcal{M}^n(e^{i\eta A}U_0) = \big(e^{iq_n^{\mathrm{st}}(A)}\mathcal{M}^n U_0\big)^{v_n[A]}. \tag{3.cccxliii}$$

For each top of level n, prescribe $u[A](y)v_n[A](y) = 1$. Interior rows then have physical datum $e^{iq_n^{\mathrm{st}}(A)}V_0$. At an outward endpoint of level $n-1$ the value prescribed for $u[A]$ uses v_{n-1}, not v_n. With the orientation of eq. 3.cccxi, covariance gives

$$e^{iq_n^{\mathrm{st}}(A)(c)} = e^{iB(c)}\,\mathrm{Ad}(V_0(c))[v_{n-1}[A](z)^{-1}v_n[A](z)]. \tag{3.cccxliv}$$

On the fully prescribed outer block the bracket is exactly the one-step factor $v_z(B_{\mathrm{int}})$ in eq. 3.cccxi. This follows by evaluating its defining one-step averaging identity on the already prescribed level-$(n-1)$ interior data. Therefore the straightened equation is $q^{\mathrm{st}}(A) = b(B)$ with the reduced datum, including its outward factors. eq. 3.cccxliv also checks orientation and multiplication order.

After an admitted Landau slice has been constructed, the physical representative is

$$\Phi(B) = (e^{i\eta\mathcal{H}(B)}U_0)^{u_B}, \qquad RD^\sharp\mathcal{H}(B) = 0, \qquad u_B v_n[\mathcal{H}(B)] = 1 \text{ at level-}n \text{ tops.} \tag{3.cccxlv}$$

An independent comb slice gives a different potential and a different gauge factor. It has the same physical orbit and the same reduced datum, but need not coincide with the pair in eq. 3.cccxlv. Equality requires that its potential already obey the Landau condition. A bound on $u_B - 1$ only at the tops cannot be extended to all bare sites without the separate comb gauge estimate.

Gauge invariance of the fine action makes $F(\mathcal{H}(B))$ the action of $\Phi(B)$. Constrained criticality is therefore described by eq. 3.cccxxxii on this slice, provided that the slice and node construction parametrize the local physical fibre modulo the residual group. The primitive gauge estimate must

prove that parametrization, its uniqueness and its admitted ball. The node identities above prove the datum correspondence; they alone do not give the quantitative gauge estimate.

For reference the actual named propagator family uses the linear part Q per unit row length of this straightened constraint. Let $D = D_U$ be the covariant site difference, let Q' be the corresponding site average to the tops, and let a have the actual row or site weight. On its admitted domain use the zero-extension site Laplacian Δ_{s}, and set

$$\begin{aligned} G' &= (\Delta_{\mathrm{s}} + Q'^{\sharp} a Q')^{-1}, \\ R &= 1 - G'Q'^{\sharp}(Q'G'^{2}Q'^{\sharp})^{-1}Q'G', \\ \mathsf{S} &= 1 - DG'RD^{\sharp}, \qquad \mathsf{G}_0^{-1} = \Delta_U^{\mathrm{W}} + DRD^{\sharp} + Q^{\sharp} a Q. \end{aligned} \tag{3.cccxlvi}$$

At a real field R is the declared orthogonal site projector; on complex fields the formula uses bilinear transposes and analytic continuation on its admitted domain. Its inverses and its relation to the chosen slice are estimates to be established, not consequences of displaying the formula.

Let $\Delta'_{\pi}[J]$ be the specified linear-current correction and let $\Delta^{(2)}[\mathsf{j}]$ be the constraint quadratic form, normalized by $\langle A, \Delta^{(2)}[\mathsf{j}]A\rangle = 2\langle C^{(2)}(A), \mathsf{j}\rangle$. The subsequent definitions are ordered:

$$\begin{aligned} \mathsf{G}^{-1} &= \mathsf{G}_0^{-1} - \Delta'_{\pi}[J], \\ \mathsf{H} &= \mathsf{G}Q^{\sharp}(Q\mathsf{G}Q^{\sharp})^{-1}, \\ \mathsf{G}_1^{-1} &= \mathsf{G}^{-1} - \mathsf{S}^{\sharp}\Delta^{(2)}[\mathsf{H}^{\sharp}J]\mathsf{S}, \\ \mathsf{H}_1 &= \mathsf{G}_1 Q^{\sharp}(Q\mathsf{G}_1 Q^{\sharp})^{-1}. \end{aligned} \tag{3.cccxlvii}$$

In particular the H inside the definition of G_1 is formed first. Replacing it by H_1 there gives a different implicit operator. Likewise Q in these formulas is not the plain derivative of $\mathcal{M}^n$, and the gauge term is not replaced by the contour soft gauge of the next step.

The next-step coarse form has the readout

$$\begin{aligned} \Delta_k &= (Q\mathsf{G}_1 Q^{\sharp})^{-1} - a - \mathsf{E}^{(2)}[\mathsf{H}_1^{\sharp}J], \\ \mathsf{A} &= \mathsf{C}_V^{\sharp}(\mathsf{G}_V^{(2)} + \Delta_k)\mathsf{C}_V, \qquad V = \mathcal{M}^k U. \end{aligned} \tag{3.cccxlviii}$$

Here C_V eliminates the actual plain-average pivots, $\mathsf{E}^{(2)}$ is that one-step plain constraint's quadratic form, and $\mathsf{G}_V^{(2)}$ is the prescribed soft contour gauge there. The last current contraction is the datum-curvature subtraction obtained when the coarse datum is itself restricted to the next-step fibre. It is not the earlier straightened $\Delta^{(2)}$.

On a physical critical pair, identifying G_1^{-1} with the actual Lagrangian Hessian plus its actual gauge and row terms makes eq. 3.cccxl–eq. 3.cccxlii the derivation of this coarse readout. If an alternative expression subtracts an additional $\mathsf{H}_1^{\sharp}DRD^{\sharp}\mathsf{H}_1$, it agrees only after that term has been shown to vanish, for example by the proved physical slice relation $RD^{\sharp}\mathsf{H}_1 = 0$. There is no corresponding automatic identity for an independent J.

Thus the precision problem contains two different tasks: prove bounds for the literal ordered family in eq. 3.cccxlvi–eq. 3.cccxlviii on its primitive independent-current domain, and identify its physical readout with the Hessian of the induced action. The latter uses the full projected-current and gauge comparison, not merely the constraint quadratic term. A proof of the first-step Wilson curved-fibre gap does not by itself perform either multilevel task.

3.11.9. *A quantitative coupled construction.* Here the primitive inverse and coefficient estimates are stated with their actual objects. This makes the existence argument a finite, checkable nonlinear reduction rather than an invocation of an unspecified implicit-function theorem.

Fix a real trial field U_0, not necessarily critical, in eq. 3.cccxxvi, with admitted constraint and slice charts. Let $Q_0 = Dq(0)$. Choose a coarse trial covector ω_0 and put

$$\begin{aligned} f_0 &= -DF(0) + Q_0^\sharp \omega_0, \qquad K_0 = D^2F(0) - \langle \omega_0, D^2q(0)\rangle, \\ \mathcal{S}_0 &= \begin{pmatrix} K_0 & -Q_0^\sharp \\ Q_0 & 0 \end{pmatrix}. \end{aligned} \tag{3.cccxlix}$$

The field is restricted to the fixed slice, and the force covectors are restricted to its dual. If the gauge kernel has not been quotiented, its gauge equation and its actual site inverse have to be included in this system. There is no inverse on an unremoved gauge kernel.

Let X, Z, Y, X^* be the declared field, multiplier, datum and force spaces with their physical weights. The primitive inverse estimate to be proved is a two-sided kernel estimate for $\mathcal{S}_0^{-1} : X^* \oplus Y \to X \oplus Z$. Its consequence used in this section is

$$\|\mathcal{S}_0^{-1}(f,b)\|_{X\oplus Z} \le C_0(\|f\|_{X^*} + \|b\|_Y), \tag{3.cccl}$$

with constants uniform over volume, depth, admissible regions, local scales and real holonomies. The precision section separates its gauge, tangent, row and seam estimates. It must also prove that the complete matrix in eq. 3.cccxlix, rather than a convenient surrogate, has this bound on the primitive trial class.

Write A for the field and $\nu = \omega - \omega_0$. Taylor's formula gives the exact equations

$$\begin{aligned} \mathcal{S}_0(A,\nu) &= \big(f_0 - R_F(A) + R_{q,\omega_0}(A) + (Dq(A) - Q_0)^\sharp \nu, \quad b - N_q(A)\big), \\ R_F(A) &= DF(A) - DF(0) - D^2F(0)A, \\ R_{q,\omega_0}(A) &= [Dq(A) - Q_0 - D^2q(0)A]^\sharp \omega_0, \\ N_q(A) &= q(A) - q(0) - Q_0 A. \end{aligned} \tag{3.ccli}$$

The right datum b here is measured from $q(0)$. The term linear in A and in ω_0 was included in K_0. Retaining it again on the right would double count the constraint curvature.

For clarity, the finite coefficient task is to verify, on the entire declared complex ball, the inequalities

$$\begin{aligned} \|R_F(A) - R_F(A')\|_{X^*} &\le c_F(r)\|A - A'\|_X, \\ \|R_{q,\omega_0}(A) - R_{q,\omega_0}(A')\|_{X^*} &\le c_{q\omega}(r)\|A - A'\|_X, \\ \|N_q(A) - N_q(A')\|_Y &\le c_q(r)\|A - A'\|_X, \\ \|(Dq(A) - Q_0)^\sharp \nu - (Dq(A') - Q_0)^\sharp \nu'\|_{X^*} &\le c_{\mathrm{mix}}(r)(\|A - A'\|_X + \|\nu - \nu'\|_Z). \end{aligned} \tag{3.ccclii}$$

Here $\|A\|_X, \|A'\|_X, \|\nu\|_Z, \|\nu'\|_Z \le r$. At a fixed finite lattice, Taylor integrals prove the inequalities with finite constants. For example

$$R_F(A) = \int_0^1 (1-t)\, D^3F(tA)[A,A]\, dt. \tag{3.ccliii}$$

The notation contracts two slots, leaving a covector. The analogous integral for $Dq - Q_0$ has one slot contracted, and that for R_{q,ω_0} has two. A uniform estimate must count the actual local coordinates in these tensors and use the force and field weights before summing. A scalar supremum bound times the total number of fine variables is not uniform in this problem.

Set $c(r) = c_F(r) + c_{q\omega}(r) + c_q(r) + c_{\mathrm{mix}}(r)$. Assume the verified inequalities give

$$C_0 c(r) \le \tfrac{1}{2}, \qquad C_0(\|f_0\|_{X^*} + \|b\|_Y) \le r/2. \tag{3.ccliv}$$

Applying $\mathcal{S}_0^{-1}$ to eq. 3.ccli defines a contraction of the closed radius-r ball into itself. Starting at zero, its successive iterates satisfy $\|x_{n+1} - x_n\| \le 2^{-n}\|x_1\|$; summing this geometric series proves convergence in $X \oplus Z$. Continuity of the map proves the equation. The same estimate on the difference of two fixed points proves uniqueness in that ball.

For two forcings whose actual maps share this ball, subtracting their fixed-point equations gives

$$\|A-\widetilde{A}\|_X+\|\nu-\widetilde{\nu}\|_Z\le 2C_0(\|f_0-\widetilde{f}_0\|_{X^*}+\|b-\widetilde{b}\|_Y) \tag{3.ccclv}$$

when their nonlinear coefficient maps agree. If those maps also change, add their evaluated difference on the common ball to the right-hand side. Its smallness must be proved from the actual coefficient comparison, not from a difference of the desired solutions.

The argument permits a noncritical trial field through the explicit f_0. It does not establish that an arbitrary regular critical field lies in this ball. That additional uniqueness statement needs a preliminary slice-closeness and local regularity argument. The raw group closeness eq. 3.cccxx is one ingredient, but does not by itself give X-closeness.

3.11.9.1. Whole-ball holomorphy and reality. Assume the finite products, means, logs, slice readouts and operator inverse are admitted on the whole complex ball used in eq. 3.cccli, with a fixed margin. If the datum parameter varies over an open disc for which eq. 3.ccccliv holds uniformly, all iterates of the fixed-point map are holomorphic and converge uniformly on smaller closed discs. Cauchy's formula on each finite collection of parameter directions then passes to the limit. The solution is holomorphic and has the same bound r. This proof does not require a volume-dependent radius.

For real reference data, conjugating the equations by $A\mapsto A^*$, $\omega\mapsto\omega^*$ and $g\mapsto(g^*)^{-1}$ preserves their finite formulas. The conjugate solution solves the equation at the conjugate datum and remains in the same ball. Uniqueness proves

$$A(B^{\mathfrak{c}})=A(B)^{\mathfrak{c}},\qquad \omega(B^{\mathfrak{c}})=\omega(B)^{\mathfrak{c}},\qquad \Phi(B^{\mathfrak{c}})=\Phi(B)^{\mathfrak{c}}. \tag{3.ccclvi}$$

At real B this is the required real solution. Gauge covariance is proved in the same way, provided the gauge maps both primitive domains and their slice normalizations to one another. The uniqueness theorem then identifies the transformed solution. For a complex gauge this proviso includes its condition number and every branch inequality; algebraic covariance alone does not make the complex core gauge saturated.

3.11.10. *Local gauges can be glued without a large holonomy assumption.* We next prove the gluing calculation used by a local regularity argument. Its hypotheses are local potential and first-difference estimates on patches of fixed size. Its conclusion does not include a componentwise Laplacian estimate; that estimate has a separate elliptic role.

Let a rectangular cube have side $m\xi$, with $\eta\le\xi$, and enlarge it by a fixed collar. Cover it by overlapping patches W_a of side $C\rho\xi$, whose centers lie on a rectangular grid of spacing comparable to $\rho\xi$. Here ρ is fixed. Assume bounded overlap and a partition of unity with

$$\sum_a\chi_a=1,\qquad \chi_a\ge 0,\qquad |\nabla^r\chi_a|\le C_r\xi^{-r}\quad (r=1,2). \tag{3.ccclvii}$$

Such a partition is obtained by sampling fixed smooth tensor bumps and dividing by their positive sum. The finite-difference product formula, or the mean value theorem applied to the smooth bumps, proves the bounds uniformly in η.

Suppose the real field has $|\partial U-1|\le\epsilon\eta^2\xi^{-2}$ and on each W_a there is a real unitary gauge k_a in which

$$U^{k_a}=e^{i\eta A_a},\qquad \xi|A_a|+\xi^2|\nabla A_a|\le C\epsilon. \tag{3.ccclviii}$$

On the real cubes used below, the elliptic section construction supplies eq. 3.ccclviii from curvature and full-current bounds. The actual current transforms by conjugation and can be carried along in the patch comparison.

We first align the constant frames. Choose a corner of the large rectangular lift as root. For each center y_a, choose the coordinate-order path from the root to y_a, and multiply k_a by the constant

$$c_a=U(\Gamma_{\mathrm{root},y_a})\,k_a(y_a)^{-1},\qquad \widehat{k}_a=c_ak_a. \tag{3.ccclix}$$

This does not change either norm in eq. 3.ccclviii, since it conjugates A_a by a constant unitary matrix. If $x\in W_a$, the transport of the locally gauged field from y_a to x along a path of length

$O(\rho\xi)$ differs from one by $C\epsilon$. The unitary product bound proves this by summing $\eta|A_a|$ on that path. Therefore $\widehat{k}_a(x)$ differs by $C\epsilon$ from the original transport along the root path followed by that local path.

For overlapping W_a, W_b, those two rooted paths differ by a strip, not an arbitrary surface spanning the whole large cube. To verify this, change their center coordinates one at a time. The difference between the centers is $O(\rho\xi)$ in each coordinate. Commuting this short displacement through the four ordered root segments sweeps at most $Cm\rho\xi^2$ area. The extra local paths sweep only $C\rho^2\xi^2$. The lattice interchange proof of eq. 3.cccxv, now counting fine plaquettes in these strips, gives

$$|\widehat{k}_a(x)\widehat{k}_b(x)^{-1} - 1| \le C_\rho m\epsilon \quad (x \in W_a \cap W_b). \tag{3.ccclx}$$

The estimate is valid on the rectangular lift that contains those paths. A periodic cube wider than half the torus is excluded from this local assertion. No global Wilson line was replaced by one; the possibly large root transports cancel in a comparison loop and conjugate its plaquettes unitarily.

The transition also has controlled derivatives. Put $r_{ab} = \widehat{k}_a\widehat{k}_b^{-1}$. For an oriented fine bond, covariance of U says

$$r_{ab}(x + \eta e_\nu) = e^{-i\eta\widehat{A}_{a,\nu}(x)} r_{ab}(x) e^{i\eta\widehat{A}_{b,\nu}(x)}. \tag{3.ccclxi}$$

Subtract $r_{ab}(x)$ and divide by η. Unitarity and eq. 3.ccclviii give $|\nabla r_{ab}| \le C\epsilon/\xi$. Taking another difference of this exact formula uses only $\nabla A_a, \nabla A_b, \nabla r_{ab}$. The derivative bound for the exponential on a fixed small raw ball gives

$$|\nabla r_{ab}| \le C\epsilon\xi^{-1}, \qquad |\nabla^2 r_{ab}| \le C(\epsilon + \epsilon^2)\xi^{-2}. \tag{3.ccclxii}$$

This proves the two derivative bounds without differentiating the long root paths.

Form $X(x) = \sum_a \chi_a(x)\widehat{k}_a(x)$. A real linear combination of SU(2) matrices is a quaternionic matrix. Its determinant is the squared Euclidean norm of its four real quaternion coordinates, so, when it is nonzero,

$$\mathcal{N}(X) = X/\sqrt{\det X} \in \mathrm{SU}(2). \tag{3.ccclxiii}$$

At a point select any active anchor a_0, and write $X = Y\widehat{k}_{a_0}$, where $Y = \sum_a \chi_a r_{aa_0}$. eq. 3.ccclx gives $\|Y - 1\| \le C_\rho m\epsilon$. If this is less than a sufficiently small fixed number, then $\det Y$ stays in a neighborhood of one not meeting zero. Thus $\mathcal{N}(X)$ is defined, independently of the selected anchor, and

$$k = \mathcal{N}(X) = \mathcal{N}(Y)\widehat{k}_{a_0}, \qquad |\mathcal{N}(Y) - 1| + \xi|\nabla\mathcal{N}(Y)| + \xi^2|\nabla^2\mathcal{N}(Y)| \le C_\rho m\epsilon. \tag{3.ccclxiv}$$

The derivative estimates follow from eq. 3.ccclvii, eq. 3.ccclx–eq. 3.ccclxii and the uniformly bounded first two derivatives of $Y \mapsto Y/\sqrt{\det Y}$ near one. When taking differences one keeps the anchor on a neighborhood containing those differences; the bounded enlarged overlap makes this possible. The resulting k itself does not depend on that choice.

In the anchor frame, U^k is

$$\mathcal{N}(Y)(x)\, e^{i\eta\widehat{A}_{a_0}(b)} \mathcal{N}(Y)(x + \eta e_\nu)^{-1}. \tag{3.ccclxv}$$

The relative endpoint product is $1 + O(\eta m\epsilon/\xi)$. The admitted small logarithm therefore defines A. Taking one difference, using eq. 3.ccclxiv, gives

$$U^k = e^{i\eta A}, \qquad \xi|A| + \xi^2|\nabla A| \le C_\rho m\epsilon. \tag{3.ccclxvi}$$

These bounds can be verified directly by differentiating the logarithm on its small fixed raw ball: the endpoint increment divided by η is $O(m\epsilon/\xi)$; its first difference is $O(m\epsilon/\xi^2)$. All remainders have an extra factor $\eta m\epsilon/\xi \le m\epsilon$, which is small. If $\xi^3|J_A(U)| \le \epsilon$, the same bound holds after k, since the current is conjugated at its fine endpoint. In particular no factor m is needed for that covariant current bound.

The normalization has an admitted holomorphic version. If the local gauges depend holomorphically on parameters and their anchored Y's remain in the same small complex neighborhood of one,

the branch of $\sqrt{\det Y}$ is the principal branch there. The formula is holomorphic and the relative normalizations agree on overlaps by the exact identity $\det \widehat{k}_a = 1$. For real gauges it is the positive square root. No absolute value of a complex determinant occurs.

The overlap argument gives the potential, first difference and covariant current bounds. For the componentwise Laplacian of this particular patched potential one would need a further estimate. The real cubes in the layered profile instead use the single gauge constructed below. Given the componentwise Laplacian bound, the discrete interior estimates give

$$[\nabla A]_{\alpha;\square} \le C_{\alpha,\rho} m\epsilon\, \xi^{-2-\alpha}, \qquad 0 < \alpha < 1. \tag{3.ccclxvii}$$

Here the input is the bounded potential and componentwise Laplacian on the larger cube, with their displayed physical scales. The constant may diverge as $\alpha \uparrow 1$. Thus this Hölder conclusion follows from those two bounds.

3.11.10.1. A single real gauge with second-order bounds. Work first in units of the cube scale, with bare spacing $\eta \le 1/13$. On a lifted box of side $s \ge 5$, assume $|\partial U - 1| \le \alpha\eta^2$ on its plaquettes and $|D_U^{\mathsf{T}} \partial U| \le \alpha\eta^2$ at its full bonds. Put $e = s\alpha$ and take it below a fixed small constant. The comb section ϕ_0 is unitary. Comparing the two comb paths at the endpoints of a bond inserts at most $3s/\eta$ plaquettes, so $\|D_0\phi_0\|_\infty \le 3e$. Here D_0 is the covariant difference of a section, formed only on bonds of the box. Smooth ϕ_0 by solving

$$(D_0^* D_0 + 1)\phi = \phi_0, \qquad \psi = D_0\phi.$$

The operator is positive and invertible in the real quaternionic space. At a site of maximum section norm the inner product of $D_0^* D_0 \phi$ with ϕ is nonnegative, by unitarity of each transport. It follows that $\|\phi\|_\infty \le 1$.

Differentiate the equation. Moving a transported difference past a perpendicular one inserts the corresponding plaquette holonomy. In the equation for ψ_μ the difference of the opposite plaquette contributions gives the covariant plaquette divergence. The remaining commutators have one curvature factor and one first difference of ϕ. At a missing perpendicular neighbor there is also an unpaired plaquette contribution of size $5\alpha/\eta$. More precisely, with $\Sigma = \|\psi\|_\infty$, the modulus is a subsolution of

$$(\mathsf{L}_{0,\mu} + 1)|\psi_\mu|(x) \le \|D_0\phi_0\|_\infty + 2\alpha + 12\alpha\Sigma + 5\alpha\eta^{-1} n_\mu(x),$$

where n_μ counts the missing perpendicular neighbors. The scalar bond Laplacian $\mathsf{L}_{0,\mu}$ uses only the available perpendicular neighbors and zero extension along direction μ. This inequality follows by taking the inner product with the unit direction of ψ_μ, using unitarity on the transported terms. At a zero the scalar left-hand side is nonpositive. To pay the boundary term, for each perpendicular direction take the one-dimensional function on N sites

$$\beta(l) = \frac{\cosh(\kappa\eta(l - (N-1)/2))}{\sinh(\kappa\eta N/2)}, \qquad 2\sinh(\kappa\eta/2) = \eta.$$

It is bounded by two, solves the massive homogeneous difference equation in the interior and gives η^{-1} at each endpoint with the absent neighbor omitted. The sum of the perpendicular barriers is a supersolution for $\eta^{-1} n_\mu$, because the zero extension in direction μ adds a nonnegative term. Scalar comparison yields $\Sigma \le \|D_0\phi_0\|_\infty + 32\alpha + 12\alpha\Sigma$. In particular $\Sigma \le 19e$ for the admitted smallness.

In the comb frame, $\phi_0^{-1}(\phi - \phi_0)$ is the flat divergence of $\phi_0^{-1}\psi$, up to an error of size $4\|D_0\phi_0\|_\infty\Sigma$. Average on a subbox of unit side up to one mesh spacing. The divergence telescopes in each coordinate, so its mean is at most 8Σ. Across one bond the section difference changes by at most $\eta(\Sigma + \|D_0\phi_0\|_\infty)$. Comparing the mean with the value at an included site gives

$$\|\phi - \phi_0\|_\infty \le 12\Sigma + 4\|D_0\phi_0\|_\infty + 4\|D_0\phi_0\|_\infty\Sigma.$$

Thus $\rho_\phi = |\phi| \ge 1/2$ and $u = \phi/\rho_\phi$ is a real gauge. On the bond $b = (x, x + \eta e_\mu)$ put $\omega_\mu(x) = \rho_\phi(x)^{-1} u(x)^{-1} \psi_\mu(x)$. The transformed link is $(1 + \eta\omega_\mu)/|1 + \eta\omega_\mu|$. In the interior the product rule

in the differentiated section equation gives

$$|\Delta_\eta \omega_\mu(x)| \le 102e + 304e \max_{x' \sim x} \eta^{-1} |\omega_\mu(x') - \omega_\mu(x)|.$$

Indeed the transported Laplacian of ψ is bounded by $\Sigma + \|D_0\phi_0\|_\infty + 2\alpha + 12\alpha\Sigma$ there. The derivative of the normalizing section contributes one term bounded by $|\phi - \phi_0||\omega|$ and an edge sum bounded by $8\Sigma \max_{x' \sim x} |\omega(x') - \omega(x)|/\eta$ before division by ρ_ϕ. To absorb the first-order term, maximize the size of a first difference multiplied by the smaller of one and the distance to the boundary. When this distance is at most 64η, use the sup bound for ω. Otherwise use the interior gradient estimate in a cube of radius one quarter of the weighted distance. The distances there and on the neighboring stencil are at least half the maximizing distance. If H is the maximum, the gradient estimate gives $H \le Ce + CeH$. Decrease the ceiling for e to absorb the last term. At distance at least one this gives $|\nabla\omega| \le Ce$, and the equation bounds $|\Delta_\eta\omega|$ on the next interior stencil by Ce.

Take the small logarithm of the normalized link, divided by $i\eta$, to obtain A. Its first difference is controlled by $\nabla\omega$, and the Laplacian has one additional chain-rule term bounded by $C\eta|\nabla\omega|^2$. The flat curl divergence is obtained separately. Expand the four factors of a plaquette to first order and take the transported differences of the three opposite plaquette pairs of a full bond. The transported linear parts give $\partial^\sharp \partial A$ up to products of A and its first differences. In the nonlinear parts the difference of opposite remainders is bounded by $CA_0A_1\eta^3$, and transport of a quadratic remainder costs $CA_0^3\eta^3$. Here A_0, A_1 are stencil suprema of $|A|, |\nabla A|$. The resulting bound is

$$|\partial^\sharp \partial A|(b) \le \eta^{-2} |(D_U^{\mathsf{T}} \partial U)(b)| + C(A_0A_1 + A_0^3).$$

Both second-order bounds are therefore Ce on the prescribed interior. This supplies the real gauge in eq. 3.ccclviii with the full current hypothesis.

3.11.10.2. The cubes used in the layered profile. Let the target cube have side $2m'\xi_j$, with m' a multiple of the separation radius ρ. Its concentric enlargement of side $(2m' + 4\rho)\xi_j$ lies in Ω_j and is shorter than half the torus. Suppose the curvature and full-current radii on elements meeting that enlargement are at most ϵ. In level-j units the radius bound gives $|\partial U - 1| \le \epsilon\eta^2$ and $|J(U)| \le \epsilon$. Writing $\partial U(p) = c(p)1 + i\eta^2 F(p)$, the scalar coefficient satisfies $1 - c(p) = |\partial U(p) - 1|^2/2$. In the transported divergence the imaginary coefficient is $i\eta^2 J(U)$. The scalar difference of each opposite pair is bounded by $\epsilon^2\eta^4/2$, so at a full bond

$$|D_U^{\mathsf{T}} \partial U| \le (\epsilon + \tfrac{3}{2}\epsilon^2)\eta^2.$$

For $j \ge 1$, use a cube of side $2m' + 2\mathfrak{r}_{\mathrm{p}}$ aligned to the $\mathfrak{r}_{\mathrm{p}}$ grid. Its left face in each coordinate is the last grid face at least four units to the left of the target. The cube then contains the full four-unit neighborhood of the target. Its further concentric enlargement by $2L\mathfrak{r}_{\mathrm{p}}$ on each side and the full plaquette stencils fit in the original 2ρ margin. These inclusions use the separation floor and $\mathfrak{r}_{\mathrm{p}} \ge 13$. Apply the real cube gauge with $\alpha = 2\epsilon$. The side of the aligned cube is at most $3m'$, so $m'\epsilon \le c$ gives all four bounds of size $Cm'\epsilon$ on that cube. At level zero the mesh is one in these units. The comb gauge already bounds the potential by $Cm'\epsilon$, and each difference in the displayed operators is a bounded stencil of these values.

For the gradient Hölder bound compare sites within distance one quarter in the scale units. Multiply the relevant component A_μ by a cutoff equal to one within distance one and supported within distance two of the first site. The cutoff and its neighbor stencils lie in the aligned cube. Write the result as $f = G'h$ for the constant-layer site inverse $G' = (\Delta + \varkappa_j Q'^* Q')^{-1}$, with Δ the positive flat Laplacian. The product rule and the four bounds give $\|h\|_\infty \le Cm'\epsilon$. The support of h meets at most 8^4 unit blocks. Apply the flat gradient Hölder bound to each supported part, using the same local gradient at both sites since the cutoff is one there and on their forward stencils. At larger distances the sup bound on the gradient suffices. Rescaling gives eq. 3.ccclxvii with $m = 2m'$. On a critical field the radius ϵ can be taken from eq. 3.ccclxxix on the entire enlargement.

3.11.11. *The site projector and the slice estimate.* Some of the gauge-slice algebra can be completed before the quantitative kernel bounds. Put $\Delta = \Delta_{\mathrm{s}}$, and suppose $G' = (\Delta + Q'^{\sharp} a Q')^{-1}$ exists, Q' is onto, and the site Gram matrix $B' = Q' G'^2 Q'^{\sharp}$ is invertible. At real data G' is symmetric. The formula in eq. 3.cccxlvi then makes R the orthogonal projection onto

$$\ker(Q'G') = \Delta \ker Q'. \tag{3.ccclxviii}$$

Indeed $G'Q'^{\sharp}(B')^{-1}Q'G'$ is the orthogonal projection onto $\mathrm{ran}(G'Q'^{\sharp})$. If $Q'\lambda = 0$, then $G'\Delta\lambda = \lambda$, so $Q'G'\Delta\lambda = 0$. Conversely Δ is injective on $\ker Q'$: if it annihilates such a λ, the invertible $\Delta + Q'^{\sharp} a Q'$ also annihilates it. The two subspaces in eq. 3.ccclxviii have the same dimension. This proves equality. On an admitted complex domain the identities remain bilinear matrix identities.

In particular

$$Q'G'R = 0, \qquad \Delta G'R = R, \qquad R\Delta G'R = R. \tag{3.ccclxix}$$

The first follows from the projector formula, and the second from $\Delta G' = 1 - Q'^{\sharp} a Q' G'$. For the actual regional sequence the site and inner-bond Laplacians satisfy $\Delta - D^{\sharp} D = \eta^{-2} n$, where $n(x)$ counts missing bare neighbors at the outer face. The separation puts these sites in the bare layer, with all their inner neighbors also in that layer. If f is supported on these sites, $G'^{-1} f$ is supported on bare tops. The site row there is evaluation, so $G'^{-1} f$ lies in $\mathrm{ran}\, Q'^{\sharp}$. Hence $Rf = 0$ and $RD^{\sharp} D = R\Delta$. Also $Q'\lambda = 0$ forces λ to vanish on the bare tops. These facts give

$$\mathsf{S}^2 = \mathsf{S}, \qquad RD^{\sharp}\mathsf{S} = 0, \qquad \mathsf{S}D\lambda = 0 \quad (Q'\lambda = 0). \tag{3.ccclxx}$$

For example the quadratic term in the square of $1 - DG'RD^{\sharp}$ reduces using $R\Delta G'R = R$. The last identity uses $\Delta\lambda \in \mathrm{ran} R$ and $G'\Delta\lambda = \lambda$. Thus S projects onto the fixed Landau slice along the infinitesimal residual gauges.

If the actual straightened rows and site readout satisfy $QD = \bar{D}Q'$, then also

$$Q\mathsf{S} = Q. \tag{3.ccclxxi}$$

This is immediate from $Q'G'R = 0$. The intertwining has to be checked with the actual outer-endpoint readout of every outward row. Scale-tagged endpoint values cannot be silently identified when they are averages at different levels. For plain rows the corresponding site readout is different even at a flat field. eq. 3.ccclxxi is therefore a consequence of the specified intertwining, not a reason to assume it.

There is a complete linear inverse for the site equation. Let E_0 be any admitted right inverse of Q'. For $f \in \mathrm{ran} R$ the unique solution of $R\Delta\lambda = f,\ Q'\lambda = b$ is

$$\lambda = G'f + (1 - G'R\Delta)E_0 b. \tag{3.ccclxxii}$$

The first constraint follows from $Q'G'R = 0$. For the other, eq. 3.ccclxix cancels the two terms $R\Delta E_0 b$. A homogeneous solution has $\lambda \in \ker Q'$ and $\Delta\lambda \in \mathrm{ran} R$, hence $\Delta\lambda = 0$, and is zero by the injectivity already proved. The formula is independent of the chosen E_0, since uniqueness identifies all choices.

For a real small field, the actual nonlinear gauge equations are the Landau condition on the logarithm of $U^g U_0^{-1}$ and the pillar-top normalization $g(y) = v_n[A](y)$ at the top of a pillar of level n. The retained seam nodes are handled by the outward factors in eq. 3.cccxliv. Their derivative consists of the site pair in eq. 3.ccclxxii, with the signs determined by the chosen infinitesimal gauge convention. The infinitesimal gauge is defined by $(d/dt)U^{e^{it\lambda}}|_0$, so the same sign is used in D, in the node derivative and in $\bar{D}$. The derivative of the node equation is the declared $Q'\lambda$, as checked from the straightening identity in eq. 3.cccxliii.

3.11.11.1. The real site correction. Use the weighted site inverse on the separated real sequence. Write $|f|_{(-2)}$ for the site sup norm with weight ξ^2. For $f \in \mathrm{ran}\, R$ and node data ν, let $\lambda(f,\nu)$ be the solution of $R\Delta\lambda = f$, $Q'\lambda = \nu$ given by eq. 3.ccclxxii. In the regional norms this solution and R satisfy

$$\|\lambda(f,\nu)\|_{Y_{\mathrm{site}}} \le C(|f|_{(-2)} + \|\nu\|_{\infty}), \qquad |Rf|_{(-2)} \le C|f|_{(-2)}.$$

The site norm includes the weighted first difference and the zero-extension Laplacian. It controls the corresponding norm $Y^{\circ}_{\mathrm{site}}$ with the inner-bond Laplacian $D^{\sharp}D$. Indeed their difference is $\eta^{-2}n$ on the bare layer, with $n \le 8$, so the comparison constant is at most nine.

Let A_0 be a preliminary real chart potential, and write A_0^w for the logarithm after applying $w = e^{i\lambda}$, with the reference U_0 kept fixed. For a top of level j the node factor of this change is $r_j = v_j[A_0^w]^{-1} w v_j[A_0]$. Let T be the node transport rotation in the straightened linearization. The nonlinear divergence and node equations use

$$D^{\sharp}A_0^w = D^{\sharp}A_0 - D^{\sharp}D\lambda + \mathcal{N}(A_0,\lambda), \qquad \mathsf{T}^{-1}\tfrac{1}{i}\log r_j = Q'\lambda + q(A_0,\lambda).$$

For the first remainder the logarithmic gauge change gives

$$|\mathcal{N}(A_0,\lambda)|_{(-2)} \le C(\|A_0\|_X + \|\lambda\|_{Y^{\circ}_{\mathrm{site}}})\|\lambda\|_{Y^{\circ}_{\mathrm{site}}}.$$

It also gives $|A_0^w - A_0|_{(-1)} \le C\|\lambda\|_{Y_{\mathrm{site}}}$. In the second remainder the straightened node derivative differs from Q' by the curvature of the reference and the variations of the averaging factors. If α_0 is the reference radius, the resulting bound is

$$\|q(A_0,\lambda)\|_{\infty} \le C(\alpha_0 + |A_0|_{(-1)} + \|\lambda\|_{Y_{\mathrm{site}}})\|\lambda\|_{Y_{\mathrm{site}}}.$$

The factor at a bare top is exactly w, so the node remainder there vanishes. These bounds use the logarithms on the full admitted ball and the literal recursive node factors.

Prescribe $r_j = \mathsf{r}$ on the corresponding tops and put $\nu_* = \mathsf{T}^{-1}(\log \mathsf{r})/i$. Let $m_0 = |D^{\sharp}A_0|_{(-2)} + \|\mathsf{r} - 1\|_{\infty}$. On the closed real ball of radius $C_0 m_0$ in the pair (f,ν), use the map

$$(f,\nu) \longmapsto \big(R[D^{\sharp}A_0 + \mathcal{N}(A_0,\lambda(f,\nu))], \nu_* - q(A_0,\lambda(f,\nu))\big).$$

Choose C_0 first to pay for the two linear forcing terms. Then decrease the ceiling for $\alpha_0, \|A_0\|_X$ and $\|\mathsf{r}-1\|_{\infty}$ so the remainders are at most half the ball radius. The continuous map sends the ball into itself, so the finite-dimensional fixed point gives the real correction. Use $RD^{\sharp}D = R\Delta$ to get $RD^{\sharp}A_0^w = 0$, and the second equation gives the prescribed top factors. The two estimates are $\|\lambda\|_{Y_{\mathrm{site}}} \le Cm_0$ and $|A_0^w - A_0|_{(-1)} \le Cm_0$. When $m_0 = 0$ take $\lambda = 0$. The construction specifies top factors. The retained seam factors follow from the row equations.

The a priori improvement in that slice is a different statement. It concerns *any* two regular configurations $U_0, e^{i\eta A}U_0$ already in the slice and with $\|\mathsf{L}A\|_{\infty}$ below a fixed admitted ceiling. Its target is

$$\|A\|_X + \|\mathsf{L}^3 D^{\sharp}DA\|_{\infty} \le B_1(\epsilon_0 + \|q^{\mathrm{st}}(A)\|_{\infty}), \tag{3.ccclxxiii}$$

where B_1 is independent of the depth and does not depend on the larger preliminary constant used to put A under the ceiling. No criticality of these two configurations is assumed. The currents of both configurations control the covariant second-order forcing. For the nonlinear group formula the forcing must be computed with the reference logarithmic differential eq. 3.cccxxxi.

Put $a_2 = \|\mathsf{L}A\|_{\infty}$, and let α_0 be the common regularity bound of the two configurations, in the normalization of the slice. Write β_0 for the maximum of the logarithmic row coordinates $|a_0(A)|$ on interior level-zero rows, and β_1 for the corresponding maximum of $|a_j(A)|$ on all interior and outward rows. Write $|f|_{(-3)} = \|\mathsf{L}^3 f\|_{\infty}$ for the bond norm. On a full bond the Wilson currents at the two configurations and the Taylor comparison of the logarithmic action bound the linear second difference by $3\alpha_0 + C_L a_2\|A\|_X$ in this norm. At an inner bond that is not full, every bond of its inner plaquettes is a level-zero interior bond. There $a_0(A)(c) = \eta A(c)$, so the stencil gives the separate bound $24\beta_0$. Thus, with $J' = D^{\sharp}DA$,

$$|J'|_{(-3)} \le \max\{3\alpha_0 + C_L a_2\|A\|_X, 24\beta_0\}.$$

In the real slice $RD^{\sharp}A = 0$. Straightening the proper rows gives $QA = \widehat{a} - C^{+}(A)$, where $\widehat{a}$ is the conjugated row coordinate, with the same norm, and $\|C^{+}(A)\|_{\infty} \le C_L(\alpha_0 + a_2)a_2$. For data on these rows, extended by zero to all other rows, $|Q^{*}\omega|_{(-3)} \le 2(1 + L^{-3})\|\omega\|_{\infty}$. Indeed the finer

row that could read a bond in the next layer would be inward, so it is absent. The same-layer and next-coarser row counts give the two displayed weights.

Use the actual inverse G_0 of the regional Wilson Hessian completed by $DRD^\sharp + Q^*Q$. If Δ' is the Wilson Hessian minus $D^\sharp D$, the slice equation is

$$G_0^{-1}A = J' + \Delta' A + Q^*(\widehat{a} - C^+(A)), \qquad |\Delta' A|_{(-3)} \le C_L \alpha_0 a_2.$$

The weighted regional inverse bound and $a_2 \le \|A\|_X$ therefore give

$$\|A\|_X \le C_1(\alpha_0 + \beta_0 + \beta_1) + C_2(\alpha_0 + a_2)\|A\|_X. \tag{3.ccclxxiv}$$

For an interior row its logarithmic coordinate is the reduced datum q^{st}. At an outward row the additional seam factor is the block average at the outer end. It reads only interior rows one level below, so the group angle inequality gives $\beta_1 \le (1+\kappa_6)\|q^{\mathrm{st}}(A)\|_\infty$. In particular no bound on inward or edge rows is needed. With α_0, a_2 below a fixed ceiling for which the last coefficient is at most one half, absorption followed by the bound on J' proves eq. 3.ccclxxiii.

To reach that slice from a real regular pair, first align the mean contours level by level with the gauge equal to one on the final pillar tops. The contour comparison gives a relative link bound $C_{\mathrm{prod}}(\alpha_0 + \alpha_1)$ on the carried links at each level, where α_1 bounds the mismatch on the retained datum. Use the truncated sequences up to each level in turn. At level zero the link logarithm in this preliminary gauge has the same bound in the field norm, since the mesh is one in its units.

At ascent to level j replace the previous logarithm by $A_0 = LA^{(j-1)}$ in the new units. The products $\eta_j A_0$ and $\eta_{j-1}A^{(j-1)}$ are equal, so the old node factors are unchanged. The field norm costs at most L^2. At the old tops the correction target r is one. At the newly promoted tops the old representative uses $v_{j-1}[A_0]$ in place of $v_j[A_0]$. The correction target is the last one-step node factor $v_{j-1}[A_0]^{-1}v_j[A_0]$, with defect bounded by $C_L|A_0|_{(-1)}$ by the full block estimate. With this target the correction cancels the initial node mismatch. Its potential stays under the fixed ceiling when $C_L L^2$ times the previous field bound fits that ceiling.

The reduced proper rows now compare the two averaged data directly. The edge row is a quotient of two links, so the mismatch there costs at most twice the link bound. At intermediate levels use the preliminary bound $C_{\mathrm{prod}}(\alpha_0 + \alpha_1)$. At the final level use α_1 on the actual retained rows: the preliminary gauge fixes interior and outward endpoints and cancels at the common seam node of an edge row. Then eq. 3.ccclxxiii resets the norm at every ascent to a fixed multiple of $\alpha_0 + \alpha_1$. At the final seam the remaining node factor is fixed by its inward-link equation, with the retained endpoint and the appropriate orientation. In particular, when the retained data are the same and the coupled system identifies $A = 0$, the normalized gauge fixes the tops and that link equation fixes every retained seam node. This yields the residual orbit on the full retained datum.

3.11.12. *The local improvement and its weighted maximum argument.* Define the distance $d_{\mathbf{B}}$ by assigning a path the length $\int ds/\xi(s)$, where $\xi(s)$ is the local pillar scale, and taking the infimum over paths. One may equivalently use the corresponding weighted lattice path distance, with a fixed comparison constant. At a seam the adjacent scales differ by L; the comparison is made using the same convention in every kernel estimate. Test plaquettes are placed at a fixed corner or center, at bounded distance in this metric.

Let $r(x)$ be the maximum local dimensionless curvature and current radius of a regular critical field, as in eq. 3.cccv, and let $v(\tau) = |\partial \mathbf{V}(\tau) - 1|$ be its assigned datum tests. For a radius R in this metric write $r_R(x)$ for the supremum over the R-ball and $v_R(x)$ for the supremum of tests in that ball. The actual local improvement estimate to be established is

$$r(x) \le C v_R(x) + \{C\sigma^2 e^{-c\delta_*\sigma} + C\sigma^4 r_R(x)\}\, r_R(x), \qquad R \le C_R L\sigma. \tag{3.ccclxxv}$$

The constants $C, c, C_R, \delta_* > 0$ must be independent of σ, depth, volume and region shape. The patch must contain the actual determining neighborhood of its cutoff fields and rows. This is a critical-field estimate. It is not an inequality for every field with small plaquettes.

The local proof is given under the recovery of the regularity radius. It uses an auxiliary separated sequence whose positive-level members are inside the trivialized cube. Extend the local potential by zero on the auxiliary torus. Constrained variations of this extension patch to constrained variations of the original field, which is how the critical equation is obtained in the auxiliary flat slice. The current created by the extension is paid in the bare-scale norm outside the positive-level members.

The datum gauge costs one further factor of σ. The datum and preliminary slice bounds are both at most $C\sigma^2 r_R(x)$. Split the flat kernel at the inner cube, then make the same split in the multiplier equation. The central datum rows grow only linearly with distance from the observation, while the outer rows and outer differentiated fields are at distance at least $c\sigma$. The field and row remainders have two small factors in the preliminary slice. Thus the contribution of the central datum, the near remainders and the far reads to the plaquette and current estimates is bounded, respectively, by

$$Cv_R(x), \qquad C\sigma^4 r_R(x)^2, \qquad C\sigma^2 e^{-c\delta_* \sigma} r_R(x). \tag{3.ccclxxvi}$$

This calculation is on the real separated geometry with the auxiliary flat-slice and local gauge estimates. Here the distance to a tested plaquette is the minimum over its corners. When an inward row is kept one also counts the pinch tests, with distance measured to their seam node. On a determining set in force all inward rows have been removed, so only tested plaquettes remain.

We now give the entire maximum argument from eq. 3.ccclxxv. Choose σ so large that $C\sigma^2 e^{-c\delta_*\sigma} \le 1/8$. Then choose the regularity ceiling r_* so small that $C\sigma^4 r_* \le 1/8$. For $r \le r_*$, eq. 3.ccclxxv becomes

$$r(x) \le Cv_R(x) + \theta r_R(x), \qquad \theta \le \tfrac{1}{4}. \tag{3.ccclxxvii}$$

Choose $\delta > 0$ with $\theta e^{\delta R} \le 1/2$, and define

$$\widetilde{v}_\delta(x) = \sup_\tau e^{-\delta d_{\mathbf{B}}(x,\tau)} v(\tau). \tag{3.ccclxxviii}$$

The triangle inequality gives $\widetilde{v}_\delta(y) \le e^{\delta d_{\mathbf{B}}(x,y)} \widetilde{v}_\delta(x)$. In particular $v_R(x) \le e^{\delta R} \widetilde{v}_\delta(x)$.

For $s > 0$ let $M_s = \sup_x r(x)/(\widetilde{v}_\delta(x) + s)$. It is finite since $r \le r_*$. eq. 3.ccclxxvii gives

$$M_s \le Ce^{\delta R} + \theta e^{\delta R} M_s, \qquad r(x) \le 2Ce^{\delta R} \widetilde{v}_\delta(x). \tag{3.ccclxxix}$$

The second inequality follows by absorption and $s \downarrow 0$. No maximum has to be attained, so the proof works on infinite volume as well when the input radius is bounded. If the datum tests in layer q are at most $\epsilon^{(q)}$, then

$$r(x) \le C' \sup_q \epsilon^{(q)} e^{-\delta d_{\mathbf{B}}(x,\text{layer } q)}. \tag{3.ccclxxx}$$

This proves the profile assertion from the local improvement, with its exact choice order.

The unweighted estimate eq. 3.ccclxxvi closes the radius in the admitted real induction. If a provisional construction is regular below the input ceiling, its output radius is $C'\|v\|_\infty$, independently of the larger provisional constant. The conditions for applying that improvement are checked before it is used. One cannot use the smaller output radius to justify a construction already outside its input ceiling.

If $v = 0$, eq. 3.ccclxxix proves that curvature and current vanish. This alone does not identify global holonomies. If, in addition, the entire retained datum is trivial, $M_{\mathbf{B}}(U) = 1$, the separated determining rows eq. 3.cccvi imply $U = 1^g$ for $g \in \mathcal{G}_{\mathrm{res}}$, including when Ω_0 has holes or several components.

Here is the geometric argument. Extend U by one outside the inner bonds of Ω_0. A plaquette meeting its complement has no corner in Ω_1, by separation; each of its bonds is therefore either an original trivial level-zero row or an added bond with value one. The extension is flat and has trivial datum for the sequence with first member replaced by the torus. If a periodic coordinate is too short for a required pillar or double block to embed, make this local construction on a compatible periodic cover. The rows and their complete averaging reads lift with the same values. The pillar

transport rule below commutes with the deck translations, so the resulting gauge descends. On each pillar with top y, define $t(x)$ as the transport from y to x inside that pillar. Flatness makes this transport independent of the path. Also every retained average equals its straight path transport: on its complete double block a flat field is a pure gauge, and exact covariance of the actual average reduces this assertion to $\mathcal{M}^q 1 = 1$.

For a bond $b = (x, x')$ inside one pillar, flatness gives $t(x)U(b)t(x')^{-1} = 1$. For adjacent pillars of the same order, close this path with their retained interior row inside its double block; that row has transport one. Adjacent pillars of different orders have orders $q, q+1$. The seam geometry gives a retained outward row from the upper top to a site w whose level-$(q+1)$ block contains the lower top. Join w to the lower top by level-q interior rows in that block. These rows and the outward row all have transport one, and they close the path through b inside the outward row's complete double block. Thus $t(x)U(b)t(x')^{-1} = 1$ in this last case as well; no omitted inward row is used. Every node is a pillar top, so $t = 1$ at the nodes. Restricting to Ω_0 and setting $g = t^{-1}$ yields $U(b) = t(x)^{-1}t(x') = 1^g(b)$ with $g \in \mathcal{G}_{\mathrm{res}}$. The argument uses the separated determining geometry, not a topological condition imposed separately on the region.

3.11.12.1. Second-order and Hölder readouts. For a local field h, exponential decay of the inverse gives a bound on h in its declared field norm. It does not automatically give a bound on a second derivative or on the ordinary Laplacian. The actual field equation must be used. In a real local gauge the covariant Laplacian and the componentwise Laplacian differ by terms containing A, a first difference of A, and at most one difference of h. On an admitted potential ball these satisfy the local numerical comparison

$$|(L_U + \Delta_\eta)h| \le C(|A|\,|\nabla h| + (|\nabla A| + |A|^2)|h|), \qquad L_U = \sum_\nu \nabla^\sharp_{U,\nu}\nabla_{U,\nu}. \tag{3.ccclxxxi}$$

Here Δ_η is the nonpositive scalar heat generator. The signs in eq. 3.ccclxxxi are therefore a plus on its left. The estimate follows by expanding each transported difference and its transpose and using $|e^{i\eta A} - 1| \le C\eta|A|$. For the second-order coefficient difference, subtract the two endpoint potentials and use $|\nabla A|$; the remaining product has two A's. Both contributions have the displayed dimensions.

Given bounds on $h, \nabla_U h, L_U h$ and on the actual gauge coefficients, eq. 3.ccclxxxi supplies a componentwise Laplacian bound. The discrete interior theorem then gives the first-difference Hölder bound. It also supplies the coarse-mesh fallback when the number of sites in the interior ball is bounded. This removes a separate Hölder estimate from the primitive list, but not the pointwise gradient bound, the covariant Laplacian bound or the local gauge construction.

For a differentiated background at a critical pair, the slice can give the separate second-order member $D^\sharp Dh$. At a noncritical independent-current pair the actual linear equation instead controls the combinations

$$(D^\sharp D + DRD^\sharp)h, \qquad D(1-R)D^\sharp h. \tag{3.ccclxxxii}$$

Their sum has to be compared to the covariant componentwise Laplacian with the actual curvature and current terms. The critical slice identity cannot be inserted at an independent-current pair. Near the outer boundary all these claims are restricted to bonds with the required neighbors; the missing-plaquette terms of the action are separate boundary forcing.

3.11.13. *The quadratic real-to-complex reduction.* The square of the complex radius is forced by the actual plaquette product. Consider a real unitary U, a complex physical potential $A = A_{\mathrm{r}} + iA_{\mathrm{i}}$, and $U' = e^{i\eta A}U$. On a patch of scale ξ, assume

$$\xi|A| \le e_1, \qquad |\partial U - 1| + |\partial U' - 1| \le e_0\eta^2\xi^{-2}, \qquad e_0, e_1 \le c. \tag{3.ccclxxxiii}$$

Transport the four oriented increments to the starting corner of a plaquette, using the real base field. With raw increments $a_b = \eta A_b$, reversing an edge uses $a_{\bar b} = -\operatorname{Ad}(U_b^{-1})a_b$. The exact product

identity is

$$\partial U'\,\partial U^{-1} = \prod_{r=1}^{4} e^{iX_r}. \tag{3.ccclxxxiv}$$

Each X_r is an oriented a_b conjugated by the preceding real base transport. Consequently $|X_r| \le \eta e_1/\xi$. The finite product expansion gives

$$\left|\prod_{r=1}^{4} e^{iX_r} - 1 - i\sum_{r=1}^{4} X_r\right| \le C\eta^2 e_1^2 \xi^{-2}. \tag{3.ccclxxxv}$$

One can prove this without a series rearrangement: the second derivative of the product with all X_r multiplied by one scalar is bounded by $C(\sum |X_r|)^2$ on the unit disc, and the integral Taylor remainder has the same bound.

The sum of transported increments is $\eta^2 \mathrm{d}_U A$, up to the terms changing the closing base transport to the identity. Those terms are bounded by $C\eta|A|\,|\partial U - 1|$. Dividing eq. 3.ccclxxxiv–eq. 3.ccclxxxv by η^2 and using eq. 3.ccclxxxiii proves

$$\xi^2 |\mathrm{d}_U A| \le C(e_0 + e_1^2). \tag{3.ccclxxxvi}$$

Indeed the closing error is at most $Ce_0e_1\eta\xi^{-3}$, bounded by $Ce_0\xi^{-2}$ since $\eta \le \xi$. The real base transports make d_U real linear on the Hermitian Lie algebra. The same estimate therefore holds for A_{r} and A_{i} separately. Applying the product expansion again shows that the real unitary configurations $e^{i\eta A_{\mathrm{r}}}U$ and $e^{i\eta A_{\mathrm{i}}}U$ have curvature at most $C(e_0 + e_1^2)\eta^2\xi^{-2}$. This is the real comparison used by the continuation argument.

Here is the precise analytic step. Let $\mathcal{F}(z_1, z_2)$ be any one of the fixed holomorphic background readouts obtained from $e^{i\eta(z_1 A_{\mathrm{r}} + z_2 A_{\mathrm{i}})}U$, with all its determining maps and gauges admitted. Suppose

$$\|\mathcal{F}(z_1, z_2)\|_{\mathrm{sc}} \le M \quad \text{for } |z_1|, |z_2| < r_0/(2e_1), \qquad e_1 \le r_0/16. \tag{3.ccclxxxvii}$$

The subscript sc means that the output is normalized by its physical scale. It does not divide by the desired smaller target radius. A two-variable Cauchy estimate gives

$$\|\mathcal{F}(1,i) - \mathcal{F}(1,0) - i\mathcal{F}(0,1) + i\mathcal{F}(0,0)\|_{\mathrm{sc}} \le CMe_1^2/r_0^2. \tag{3.ccclxxxviii}$$

For completeness, expand on a polydisc of radius $R = r_0/(4e_1) \ge 4$. Each coefficient of total degree n is at most MR^{-n}. The displayed linear combination annihilates degrees zero and one. There are $n+1$ monomials of degree n; the sum over $n \ge 2$ is bounded by CMR^{-2}. This proves eq. 3.ccclxxxviii with no dependence on the number of lattice variables.

The three real configurations on the right of eq. 3.ccclxxxviii are treated by the real background estimate, using eq. 3.ccclxxxvi. If the actual crude analytic estimate has $M/r_0^2 \le C_{\mathrm{geom}}$, this gives

$$\|\mathcal{F}(1,i)\|_{\mathrm{sc}} \le C_{\mathrm{geom}}(e_0 + e_1^2). \tag{3.ccclxxxix}$$

Thus the hereditary complex estimate is reduced to a fixed-radius crude analytic bound and the real estimate. It is not an independent assumption of the desired improved radius. If r_0 depends on a running field normalization, its actual factor in M/r_0^2 must be retained. A bound on a shrinking disc without this ratio does not prove eq. 3.ccclxxxix. The physical and Gaussian-coordinate conversion in the domain estimates determines which radius enters that ratio.

3.11.14. *Restriction is an exact constrained-variation argument.* The iterated average has a stronger locality than an arbitrary composition of finite-range maps. A level-j row reads the two level-j endpoint blocks and their joining bonds. To prove this, proceed by induction. At one step this is its definition. At the next step, a block is the disjoint union of its L^4 subblocks. An internal contour reads only subblocks inside that block. The straight segment between corresponding points of two adjacent blocks reads subblocks in their union and their joining bonds. The lower-step locality closes the induction. The fixed local lift includes all these paths.

For a determining row these two blocks miss the next region, and they lie in the preceding region, by the seam geometry. Their diameter in $d_{\mathbf{B}}$ is bounded by a constant depending only on the fixed local geometry. The number of bare variables can be large; the bound is on the physical determining neighborhood, not on that number.

Consider two aligned separated sequences with $\Omega'_q \subset \Omega_q$, and let $\mathbf{B}'$ be the new determining set. The smaller regions give a refinement of the local top scales. An old row's value can be evaluated from the new determining values and the fixed field outside Ω'_0. Here is a terminating algorithm that proves the assertion.

Start with the averaging expression for an old row of level j. No endpoint block lies in Ω'_{j+1}, since it misses Ω_{j+1}. If the row touches Ω'_j, it is a new determining row and its value is prescribed. Its full neighborhood is inside Ω'_0 by separation when $j \geq 1$. If neither endpoint lies in Ω'_j, both endpoint blocks are entirely outside that region, by alignment. Expand its one-step formula into level-$(j-1)$ row values. Their endpoint blocks have no point in Ω'_j. A lower row touching Ω'_{j-1} is prescribed; otherwise expand it again. The index strictly decreases. At level zero the bond is either a prescribed new row or a bond of the fixed exterior.

Rows whose determining neighborhood meets the boundary of Ω'_0 cause no exception. If a level-r endpoint were in Ω'_r, the sum of the gaps below that level and the chosen $\rho \gg L$ would put its two-block neighborhood inside Ω'_0. Thus such a row is expanded until its bare exterior bonds are fixed. This proves the finite factorization

$$M_{\mathbf{B}}(U) = \mathcal{F}_{\mathbf{B},\mathbf{B}'}(M_{\mathbf{B}'}(U|_{\Omega'_0}), U|_{\text{exterior}}) \tag{3.cccxc}$$

for those rows affected by an interior variation. The function $\mathcal{F}$ is built from the actual products, means and averages just evaluated. No linearization is involved.

Let U_t be a differentiable local variation on the new fibre, and extend it by the unchanged field outside Ω'_0. The level-zero new datum fixes every boundary-layer bond: its free bonds can touch only Ω'_1, which is separated from $(\Omega'_0)^c$ by more than two bare spacings. Consequently every old plaquette changed by the variation is an inner plaquette of Ω'_0. The remaining old action terms are constant, and eq. 3.cccxc fixes every old constraint. Therefore

$$\frac{d}{dt} A_{\Omega'_0}(U_t)\Big|_0 = \frac{d}{dt} A_{\Omega_0}(\widetilde{U}_t)\Big|_0 = 0 \tag{3.cccxci}$$

whenever U is critical for the old problem. This also explains why an arbitrary cut with freely varying boundary bonds would not prove the same statement.

The new local scales are no larger than the old scales at their elements, so the normalized fine curvature bound improves. The current needs a separate boundary check, because the new action omits some old plaquettes. Write j_{old} and j_{new} for the two left-variation currents, in the physical normalization used above. If a bond has the same incident retained plaquettes in both actions, these currents agree and its new current weight improves.

Every remaining changed-current bond is within a fixed bare plaquette distance of the new boundary. The gap between Ω'_1 and $(\Omega'_0)^c$ therefore puts it in the bare boundary layer, where its new local scale is η. The left-variation formula has at most six retained plaquette contributions. Unitarity and the fixed trace normalization give

$$\eta^3 |j_{\text{new}}(b)| \leq C_\partial \max_{\substack{p \subset \Omega'_0 \\ p \ni b}} |U_p - I| \leq C_\partial \epsilon_{\text{old}}. \tag{3.cccxcii}$$

The maximum is zero when there is no retained incident plaquette. Here ϵ_{old} is the old regularity parameter; the normalized fine curvature estimate bounds each displayed bare plaquette by that parameter. This proves current regularity with a fixed boundary constant. It does not require monotonicity of the current under restriction of the action. The new datum is regular by the actual averaging estimate. On its two-block neighborhoods the smallest old scale is at least its new scale

divided by L, giving the fixed seam loss $C_L L^2$. Mixed tests are the same physical averages by the finite factorization. Let C_{res} dominate 1, C_∂, and the stated datum and seam constant $C_L L^2$. The restriction identity is asserted when $C_{\mathrm{res}}\epsilon_{\mathrm{old}}$ lies below all the corresponding regularity input ceilings of the real uniqueness theorem. Under this actual admission condition,

$$U_{\mathbf{B}'}\Big(M_{\mathbf{B}'}(U_{\mathbf{B}}(\mathbf{V})|_{\Omega_0'})\Big) = U_{\mathbf{B}}(\mathbf{V})|_{\Omega_0'} \pmod{\mathcal{G}_{\mathrm{res}}(\mathbf{B}')}. \tag{3.cccxciii}$$

This conclusion uses regular critical uniqueness, not global minimization. It is a complete reduction of the restriction identity to that theorem.

The same argument proves the background nesting used for the next step. In a depth-$(k+1)$ problem the single inner node of each last block permits an axial mean representative there. Its k-fold average on the bonds touching Ω_{k+1} is independent of the representative chosen: the gauge relating two such representatives is one at the block centers and, by their axial means, at every level-k site in the block. Covariance fixes those coarse bonds. Freeze that averaged field as the new last datum and apply eq. 3.cccxciii to the truncation. Thus the shorter background and the longer one are the same orbit on their common region. No new effective action is introduced by this identity.

3.11.15. *Collars and joined sequences.* Take $\mu \geq \max\{\rho, \mathfrak{M}, L^2\}$ to be a power of L, with $\rho \geq L^2$. A part A_a is a union of cubes of side $s_a = \mu\xi_{j_a}$ at level j_a. Write $A_a^{(-r)}$ for the result of removing r layers of these cubes, and use cube-wise meets throughout. For distances use the closed representatives of the cubes. Suppose that the four-layer region $F_a = A_a \setminus A_a^{(-4)}$ lies in the ambient layer j_a and that for $a \neq b$,

$$\mathrm{dist}_\infty(A_a^c, A_b^c) \geq 10\max(s_a, s_b).$$

Put $W = \bigsqcap_a A_a$, $W^{(-r)} = \bigsqcap_a A_a^{(-r)}$, and $Q_a = A_a \setminus A_a^{(-3)}$. If $x \in F_a$, its distance from A_a^c is at most $4s_a$, so its distance from A_b^c is at least $6s_b$. The entire s_b-cube through x is then in $A_b^{(-4)}$. In particular $Q_a \subset F_a \subset W$, and the wide collars Q_a are pairwise disjoint.

The μ-tower of A_a has $A_{a,0} = A_a$. For $0 \leq q < j_a$, take

$$A_{a,q+1} = \bigcup_{\substack{C \text{ of side } \mu\xi_{q+1},\ C\subset A_{a,q} \\ \mathrm{dist}_\infty(C, A_{a,q}^c)\geq \mu\xi_{q+1}}} C. \tag{3.cccxciv}$$

Here the indicated aligned partitions exist whenever the level-j_a partition of side s_a exists. The construction gives

$$\mathrm{dist}_\infty(A_{a,q}^c, A_{a,q+1}) \geq \mu\xi_{q+1} > \rho\xi_q. \tag{3.cccxcv}$$

At depth q, every cube of side $\mu\xi_q$ at distance at least $2\mu\xi_q$ from A_a^c lies in the tower. Indeed, let C be such a cube at depth $q+1$. Every depth-q cube meeting its open $\mu\xi_{q+1}$-neighborhood has distance at least $\mu\xi_{q+1} - \mu\xi_q \geq 2\mu\xi_q$ from A_a^c. By induction these cubes lie in $A_{a,q}$, which proves that C passes the next erosion. Thus $A_a^{(-2)}$ lies in every member of the tower of A_a up to depth j_a.

Define

$$\Theta_q^a = \begin{cases} A_{a,q}, & q \leq j_a, \\ A_a^{(-2)}, & q > j_a, \end{cases} \qquad \Omega_q^W = \Omega_q \sqcap \bigsqcap_a \Theta_q^a.$$

The sequence decreases and has first member $\Omega_0 \sqcap W$. For $q \leq j_a$ the mask is a union of ambient level-q cubes by grid refinement. For $q > j_a$, the ambient region misses F_a. Intersecting it with $A_a^{(-2)}$ therefore selects exactly those ambient cubes on the interior side of the collar. This proves alignment.

To check separation at q, first use the ambient gap for the complement of Ω_q. For a mask with $q < j_a$ use eq. 3.cccxcv. For $q \geq j_a$, the points of Ω_{q+1}^W lie in $A_a^{(-4)}$, while the complement of Θ_q^a lies at distance at most $2s_a$ from A_a^c. At $q = j_a$ this gives a gap of at least $2s_a$. At $q > j_a$ a shortest

segment from Ω_{q+1}^W to the complement of Θ_q^a crosses the surface at distance $3s_a$ from A_a^c. That surface lies in $F_a \subset \Omega_q^c$. The ambient gap then bounds the segment's length from below. The same argument applies part by part, so the joined sequence has the prescribed separation. A smaller first member can be used when Ω_1^W is a union of $\mu\xi_1$-cubes and is at distance at least $\mu\xi_1$ from $(\Omega_0 \sqcap W)^c$. In that case enlarge Ω_1^W by one layer of those cubes to obtain the collared first member. It stays inside the full first member and keeps a gap of at least $\mu\xi_1$ from its own complement to Ω_1^W.

On $W^{(-2)}$ the positive-index masks leave the ambient regions unchanged. In particular, on bonds of the joined first member with both ends in $W^{(-2)}$, the determining rows are the ambient rows. A new row of level q can arise only when an end that was in Ω_{q+1} is cut out of the new region at index $q+1$. That cut must occur in a tower with $q < j_a$, since the level-j_a boundary collar misses Ω_{j_a+1}. The removed end is at distance at most $2\mu\xi_{q+1} \le 2s_a$ from A_a^c, by the interior inclusion just proved. It lies in $A_a \setminus A_a^{(-2)}$. Its other end is within one level-q spacing and lies in Q_a. Both ends are therefore in the unique Q_a that contains the row. These are the collar rows.

The localized datum agrees with the original datum on old rows. On a new collar row it is the exact face lift of the ambient level-j_a datum:

$$V^{\mathrm{lift}}(b) = \begin{cases} 1, & b \text{ stays in one ambient } j_a\text{-block}, \\ V_{j_a}(c), & b \text{ crosses from the block of } c_- \text{ to that of } c_+. \end{cases} \tag{3.cccxcvi}$$

The orientation of a reverse bond uses the group inverse. On each successive grid the central straight route crosses a fixed coarse face once. An internal contour is one. The one-step average of this lift is therefore exactly the preceding lifted datum, by its defining exponential average. This proves constraint compatibility. The lift can concentrate curvature on its faces; it is not asserted to be a regular fine configuration. Its role is to prescribe the collar data for the localized background.

For a tested plaquette p of level q, let $\mathcal{R}(p)$ be the union of the spacing-ξ_q cubes of its corners. Its diameter is at most $2\xi_q$ in the sup distance. It is contained in W, by separation at positive levels and by the inner-bond condition at level zero. Every joined test is of one of two kinds. Either $\mathcal{R}(p) \subset W^{(-2)}$, or $\mathcal{R}(p) \subset Q_a$ for a part with $q \le j_a$. To check this, fix a. If $q \le j_a$ and some point of $\mathcal{R}(p)$ has distance at most $2s_a$ from A_a^c, the whole test lies at distance at most $2s_a + 2\xi_q < 3s_a$, hence in Q_a. If no such point exists, the test lies in $A_a^{(-2)}$. If $q > j_a$, a corner in Ω_q^W has distance at least $4s_a$ from A_a^c. When $q = j_a + 1$, the test diameter keeps the whole test at distance greater than $2s_a$. When $q > j_a + 1$, a segment to a point within distance $2s_a$ would meet $F_a \subset \Omega_{q-1}^c$ within $2\xi_q$ of the corner. The ambient gap excludes this since $\rho > 2L$.

In the interior case all determining rows used by the test are ambient rows. The holonomy, including its one-step averages on mixed rows, is the original holonomy. In the collar case the joined datum on the test is the lift from level j_a. A common row in that collar is necessarily of level j_a, so its prescribed value agrees with the lift as well. The exact one-step averaging identity for eq. 3.cccxcvi reduces a mixed test to a test of this same lift. Its holonomy is one unless the plaquette crosses two ambient faces, in which case it is the holonomy of the corresponding level-j_a plaquette of Q_a. All its ambient defining rows lie in W. Thus the joined datum is determined by the ambient rows with both ends in W. It inherits their test bound ε_1 with no increase, provided the bound is imposed on the ambient tests whose corner cubes are contained in W. The real background theorem applies to this regular datum on the joined sequence when its geometric floors and regularity radii hold. The reference field is the normalized representative of the resulting regular critical orbit.

3.11.16. *Response, collars and a common admitted path.* The source direction in a datum derivative includes the reduced-datum map. At a critical solution, differentiating eq. 3.cccxxxii gives

$$\begin{pmatrix} K & -Q^\sharp \\ Q & 0 \end{pmatrix} \begin{pmatrix} \dot{A} \\ \dot{\omega} \end{pmatrix} = \begin{pmatrix} 0 \\ Db\,\dot{B} \end{pmatrix}. \tag{3.cccxcvii}$$

No derivative of F with respect to B occurs in fixed reference coordinates. If the reference or an independent current also changes, its actual derivative is a force in the first row and a datum force in the second. The fixed-reference response calculation supplies those terms.

Assume the actual coupled inverse has weighted pointwise kernels for both columns and all declared readouts. In normalized coordinates write its field–datum entries as T_{yd}. For a point source at row c, eq. 3.cccxiv gives

$$\dot{A}(y) = \sum_d T_{yd}(Db)_{dc}e, \qquad \|\dot{A}(y)\|_{X(y)} \le Ce^{-md_{\mathbf{B}}(y,y_c)}|e|. \tag{3.cccxcviii}$$

The sum contains only $d = c$ and outward rows whose one-step outer block contains the interior row c. Its number and distance from c are bounded at fixed geometry; its length weights change by only one factor of L. The triangle inequality proves the exponential estimate from the inverse's entry bound. The same calculation applies to the multiplier and to each proved differentiated field readout.

For an extended source, the required bound is a row *sum*, not just a bound on each entry. If the normalized matrix satisfies $\sup_y \sum_c e^{md(y,y_c)}\|T_{yc}\| \le C$, then a source supported on $\mathcal{C}$ obeys

$$\|\dot{A}(y)\|_{X(y)} \le Ce^{-md_{\mathbf{B}}(y,\mathcal{C})}\|\dot{B}\|_\infty. \tag{3.cccxcix}$$

If kernels are written with cell measures, those measures are included in this Schur row sum. Mixing a measure-weighted kernel convention with unweighted point entries would give the wrong source normalization.

The current derivative must be read from the actual local Wilson current at $e^{i\eta A}U_0$, including its logarithmic differential. Its stencil contains second-order field terms. The same is true of the covariant Laplacian member. Once these readouts and the pointwise gradient have the weighted bounds, the interior theorem gives their gradient Hölder member with any fixed exponent below one. The node derivative follows from the actual differentiated node factor. Its weighted bound is another readout of the primitive operator package. The mere algebraic existence of $v_n[A]$ does not bound the product of its derivatives over many levels.

Suppose two real data sets on a joined sequence differ only on its collar rows and have been put into a common node frame. Write them there as $V_1 = e^{iB}V_0$, where $\|B\|_\infty \le C_\mu\epsilon$. The frame comparison is made by the exact finite contour reconstruction eq. 3.cccxvii–eq. 3.cccxx. At every collar it involves one ambient level and its finer tower; it must respect the recorded old edges. This is the datum alignment step. The smallness condition on ϵ depends on μ.

For this comparison, the output norm $X(y)$ uses the local scale of the joined sequence, whereas $d_{\mathbf{B}}$ is the ambient metric. Joined scales are no larger than ambient scales, so the native joined path distance dominates $d_{\mathbf{B}}$. The native weighted Schur bound therefore implies the same bound with this ambient exponential weight and unchanged joined source and output normalizations.

Take the actual path $V_t = e^{itB}V_0$. Assume it stays in the common admitted datum ball. Integrating eq. 3.cccxcix gives a field comparison whose forcing is supported only on the collar. In the ambient metric each collar point is within $C\mu$ of W^c, because the supplied collar lies in one ambient layer. Hence

$$\|f(y)\|_{X(y)} \le C_\mu\epsilon e^{-md_{\mathbf{B}}(y,W^c)}, \qquad C_\mu \le C_\mu^{(0)}e^{Cm\mu}. \tag{3.cd}$$

Indeed $d_{\mathbf{B}}(y,\mathcal{C}) \ge d_{\mathbf{B}}(y,W^c) - C\mu$; eq. 3.cccxcix and the fundamental theorem of calculus prove the assertion. The factor $C_\mu^{(0)}$ is the explicit finite alignment and path constant. It is not claimed uniform as μ tends to infinity. Where the joined and ambient scales agree, this is also an ambient output-norm bound. At a finer tower element, stronger ambient readout weights require the separate scale factors and lag or small-source estimate in eq. 3.cdxix–eq. 3.cdxxi; they are not absorbed into C_μ.

The physical comparison has the form $U|_W = (e^{i\eta f}U_W^\circ)^w$. At tops away from the collar the node identity prescribes $w = v_q[f]^{-1}$. At other points it has no specified normalization. In particular

eq. 3.cd is a bound on the comparison potential and its declared readouts, not a bound on that gauge at every fine site.

3.11.16.1. Comparison with the real joined background. Let V be a real datum with all test holonomies within ε_1 of one. Fix the collar width μ. Take the no-inward determining sets, the separation and weighted-response floors of the real background theorem, and at least 6ρ sites in each direction at the last level, with ρ taken above those floors. Decrease ε_1 so that the radii used below are admitted. Let U be a critical configuration in the regular orbit of V, and let U°_W be the normalized representative of the regular orbit of V^W. The orbit radius ε_0 obeys $B_3\varepsilon_1 \le \varepsilon_0 \le a_0$. Regularity improvement puts U at radius $\epsilon = B_3\varepsilon_1$. By eq. 3.cccxciii, $U|_{\Omega_0^W}$ is critical at its induced datum $M_{\mathbf{B}^W}(U|_{\Omega_0^W})$, which agrees with V^W on common rows. We compare the induced datum with V^W in the same node frame.

In Q_a with $j = j_a \ge 1$, each level-q average $W_q = \mathcal{M}^q U$, $0 \le q \le j$, obeys

$$\max_{p \text{ inner in } Q_a} |\partial W_q(p) - 1| \le 2\epsilon L^{2(q-j)}.$$

This is the averaging curvature bound in the ambient layer j. At $q = j$ the inner bonds of Q_a are determining rows, so $W_j = V_j$ there. With C_{lift} the constant of the finite alignment estimate eq. 3.cccxvii–eq. 3.cccxx there is a real gauge on Q_a, equal to one on level-j sites, whose level-q averages for $q < j$ differ from the lift of W_j by at most

$$2C_{\mathrm{lift}}\epsilon/(L^2-1).$$

The denominator comes from summing the smaller curvature bounds over $q < j$. The gauges on the wide collars combine with the identity elsewhere to give a gauge g on the joined first member. It leaves all common rows unchanged. Indeed, if a common row has an end in Q_a, its layer end is either in F_a, in which case the row has level j_a, or outside F_a. In the latter case the row would have length at least s_a, hence level at least $j_a + 2$ since $\mu \ge L^2$. Separation would put its end in Q_a inside Ω_{j_a+1}, which is impossible. Thus on every common row meeting a gauge support, the gauge equals one at the relevant endpoints. There are no new rows of a part of level zero.

Consequently the induced datum of $(U|_{\Omega_0^W})^g$ is $e^{iB}V^W$, with $B = 0$ away from the collar rows. For the discrepancy on a collar row use the intrinsic logarithm. Once $2C_{\mathrm{lift}}\epsilon/(L^2-1) < 1$, the logarithm is bounded by $\pi/3$ times the group discrepancy. In particular

$$\|B\|_\infty \le \frac{2\pi C_{\mathrm{lift}} B_3}{3(L^2-1)}\varepsilon_1. \tag{3.cdi}$$

Take the right-hand side below the radius r_{B} of the joined response polydisc. The line tB now lies in that polydisc. The real endpoints represent the regular critical orbits at V^W and $e^{iB}V^W$. This uses gauge covariance of restriction and uniqueness at the enlarged regularity radius of the induced datum. Let $\mathcal{H}_W$ denote the response in its normalized slice. The comparison field is $f = \mathcal{H}_W(B)$, and restoring the gauges gives

$$U|_{\Omega_0^W} = (e^{i\eta f}U^{\circ}_W)^w.$$

Outside the wide collars $g = 1$. The residual gauge fixes the nodes, so at the level-q tops there $w = v_q[U^{\circ}_W; f]^{-1}$. If all parts have level zero, $B = f = 0$ and the comparison is by a residual gauge.

Write $\mathsf{N}_x(f)$ for the maximum of the potential, first covariant difference and covariant $D^{\mathsf{T}}D$ readouts at a joined bond x, multiplied by the first, second and third powers of the joined top spacing, respectively. The point response at a collar row c with top y_c is bounded in this norm at the top y of x by $B_5 e^{-\delta_0 d_{\mathbf{B}^W}(y,y_c)}$ times the size of the row increment. Use the part of the rate $\delta_0/2$ that gives a uniform sum of row weights, as in eq. 3.cccxcix. For a collar point, the distance to W^c in the ambient metric is at most 12μ. Indeed the path to the corresponding A^c_a stays in the single layer j_a until it reaches the boundary and has bare length at most $12\mu L^{j_a}$. For a path from y to a collar row, stop the path when it first reaches the boundary of $W^{(-3)}$. Up to that point the

ambient and joined layer weights agree. The stopping point is in a wide collar, and the preceding bound and the triangle inequality therefore give

$$\inf_c d_{\mathbf{B}^W}(y, y_c) \;\geq\; d_{\mathbf{B}}(y, W^c) - 12\mu.$$

The inequality also holds if y already lies in a wide collar. Integrating the derivative of $\mathcal{H}_W(tB)$ over $0 \leq t \leq 1$, using eq. 3.cdi, gives

$$\mathsf{N}_x(f) \leq C_\mu \varepsilon_1 e^{-\delta_0 d_{\mathbf{B}}(y, W^c)/2}. \tag{3.cdii}$$

Here the row sum and the alignment constant are independent of the depth and volume, and the conversion of distances costs at most $e^{6\mu\delta_0}$.

In this gauge the difference of plaquette variables is bounded by the first covariant differences and the quadratic remainder in f. The current difference also uses $D^{\mathsf{T}}Df$. On these fixed stencils the assigned scales differ by at most one level, and changing the observation point within the stencil costs a fixed factor in the exponential. Hence the plaquette difference at p and the bare-unit current difference at a full bond b have, in addition to the right-hand side of eq. 3.cdii measured at the corner or endpoint, the factors $L^{-2\lambda^W(p)}$ and $L^{-3\lambda^W(b)}$, respectively. Here λ^W is the assigned level in the joined sequence. This last power uses $J^{\mathrm{bare}} = L^{-3i}J^{(i)}$ when the current is calculated in level-i units.

Two separated sequences which agree on W, with real data agreeing on all determining bonds with both ends in W, have the same joined datum and normalized joined background. The distance from an interior point to W^c is the same for the two sequences, since the initial part of any path up to its first exit has the same layer weights. Apply the estimate to each background against this common joined background. For plaquettes and full-bond current stencils in $W^{(-2)} \sqcap \Omega_0^W$ the assigned levels there are the ambient ones. The triangle inequality gives the comparison of the two readouts, with twice the constant, in the gauges just specified.

The real comparison supplies the endpoint estimate on these joined domains. To use it for complex retained forms, we must first admit the full and restricted histories on one domain of independent complex potentials and currents, with the actual collar substitutions and their remaining radius margins. The real datum path above varies neither an independent current nor the history's stored variables. The fixed-tower complex response also keeps its determining sequence fixed. A comparison of the complete forms on that common domain, including the error from discarded chains, is needed before transferring a positive lower bound to a retained form.

3.11.16.2. The real base of a layered domain. Let $e(x)$ be a regularity profile for a real critical configuration, so it bounds the scaled curvature and the current at full bonds based at x. Use a separated sequence with gaps greater than $8\rho L^q$ between levels q and $q+1$, and with at least 6ρ top sites in each torus direction. On a nonempty aligned localization X' of M_1L^i-cubes, intersect the sequence with the M_1-tower of X'. For each depth $p \leq i$, restriction of the critical configuration is critical at the induced datum by the restriction argument for eq. 3.cccxciii. The profile bound persists for the plaquettes and full bonds of the localized first member. Their assigned level can only decrease, and the current at those full bonds has the same incident plaquettes. A current of the restricted action at a changed stencil instead uses eq. 3.cccxcii and its bare-layer bound. If e' is the profile supremum on the localized first member, the tested plaquettes of the induced datum have defects at most $C_L e'$, by averaging on their full backward cells. Use the same datum ceiling for the tested seam holonomies if present. Take e' below the test and orbit ceilings, including $L^2 e'$ below the curvature radius of one-step averaging and $C_L e'$ below the datum radius of the tower. The same restriction then lies in the regular orbit of the induced datum. This identifies the normalized tower configuration with the restriction up to its residual gauge.

For a point of original level $\lambda(x)$, the layer of the localization is $r = \min\{\lambda(x), i\}$. A sufficient profile inequality for layer radius b_r is

$$e(x)L^{-2(\lambda(x)-i)_+} \leq b_r. \tag{3.cdiii}$$

In level-i units let $\xi = L^{-i}$ and $\xi_r = L^{r-i}$. The curvature bound on this layer is $b_r\xi^2\xi_r^{-2}$ at plaquettes in the field's domain. In converting the full-bond current from bare units, the factor L^{3i} multiplies its bound $e(x)L^{-3\lambda(x)}$. The extra suppression at $\lambda(x) > i$ has exponent three, so the same condition gives $b_r\xi_r^{-3}$. At a smaller observation level i'', the radii on layers $r < i''$ can be kept, and the new top radius can be chosen to dominate

$$\max_{i''\le r\le i} b_r L^{-2(r-i'')}.$$

This is the profile comparison for all nested subdomains whose tower grids are aligned.

The gauge clauses require a separate local estimate. For a cube of side $C_{\mathrm{g}}ML^r$ in bare units, take the profile supremum $e_\square$ on its $8\rho L^{r-1}$ neighborhood. In the nonwrapping geometry the local transport and critical background estimate supplies a real gauge with both $\xi_r|A|$ and $\xi_r^2|\nabla A|$ bounded by $C_L C_{\mathrm{g}} M e_\square$. In using it require that the profile is below the one-step curvature ceiling and that $2\mathsf{k}_L C_{\mathrm{g}} M L e_\square \le \rho a_1$, where k_L is the transport constant and a_1 the regular datum ceiling. Require also that this gauge bound fits the gauge radius of the layer. These checks, together with eq. 3.cdiii, give the real initial triple $(U, 0, J(U))$ in the layered domain with the plaquette and full-bond tests just described. If the domain also tests the restricted current at changed stencils, its bare-layer radius must allow the boundary bound above. The potential slot is zero here. Admission of the varied potential and independent current along the complex path requires the margins in the following argument.

3.11.16.3. Admission is checked for every object. The assumption on the common path can be reduced to a finite first-exit calculation. List all the actual core quantities $\mathcal{R}_\beta(t)$, their strict bounds r_β, and initial margins $s_\beta = r_\beta - \mathcal{R}_\beta(0) > 0$. Include small logarithm branches, mean Jacobians, current ceilings, gauge condition numbers, site Gram inverses, field inverses and tower clauses. If an inverse is an atomic object, its norm or its distance from singularity is one of these tests.

While the path is admitted, suppose its actual response and coefficient estimates give

$$|\mathcal{R}_\beta(t) - \mathcal{R}_\beta(0)| \le K_\beta t\,\|B\|, \qquad K_\beta\|B\| \le s_\beta/2 \quad \text{for every } \beta. \tag{3.cdiv}$$

At a proposed first exit every inequality still has half its margin. On a finite lattice the bounded coordinates have a limiting point. The branch and inverse margins extend every atomic formula there, and the uniform coupled inverse and coefficient bound extend the solution by its local contraction. This contradicts a first exit before $t = 1$. The constants must be uniform in the lattice, but compactness here is only the finite-dimensional continuation argument.

Checking only curvature in eq. 3.cdiv would not suffice. Nor does a response bound at already admitted points establish that every substitution is admitted. The actual inner substitution also includes the fluctuation, its amplified window datum, the coarse background, the cutoff, and the independent-current readout. Each has its own test in this finite list. The domain estimates give the physical/Gaussian radius conversion and the slow-radius inequalities used to verify those numerical margins.

3.11.17. *Gluing real constructions and their analytic maps.* There are two different gluing arguments. For real data, uniqueness among all regular critical orbits identifies constructions made in different neighborhoods. Applying the unique comb normalization outside the nodes identifies the representatives themselves. For complex data one uses either a common contraction neighborhood or analytic uniqueness on the relevant connected overlap.

The analytic uniqueness fact can be proved directly. If two holomorphic maps on a connected complex datum ball agree on a real open ball, their difference vanishes on a complex polydisc. Fix all coordinates but one to be real and apply the one-variable identity theorem. Then allow that coordinate to be complex and repeat with the next. This proves vanishing on the polydisc.

Continuation along a finite chain of intersecting polydiscs in the connected domain proves equality everywhere.

For maps with different real centers this argument applies to each connected component of their complex overlap that contains the required real open overlap. It does not identify an unrelated overlap component without such an argument. An alternative is to put both solutions into a single admitted reference chart and the single uniqueness ball of eq. 3.cccliv. That gives equality pointwise on the common chart, without an overlap connectedness claim. The chart transition includes its node factors and gauge, not just a difference of coarse logarithms.

Let $\mathcal{D}$ be the real admitted datum domain covered by these local constructions. It is open in the finite product of real group coordinates. Every local fixed point is continuous in its datum by the uniform contraction estimate. The comb representative is continuous on the admitted mean branches. On overlaps the representatives agree, so these give a continuous, hence Borel, real background map on $\mathcal{D}$. Equivalently choose a countable chart cover from the countable basis of this finite-dimensional manifold and use the first chart containing each point; overlap agreement makes this a Borel map.

If an integral uses this map only under a cutoff supported in $\mathcal{D}$, one can assign the identity outside $\mathcal{D}$ to obtain a Borel extension. This is only a definition outside the regular problem. It makes no claim about its fibre or criticality. Holomorphic integrals use the actual common complex domain and its parameter-independent reference measure; the Borel extension is not an analytic substitute for that domain.

3.11.17.1. Measurability of the real background tests. Fix the finite lattice, determining regions, and numerical parameters. In real matrix coordinates, G is algebraic. The intrinsic logarithm has the graph $X \in \mathfrak{g}$, $|X| < \pi$, $e^{iX} = H$; the exponential on this bounded set is restricted analytic. The finite equations defining a mean, together with the requirement that their solution be unique, therefore define its graph and its domain in $\mathbb{R}_{\mathrm{an}}$. The actual three branches of $\mathcal{M}$, its finite iterates, the determining-data map, and the prescribed axial gauge conditions are definable as well. We use closure under real quantification and cell decomposition in this structure [Edm00].

It remains to check the criticality condition, which quantifies over all differentiable curves in a fibre. Write $C_d = \{U : M_{\mathbf{B}}(U) = d\}$ and regard it as a definable subset of a finite-dimensional real matrix space. At $U \in C_d$ define the contingent cone by the finite formula

$$\begin{aligned} v \in T_d(U) \quad \Longleftrightarrow \quad & \forall \epsilon > 0 \; \forall \delta > 0 \; \exists t, z : \\ & 0 < t < \delta, \quad |z - v| < \epsilon, \quad U + tz \in C_d. \end{aligned}$$

The velocities of two-sided differentiable curves in C_d through U are exactly $T_d(U) \cap (-T_d(U))$. One inclusion follows from the difference quotients. For the converse, if $v \in T_d(U)$, then $(0, v)$ belongs to the closure of the definable set $\{(t, z) : t > 0,\ U + tz \in C_d\}$. Definable curve selection and one-variable monotonicity [Kur98, Lemma 2 and Proposition 1] give, after reparametrizing by the positive coordinate t, a differentiable curve $z(t)$ tending to v. Thus $U + tz(t)$ lies in C_d and has right derivative v at 0. If also $-v \in T_d(U)$, apply the same argument to $-v$ and reverse time on that branch. The two branches joined at U are differentiable on an open interval and have derivative v at 0.

The Wilson action has a polynomial extension in real matrix coordinates, using the conjugate transpose for inverse link variables. Hence the source criticality condition is exactly

$$\forall v \in T_d(U) \cap (-T_d(U)), \qquad DA_{\Omega_0}(U)v = 0.$$

It is therefore definable even at a singular fibre. Adding the prescribed regularity inequalities defines the relation $\mathscr{C}(d, U)$ of all regular critical configurations. The minimal-orbit domain is given by

$$\begin{aligned} & \exists U \; \mathscr{C}(d, U), \\ & \forall U_1, U_2 \quad \mathscr{C}(d, U_1) \wedge \mathscr{C}(d, U_2) \Longrightarrow \exists g \in \mathcal{G}^{\mathrm{res}}(\mathbf{B}) \quad U_2 = U_1^g. \end{aligned}$$

The residual group fixes every prescribed node, including seam nodes; it is a finite-dimensional compact algebraic group. Gauge invariance of $\mathscr{C}$ makes this formula precisely the condition that the nonempty set of regular critical configurations be one orbit.

The gauge-invariant action and plaquette readouts have definable graphs obtained by quantifying over this orbit. The prescribed representative in Ax° has a definable graph on its exact domain of existence and uniqueness. For a block axial readout on Y, retain the conditions that Y consists of nodes, that $B(Y) \setminus Y$ contains no nodes, and that the required means exist. Gauge covariance supplies a representative in this gauge; two such representatives differ by a residual gauge transformation equal to the identity on $B(Y)$. Their averaged fields therefore agree on the interior bonds used by the test. Existential quantification over these representatives defines that same single-valued readout, without choosing a different representative.

Finally, in the averaged-background problem let $\mathsf{W}_d^{\mathrm{reg}}$ be the prescribed constrained regular set, and write $a_d(w) = A_K(U_k(w))$. The preceding orbit formula and gauge invariance make both this set and this action readout definable. The graph of its unique attained minimum is exactly

$$\begin{aligned} w \in \mathsf{W}_d^{\mathrm{reg}}, \qquad & \forall z \in \mathsf{W}_d^{\mathrm{reg}}, \quad a_d(w) \le a_d(z), \\ & \forall z \in \mathsf{W}_d^{\mathrm{reg}}, \quad a_d(z) = a_d(w) \Longrightarrow z = w. \end{aligned}$$

Its projection is the exact existence set used in the definition. Cell decomposition makes these domains and their single-valued maps Borel. Consequently the real background tests, with their prescribed failure values when an object is undefined, are Borel. Existence of the required orbit and attainment of the minimum on the intended supports use the corresponding real estimates.

3.11.18. *Two finite mechanisms that prevent growth with depth.*

3.11.18.1. Eliminating the multiplier. It is unnecessary to assume an a priori small multiplier in a uniqueness statement once its actual row lift is bounded. Fix $Q_0E_0 = 1$, and write $Dq(A) = Q_0 + C'(A)$. At a critical field, eq. 3.cccxxxiii gives

$$[1 + (C'(A)E_0)^\sharp]\omega = E_0^\sharp DF(A). \tag{3.cdv}$$

If $\|(C'(A)E_0)^\sharp\|_{Z\to Z} < 1/2$, the bracket has its convergent Neumann inverse, and the multiplier is the explicit function

$$\omega(A) = [1 + (C'(A)E_0)^\sharp]^{-1} E_0^\sharp DF(A). \tag{3.cdvi}$$

The required transpose bound is a consequence of the column as well as row estimate of the actual lift, with the declared force and multiplier amplitudes. It does not follow from an unweighted supremum bound on E_0.

Suppose on a field ball $\|DF(A)\|_{X^*} \le \gamma$, $\|DF(A) - DF(A')\|_{X^*} \le C_F\|A - A'\|_X$, $\|E_0^\sharp\| \le C_E$, and the bracket's perturbation has Lipschitz constant C_N. The inverse difference identity gives

$$\begin{aligned} \|\omega(A)\|_Z &\le 2C_E\gamma, \\ \|\omega(A) - \omega(A')\|_Z &\le (2C_EC_F + 4C_E\gamma C_N)\|A - A'\|_X. \end{aligned} \tag{3.cdvii}$$

The second constant need not be small. However a field fixed-point equation reads it through the small factor $C'(A)^\sharp$. If $\|C'(A)^\sharp\| \le cr$ and its Lipschitz constant is c, then

$$\|C'(A)^\sharp\omega(A) - C'(A')^\sharp\omega(A')\|_{X^*} \le \{cr\,\mathrm{Lip}(\omega) + 2cC_E\gamma\}\|A - A'\|_X. \tag{3.cdviii}$$

The coefficient is small with $r + \gamma$. This is the field-only form of the coupled contraction. It shows why a non-small derivative of the multiplier is not an obstruction.

Alternatively suppose the two-component iteration has a Lipschitz matrix bounded by $\left(\begin{smallmatrix} \epsilon & \epsilon \\ C & \epsilon \end{smallmatrix}\right)$. In the norm $\max(\|A\|_X, \Theta^{-1}\|\omega\|_Z)$ its row sums are at most $\epsilon + \epsilon\Theta$ and $C/\Theta + \epsilon$. Choose a fixed $\Theta \ge 4C$ first, then $\epsilon(1 + \Theta) \le 1/4$. Both row sums are less than one half. The admitted multiplier radius must be at least Θ times the field radius used by this ball. These choices are made with the actual physical norms, not by suppressing the multiplier dimension in notation.

3.11.18.2. Separation certificates for the region operations. For sets, write the gap condition as $N_{\rho\xi_q}(\Omega_{q+1}) \subset \Omega_q$, where N_r is the metric neighborhood. Unions preserve it, since $N_r(\bigcup A) = \bigcup N_r(A)$. Intersections also preserve it, since $N_r(\bigcap A) \subset \bigcap N_r(A)$. Thus levelwise cube-wise unions and meets of separated aligned sequences are separated and aligned.

Enlargement and rounding spend a computable part of the gap. If the next region is enlarged by at most $a\xi_{q+1}$, its distance to the old complement decreases by at most $aL\xi_q$. Rounding to aligned $\mathfrak{M}\xi_{q+1}$ cubes adds at most $C\mathfrak{M}L\xi_q$. Hence

$$\mathrm{gap}_{\mathrm{new}}(q) \geq \{\rho - L(a + C\mathfrak{M})\}\xi_q. \tag{3.cdix}$$

An enlargement of the current region can only improve this lower bound. If the total finite list of enlargements spends at most half the initial coefficient, all resulting gaps remain at least $\rho\xi_q/2$. The list must be counted for the actual construction; repeating an unrecorded erosion arbitrarily many times is not covered by this claim.

This gives a mathematical certificate for each sequence used in the induction: its levels are unions and meets of the declared cube families, its finite enlargements have the total cost eq. 3.cdix, and the only change of local scale in a collar is the single-layer change proved in eq. 3.cccxciv–eq. 3.cccxcv. The original label sequence, the extension by the next-step domain, healed sequences, prepared sequences and stage sequences, towers, joined strip and glued regions, and cube-wise localizations all require such a certificate from their actual definitions. The history construction supplies the first cube families; the elementary closure facts above supply the geometric conclusion once that finite certificate is verified.

3.11.18.3. The two-radius datum descent. A section may lose a constant $C_\downarrow \geq 1$ on tests near its seam and be exact away from that seam. It would be incorrect to iterate the global bound $\epsilon \mapsto C_\downarrow\epsilon$. The relevant object is the finite dependency graph of tests.

At every descent stage assign an input vertex to each actual test read by the section and an output vertex to each resulting test. A good edge carries coefficient one. A bad edge carries at most $C_\downarrow$ and has its input in the seam determining collar. The finite section estimate has the form

$$t_{\mathrm{out}}(\tau) \leq \max_{\tau' \to \tau} c(\tau', \tau) t_{\mathrm{in}}(\tau'), \qquad c \in \{1, C_\downarrow\}. \tag{3.cdx}$$

A sum over finitely many local tests is absorbed in $C_\downarrow$ at the bad edge, not added at each later exact transfer.

Assume that a seam collar's full test-determining neighborhood is disjoint from the output footprints of the previously spoiled collars. This is the specific collar condition to check using eq. 3.cdix; disjoint geometric faces without their determining neighborhoods would not suffice. Then a directed dependency path meets at most one bad edge. Iterating eq. 3.cdx gives

$$t_{\mathrm{final}}(\tau) \leq \max_{\pi \text{ ending at } \tau} \prod_{e \in \pi} c(e) \, \max t_{\mathrm{initial}} \leq C_\downarrow\epsilon. \tag{3.cdxi}$$

This proves the uniform descent bound. At the input to each fresh collar the radius is still ϵ. Away from those collars the carried radius may be $C_\downarrow\epsilon$, but the next exact transfer does not multiply it.

The estimate is a complete finite graph argument. Its model inputs are the actual one-step section estimate and the collar-neighborhood certificate. A pointwise regularity estimate for a section with no record of where it loses its constant does not imply this two-radius conclusion. The same distinction is needed when sections are folded onto boxes: every reflected or translated determining neighborhood must remain in its recorded collar.

3.11.19. *Criticality through two actual averaging levels.* The induction changes the number of constraints. Its chain rule must use the induced fine action, not a fresh coarse Wilson action. Let m be the actual datum map for a truncation, let r be its next-step average, including the actual outward reduced datum, and suppose the weaker constraint is $r \circ m$. Let $\Psi(V)$ be a differentiable section with $m(\Psi(V)) = V$, critical for the fine action F on each m-fibre. Define $S(V) = F(\Psi(V))$.

Every fine tangent vector h at $\Psi(V)$ has the exact decomposition

$$h = D\Psi(V)\, Dm(h) + h_{\mathrm{vert}}, \qquad Dm(h_{\mathrm{vert}}) = 0. \tag{3.cdxii}$$

This follows by differentiating $m \circ \Psi = 1$. The derivative of F annihilates h_{vert}. Consequently

$$DF[h] = DS[Dm(h)]. \tag{3.cdxiii}$$

If $Dr\, Dm(h) = 0$ and V is critical for S on its r-fibre, this is zero. Conversely, if $\Psi(V)$ is critical on the $(r \circ m)$-fibre, test with $h = D\Psi\, v$, $Dr\, v = 0$, to see that V is critical for S. Thus

$$\Psi(V) \text{ is critical on } (r \circ m)^{-1}(r(V)) \iff V \text{ is critical for } S \text{ on } r^{-1}(r(V)). \tag{3.cdxiv}$$

In orbit coordinates, choose the admitted representatives and carry the node gauges through both maps. The residual gauge directions contribute zero by invariance. The same proof then applies to the quotient tangent vectors. Its geometric premise, $r \circ m$ equal to the desired weak constraint, is the finite averaging identity and the outward factor in eq. 3.cccxliv; it is not a formal convention about the names of the two data sets.

This supplies a precise noncircular order for constructing depth $k+1$. Assume the real backgrounds through depth k have already been constructed on their admitted domains, together with the needed actual readouts. Complete the last coarse datum to a datum for the depth-k truncation by the one-step section, leaving all earlier rows unchanged. At an outward last row its pivot crosses from an inner block to the outer block. That pivot is not an earlier kept inward row, precisely because those rows were omitted. The finite pivot chart therefore supplies a local constraint correction. Its regular-test and collar estimates are the section task in eq. 3.cccxxviii and eq. 3.cdx, not an assumption of a critical field.

The available background at the completed datum is a trial field for the weaker problem. It is already critical in its vertical directions, but need not be critical for the weak constraint. Its remaining force is the derivative of the induced action S_k on the last coarse datum. Its Hessian is the actual readout eq. 3.cccxl–eq. 3.cccxlviii. The primitive inverse and finite coefficient estimates for that readout are established on the real primitive class before solving the weaker problem. They may use the backgrounds of depths at most k; they must not use the unknown depth-$(k+1)$ critical field.

The lower background is evaluated on the admitted analytic datum neighborhood already constructed at depth k. Exploring this coarse variation does not restart the real datum descent at every point. The marked two-radius class is needed to construct its real center; the actual whole-disc continuation and its fixed margins control the subsequent coarse variation.

Apply the one-step coupled construction to S_k and its actual plain constraint chart, with its prescribed soft gauge. The soft gauge has to be removed or identified by the actual gauge equation on the physical solution; its mere positivity does not make a critical point of the soft action critical for S_k. Once that identity is proved, eq. 3.cdxiv makes the lifted fine field critical for the desired depth-$(k+1)$ problem.

Suppose its provisional regular radius is $C_{\mathrm{up}}C_{\downarrow}\epsilon$. All constants here are the fixed section, inverse and coefficient constants, independent of k. Require

$$C_{\mathrm{up}}C_{\downarrow}\epsilon < r_*, \qquad C_{\mathrm{prof}}\epsilon < r_{\mathrm{induct}}, \tag{3.cdxv}$$

where r_* is the input ceiling of eq. 3.ccclxxv, and r_{induct} is the radius promised to the next induction step. The profile estimate then resets the output to $C_{\mathrm{prof}}\epsilon$. The two-radius datum certificate prevents $C_{\downarrow}$ from compounding during the completion. This proves closure of the radius induction from its listed estimates.

At depth zero all the fine bonds are datum: there are no free fibre directions. The finite plaquette derivative gives $\xi_0^3|J_A| \le C \sup|\partial V - 1|$, because a bond meets at most six inner plaquettes and $\xi_0 = \eta$. This is the base regularity assertion. The first nontrivial constraint chart and physical

background step are the finite results already proved. They realize those instances of the induction, not the uniform multilevel estimates that its later steps require.

3.11.19.1. Uniqueness among regular orbits. Take two regular critical fields for the same datum. Put the first in the reference role. The preliminary contour alignment and eq. 3.cccxx give a raw closeness below the fixed gauge ceiling after choosing the common regularity radius small enough. The actual site correction puts the second field in the reference slice. Its a priori estimate in eq. 3.ccclxxiii gives $\|A\|_X \le B_1\epsilon$, independent of the preliminary constants. Both configurations then lie in the single uniqueness ball of the coupled construction.

There is no independent multiplier hypothesis: eq. 3.cdvi–eq. 3.cdvii bound the multiplier from the actual current and row lift. Thus the two solutions of eq. 3.cccxxxii, with the same reduced datum, are equal in that slice. Their relating gauge is one at the nodes by the node normalization. They belong to one residual orbit. On the admitted real regional sequence the site correction and eq. 3.ccclxxiii give the field in the ball used here. The uniqueness assertion also uses the admitted coupled system for the full set of retained rows.

3.11.20. *Why the physical soft gauge disappears from stationarity.* There is an exact local argument for the gauge step used in the physical construction. Let $S(V)$ be a gauge-invariant coarse action and fix its plain one-step averages. Assume each interior block has no prescribed node except its center. For each noncenter x let $T_{y,x}(V)$ be the admitted mean transport from its center. Let $T^0_{y,x}$ be a fixed reference transport, and put

$$G_{\mathrm{soft}}(V) = \sum_{y,x\neq y} \kappa_{y,x}\left(1 - \tfrac{1}{2}\,\mathrm{tr}[T_{y,x}(V)(T^0_{y,x})^{-1}]\right), \qquad \kappa_{y,x} > 0. \tag{3.cdxvi}$$

The coefficients are fixed on the variation under consideration. The absolute gauge is the case $T^0_{y,x} = 1$. All transports and reference ratios lie on the regular branch near the identity.

A gauge h equal to one at the block centers preserves the plain average by covariance. Vary only $h(x) = e^{itH}$ at one noncenter site. Every other mean transport is unchanged, and $T_{y,x}$ changes to $T_{y,x}e^{-itH}$. Gauge invariance gives no derivative of S. If $S + G_{\mathrm{soft}}$ is critical on this fibre,

$$\mathrm{tr}[(T^0_{y,x})^{-1}T_{y,x}H] = 0 \quad \text{for all traceless } H. \tag{3.cdxvii}$$

The orthogonal complement of the traceless 2 by 2 matrices under the trace pairing is the scalar matrices. The determinant is one, so $(T^0)^{-1}T$ equals 1 or -1. The admitted branch excludes -1. Thus

$$T_{y,x}(V) = T^0_{y,x} \quad \text{at every such site.} \tag{3.cdxviii}$$

At these values the differential of G_{soft} is zero for every field variation, not only a gauge variation: the derivative of the trace at the identity annihilates the traceless tangent. Consequently the critical point is critical for S on the fibre.

Conversely a physical critical point in this prescribed transport gauge is critical for $S + G_{\mathrm{soft}}$. The proof holds for real unitary fields and on an admitted complex branch using the bilinear holomorphic derivative. The positive real coefficient may be replaced in the complex statement by an admitted nonzero coefficient.

This argument explains all its scope requirements. A retained seam node cannot be varied, so eq. 3.cdxvii need not hold there. The no-inward geometry removes that obstruction. A sharp regular-box cutoff must be constant on the stationary neighborhood; otherwise its derivative is an extra term. An independent-current auxiliary action containing linear source subtractions is not the gauge-invariant physical S in this argument. Its physical matching must first identify the action and gauge terms. Finally the choice of relative or absolute gauge still matters off the axial locus, as eq. 3.cccxxxvi–eq. 3.cccxxxvii show.

3.11.21. *Ambient towers and their scale factors.* The tower of a localized field may sit inside a deeper separated sequence. At an element write l for the ambient scale and $\xi' \le l$ for the tower scale. The natural tower curvature and current readouts are multiplied by the same squared scale ratio:

$$\left(\frac{l}{\xi'}\right)^2 (\eta^{-2}\xi'^2|\partial U - 1|, \xi'^3|J|) = (\eta^{-2}l^2|\partial U - 1|, l^2\xi'|J|). \tag{3.cdxix}$$

The current factor is $l^2\xi'$, not l^3. This is the two-power improvement asserted by the tower estimate, not the three-power dimensional weight of a fully ambient current. Under a unit change by t, η, l, ξ' multiply by t, A by t^{-1}, and J by t^{-3}. Both entries of eq. 3.cdxix are invariant. This calculation fixes the weights in a joined sequence independently of an index convention.

The ambient estimate is proved in Prop. 3.138 for every fixed pair of contained separated sequences. At a settled element write $s(x) = l(x)/\xi'(x)$. The near input is cut off on a ball of radius $l(x)$; its weighted tower norm gains $s(x)^{-1}$, so the quadratic Cauchy remainder pays the factor $s(x)^2$. For a far input bond b, the actual geometry gives

$$d'(x, x_b) \ge d^\flat(x, x_b), \qquad s(x) \le 1 + d'(x, x_b), \qquad \frac{s(x)}{s(x_b)} \le L^{2+2d'(x,x_b)/\rho}. \tag{3.cdxx}$$

The complete row read has bounded diameter in d', and its raw logarithmic derivative contributes $s(x_b)^{-1}$. Thus, with $D = d'(x, x_b)$ and the fixed rate reserve,

$$s(x)^2 e^{-md'(x,y_c)} s(x_b)^{-1} \le C(1 + D)e^{-(m-2\log L/\rho)D} \le Ce^{-2\delta D}. \tag{3.cdxxi}$$

This is the far-input estimate; a positive distance gain is not needed for the near input. The physical current follows from the differentiated constrained Euler equation, with all six plaquettes and the actual row-transpose densities retained. The output weights are precisely eq. 3.cdxix. The real reference, determining tower and ambient sequence remain fixed in the comparison. Constants are uniform over those geometries. The smaller rate in Prop. 3.138 includes the scale-ratio and carrier losses. Fixed higher derivatives follow on smaller analytic domains with their own Cauchy constants.

3.11.21.1. Outer and inner substitutions. For an outer substitution $\mathbf{U} \mapsto e^{i\eta\mathbf{A}}\mathbf{U}$, the finite product formula gives, in normalized first-order norms,

$$e_{0,\mathrm{new}} \le C(e_{0,\mathrm{old}} + \|\mathbf{A}\|_1 + \|\mathbf{A}\|_1^2), \qquad e_{1,\mathrm{new}} \le e_{1,\mathrm{old}} + C\|\mathbf{A}\|_1. \tag{3.cdxxii}$$

Here $\|\mathbf{A}\|_1$ uses the local length and derivative factors, and e_0 includes all actual tower curvature readouts. For a tower entry the same inequality uses its applicable admitted readout estimate: the settled estimate at a settled element and the boundary estimate otherwise. It does not follow merely from the elementary plaquette formula. Current and atomic branch tests have their own finite Lipschitz estimates. If the old tests use half the target radii, the inequalities $\alpha_0 \le \alpha_1$, $\alpha_1^2 \le C\alpha_0$, and $\|\mathbf{A}\|_1 \le c\alpha_0$ leave the needed margin once c is chosen from these actual constants.

For the inner substitution, the datum is the actual window expression $\varsigma B + B'$, $0 \le \varsigma \le 1$. The first term comes from the averages of the sum of the coarse background and the fluctuation in the specified order of multiplication. The second is its boundary correction. It is not an independent scalar source. The entire nonlinear datum must first be placed in its absolute physical disc. The free response and its amplification are then applied, with the current computed from the same composed field.

The numerical age reduction can be stated without suppressing its source of smallness. Write $\delta_n = \alpha_n s_n$ for the final physical fluctuation amplitude, $\rho_j = \delta_n/\alpha_j$, $a = n - j$, and now $\sigma = L^{-a}$. The ordinary slow-radius estimate is $\alpha_n/\alpha_j \le C\sqrt{1 + a}$. The independent-coordinate datum radius satisfies $\alpha_j/r_{B,j} \le C$ on the actual near window class. If the actual fluctuation amplitude and

window response obey

$$\frac{\delta_n}{r_{B,j}} \le C\rho_j, \qquad \frac{C_{\mathrm{ax}}\delta_n\sigma}{r_{B,j}} \le Cs_n\sqrt{1+a}\,L^{-a}, \qquad a = n-j \ge 0, \tag{3.cdxxiii}$$

then the second quantity is uniformly small at all ages by choosing the common small fluctuation constant first. Indeed $\sup_{a\ge 0}\sqrt{1+a}L^{-a} < \infty$. Young ages cause no exception once that constant is chosen with the actual response and radius factors.

This verifies the central datum-disc margin. The full datum also needs the separate absolute ceiling eq. 4.xxx. To infer that the complete inner substitution belongs to every running core, the actual local window map must put its background-plus- fluctuation pair in the primitive class, including the entire outgoing physical amplitude, its gradient, the independent current, the tower and the atomic branch tests. An increment bound alone does not control that outgoing amplitude. The first-exit list eq. 3.cdiv and the domain estimates isolate those remaining finite inequalities.

3.11.22. *A real one-step section at a seam.* The finite section used in the descent can be made explicit. Work for this paragraph on the level-k lattice, so a new block contains L^4 sites. The old level-k data are prescribed outside the next region and on its exterior bonds; the newly prescribed data are on the level-$(k+1)$ rows touching the next region. Assume all ordinary and mixed plaquette tests are at most ϵ, and use an embedded two-block neighborhood for every new pivot.

For a block outside the next region, all its internal level-k bonds are old prescribed data. Compute their real mean transports and use the gauge $h(x) = T_{y,x}$, $h(y) = 1$, inside that block. The average covariance fixes all level-$(k+1)$ endpoint values. The internal transport means become one, exactly. eq. 3.cccxvi–eq. 3.cccxviii then put every internal old bond within $C_L\epsilon$ of one. This intermediate gauge is permitted to change the old datum; it will be undone at the end. It is not a residual gauge of the original fixed datum.

Complete the unassigned level-k field in this frame as follows. Inside each new block put its internal bonds equal to one. On every fine bond crossing a new coarse face put the given coarse value $V(c)$. Leave all old prescribed bonds unchanged. The no-inward convention ensures that these instructions do not prescribe an old fixed bond twice: every crossing bond with an endpoint in the new region was omitted from the old determining set.

The curvature of this trial completion is at most $C_L\epsilon$. Here is the full local check. A fine plaquette crossing no coarse face is either an old plaquette or has value one. A plaquette crossing one face has equal coarse transports on its two parallel crossing bonds; they cancel, up to internal old transports already within $C_L\epsilon$ of one. A plaquette crossing two faces corresponds to one coarse corner. If all of its coarse edges are new, its product is the new coarse plaquette. If some are old exterior edges, eq. 3.cccxviii replaces each old crossing bond by its actual coarse mean with error $C_L\epsilon$. The resulting product is exactly the assigned mixed test. These alternatives exhaust the 0, 1 and 2 coordinate faces that a fine plaquette can cross. All prefactors are unitary.

For a new coarse row, its inner internal transports are one and its outer internal transports are one or within $C_L\epsilon$ of one. Each straight route crosses its coarse face once. The defining closed logarithmic factors are therefore $O(C_L\epsilon)$. Its actual average differs from the desired $V(c)$ by that amount. There is no smallness assumption on $V(c) - 1$.

Correct this discrepancy on the assigned crossing pivot. The finite pivot chart gives a uniformly invertible real derivative and a fixed admitted radius depending on L. For ϵ below its fixed threshold it gives a pivot logarithm t_c with

$$\mathcal{M}(V^{\mathrm{trial}}[t_c])(c) = V(c), \qquad |t_c| \le C_L\epsilon. \tag{3.cdxxiv}$$

The internal transport paths contain no crossing pivot, and a straight segment of another coarse row contains no such pivot: the segment either has a different orientation or crosses a different coarse face. Thus its average does not depend on t_c. All these corrections can be performed independently. No norm cost is proportional to the number of new rows.

A fine plaquette has at most four corrected edges. Its unitary product changes by at most $4\sup_c |t_c|$ times a fixed small-chart constant. The completed datum therefore satisfies

$$\sup|\partial V^{\downarrow} - 1| \le C_{\downarrow}\epsilon, \qquad \mathcal{M}(V^{\downarrow})|_{\Gamma_{k+1}} = V_{k+1}, \qquad V^{\downarrow}|_{\Gamma_k} = V_k. \tag{3.cdxxv}$$

Undoing the intermediate unitary gauge restores the old prescribed values and preserves these test bounds. Mixed tests for the completed truncation are checked by the same corner argument. The one-step coarse constraint is exact.

This is a real finite section with a fixed constant $C_{\downarrow}(L)$. Its hypotheses include the actual ordinary and mixed tests, the regular finite mean branch and the pivot support premise. Its output is a coarse datum, not a regular fine critical field. In a refinement where no seam is present, the face lift is already exact before the pivot corrections. To use a coefficient one in the two-radius graph eq. 3.cdx, one records only the test coordinates on which that exact transfer preserves the original test; the remaining corner and pivot coordinates belong to the spoiled collar footprint. Their future determining neighborhoods must satisfy the disjointness certificate of that graph.

The finite construction does not prove a smoothed trial bound for the bare current at arbitrary depth. It supplies the one-step datum completion used before the lower background is evaluated. The regular fine trial then comes from that already constructed lower background, as in eq. 3.cdxii–eq. 3.cdxv. This avoids mistaking the face-supported datum for the desired continuum scale potential.

3.11.23. *Descent of the datum and ascent of the critical field.* The induction on the number of levels need not preserve an exact one-step average during the descent of the datum. It must preserve the older rows exactly and leave a uniformly small error on the new rows. The coupled critical equation removes this error during the ascent. The following argument keeps the error from acquiring a factor at each level.

We use the no-inward determining sets of eq. 3.cccvi. In addition to the geometry already specified, fix powers $\mathfrak{M}, R_1, \rho$ of L with

$$L \ge 13, \qquad \mathfrak{M} \ge \mathfrak{m}^{\mathrm{s}}, \qquad R_1 \ge L, \qquad R_1\mathfrak{M} \ge L^2\rho, \qquad \rho \ge \mathfrak{r}^{\mathrm{s}}.$$

Every level-k coordinate circle has at least 6ρ sites. The gap in eq. 3.ccciv is greater than $R_1\mathfrak{M}\xi_j$. The fixed floors $\mathfrak{m}^{\mathrm{s}}, \mathfrak{r}^{\mathrm{s}}$ depend on L. Empty regions and regions equal to the whole torus are allowed. These are quantitative restrictions on the geometry; separation with an unspecified constant is not a substitute for them.

Let $\mathbf{B}^{(n)}$ be the determining set of the truncated sequence $(\Omega_0, \dots, \Omega_n)$, with all its inward rows removed. Its last member contains the level-n bonds inner to Ω_0 that touch Ω_n. Its earlier members agree with the corresponding retained members of $\mathbf{B}$.

3.11.23.1. The two radii for a datum. Fix the constant $C_{\downarrow} \ge 1$ of the finite seam construction. A datum belongs to $\mathcal{D}(\varepsilon)$ if all its ordinary and mixed test holonomies are defined and within $C_{\downarrow}\varepsilon$ of one, and the tested plaquettes of levels $j-1, j$ within $6\xi_j$ of $\partial\Omega_j$ are within ε of one. All distances in this paragraph use level-k units. For a determining set retaining inward rows, one must also impose the ε bound on each pinch holonomy. Such holonomies compare the two retained transports ending at the same seam node; they are additional compatibility tests. They are absent for the determining sets used here.

For $C_{\downarrow}\varepsilon \le \varepsilon_{\downarrow}$ the finite seam construction gives data $V^{(n)}$ on $\mathbf{B}^{(n)}$, with $V^{(k)} = V$, such that

$$V_j^{(n)} = V_j \qquad \text{on the original rows of level } j \le n, \tag{3.cdxxvi}$$

$$|\mathcal{M}(V_{n-1}^{(n-1)})(c)(V_n^{(n)}(c))^{-1} - 1| \le C_{\downarrow}\varepsilon \qquad (c \in \Gamma_n^{(n)}). \tag{3.cdxxvii}$$

The descended datum satisfies $V^{(n)} \in \mathcal{D}(\varepsilon)$.

Here is the reason for using two radii. In a last-level cell the unassigned fine bonds are filled by the face lift: internal bonds are one, and bonds crossing a coarse face carry its coarse value, in the local

transport frame. A fine plaquette deep inside the new region has value one or the corresponding coarse plaquette. It therefore inherits the larger bound without another factor. Near the seam the comparison with the old prescribed bonds costs $C_{\downarrow}$. All tests used in that comparison lie within three coarse spacings of the row or plaquette under consideration. They are within six spacings of the current boundary and hence obey the smaller bound. Separation keeps these tests outside the region altered in the preceding descent step. Older tests remain unchanged. This proves the assertions by downward induction; the bound is $C_{\downarrow}\varepsilon$, not $C_{\downarrow}^{k-n}\varepsilon$.

This descent only asserts eq. 3.cdxxvii at a general seam row. Its average is exact when both row endpoints and their sup-norm neighbor shells of one level-n spacing lie in the new region. The independent pivot corrections of eq. 3.cdxxiv produce a different finite section under their stated support premise. The present induction uses neither equality of these sections nor exact seam averages during descent.

3.11.23.2. The one-level analytic input. Write $\mathfrak{U}'_n(r)$ for the regularity class with curvature and full-bond current at radius r. In bare units ($\eta = 1$), if $j_n(e)$ is the largest $j \le n$ for which e has a corner in Ω_j, its tests are

$$|\partial U(p) - 1| < rL^{-2j_n(p)}, \qquad |\eta D_U^{\mathsf{T}} \partial U(b)| < rL^{-3j_n(b)}.$$

The second expression is the covariant plaquette divergence on full bonds; the truncated boundary action has its separate boundary current. This convention is needed in applying the local regularity estimate.

The analytic step needed in this induction has the following precise form. Let $\varepsilon' > 0$ be small enough that $L^3 B_3^{\mathrm{s}} \varepsilon' \le c_{10}$ and $K_9 L^3 B_3^{\mathrm{s}} \varepsilon' \le a_5(\rho)$, where K_9 is the provisional regularity constant below. Suppose the new datum has all test holonomies defined and strictly within ε' of one, and a regular field $U_0 \in \mathfrak{U}'_{n-1}(B_3^{\mathrm{s}}\varepsilon')$ has the prescribed averages on all older rows and differs from the desired level-n average by at most ε'. The coupled equation, followed by regularity improvement, must produce a critical field for the new datum in $\mathfrak{U}'_n(B_3^{\mathrm{s}}\varepsilon')$. The same constants and smallness thresholds must apply at every truncation. This is an assertion about the actual row equations, their node factors and the Wilson current.

The quantitative use of the coupled equation is as follows. In level-n units put $\alpha_0 = L^3 B_3^{\mathrm{s}} \varepsilon'$. The old field is in the new regularity class at radius α_0. The datum displacement vanishes at every older row, and at the new rows it is

$$B_n(c) = \frac{1}{i} \log\{V_n(c)(\mathcal{M}^n U_0(c))^{-1}\}, \qquad \sup |B_n| \le \frac{\pi}{2}\varepsilon' \le \alpha_0.$$

The boundary derivative of the inner Wilson action is bounded in the force norm by $6\alpha_0$: at a full bond this is the current estimate, and at a boundary bond it follows by summing its at most six incident inner plaquettes. Such a bond is on the bare layer, so the three required powers of the local spacing are exactly the bare powers.

Work on the original bare region of the new truncation. Write $q(A)$ for the straightened rows and $b^\natural$ for their prescribed values. The outward factor in eq. 3.cccxliv is determined by the already prescribed interior rows of the next finer block. Those displacements are zero in this ascent, so the factor is one and $\|b^\natural\|_\infty \le \alpha_0$. Write $K_A = q'(A)$ and F for the inner Wilson action in the logarithmic chart based at U_0. The equations are

$$F'(A) + DRD^\sharp A = K_A^\sharp \omega, \qquad q(A) = b^\natural.$$

In the isometric row frames of the regional inverse, write $T^{-1}q(A) = Q^\natural A + C(A)$ and $\widehat{b} = T^{-1}b^\natural$, using dimensionless row coordinates. Then

$$F'(A) + DRD^\sharp A = F'(0) + \Delta_R A + \mathcal{V}(A), \qquad \Delta_R = D^\sharp D + DRD^\sharp + \Delta'.$$

Here D in the curl term is covariant at U_0, and Δ' is the curvature correction to the covariant curl Hessian of the inner Wilson action. Let H_0 be the energetic row lift for the regional inverse

and $\widetilde{G}_0$ its constrained inverse. Thus $Q^\natural H_0 = 1$, $Q^\natural \widetilde{G}_0 = 0$, and $\ker \widetilde{G}_0 = \operatorname{ran} Q^{\natural\sharp}$. With $\mathcal{G}(A) = F'(A) + DRD^\sharp A$, the field equation is

$$w(A) = (1 + H_0^\sharp C'(A)^\sharp)^{-1} H_0^\sharp \mathcal{G}(A),$$
$$\Psi(A) = \widetilde{G}_0[-F'(0) - \mathcal{V}(A) + C'(A)^\sharp w(A)] + H_0[\widehat{b} - C(A)].$$

Applying $Q^\natural$ to $A = \Psi(A)$ gives the exact row equation. The identity $\widetilde{G}_0 \Delta_R = 1 - H_0 Q^\natural$ puts the residual of the linear field equation in $\ker \widetilde{G}_0$. Applying $H_0^\sharp$ identifies its multiplier as $w(A)$, giving $\omega = Tw(A)$.

The multiplier estimate uses only first differences of A, by the identity

$$H_0^\sharp \mathcal{G}(A) = H_0^\sharp[F'(0) + \Delta' A + \mathcal{V}(A)] + (DH_0)^\sharp DA + (D^\sharp H_0)^\sharp RD^\sharp A.$$

The weighted column estimates for the lifts bound this by $K_8(\mathsf{j} + \|A\|_X + |\mathcal{V}(A)|_{(-3)})$, where $\mathsf{j} = |F'(0)|_{(-3)}$. In the difference of the expressions at two fields, $F'(0)$ cancels. Let K_1, K_7 be the bounds of $H_0, \widetilde{G}_0$ in the row-to-field and force-to-field norms, and set $K_8 = K_1(19 + 12K_1^3)$, $K_5 = 2(K_7 + K_1)$ and $\Theta = 4K_8$. The bound on the Neumann perturbation is $4K_1 L^3 \epsilon^* \le 1/8$, where $\|C'(A)^\sharp\|_{\infty\to(-3)} \le 4L^3\epsilon^*$. Use $\operatorname{Lip}(\mathcal{V}) \le 4C_{4,\mathrm{svar}} L^4 r$, $\operatorname{Lip}(C'^\sharp) \le 2L^4 C_3^\natural$ and $\operatorname{Lip}(C) \le L\epsilon$. Here ϵ, ϵ^* are the row and transpose error bounds at $(\alpha_0, r_\circ)$, both $O(\alpha_0 + r_\circ)$. The inverse difference identity gives $\|w(A)\|_\infty \le (17/7)K_8 r$ and $\operatorname{Lip}(w) \le 3K_8$ for $\mathsf{j} \le r \le r_\circ$. In the difference of $C'(A)^\sharp w(A)$ use the small bound on $C'(A)^\sharp$ with the difference of w, and the small bound on w with the difference of C'. The resulting contraction constant is at most

$$K_7[4C_{4,\mathrm{svar}} L^4 r_\circ + 6K_8 L^4 C_3^\natural r_\circ + 12K_8 L^3 \epsilon^*] + K_1 L\epsilon.$$

Choose the fixed chart thresholds as in the regional contraction estimates, so this is at most $1/2$. They also ensure that $\alpha_0 + 3L^2 r_\circ < L^{-2} c_{2,\mathrm{sobj}}$, the curvature ceiling for the physical stationarity argument. At zero the inverse bounds give $\|\Psi(0)\|_X \le (K_5/2)(\mathsf{j} + \|b^\natural\|_\infty)$. The threshold c_{10} keeps $r = K_5(\mathsf{j} + \|b^\natural\|_\infty) \le 7K_5\alpha_0$ within the fixed contraction radius $r_\circ$. Both closed balls are mapped into themselves, so their unique fixed points coincide.

For a real infinitesimal gauge λ, write $\delta_\lambda A$ for its bond tangent and $\varrho_A \lambda$ for the derivative of the normalized pillar-top values. After the site row conjugation the linear part of the site pair is $(-R\Delta_{U_0}\lambda, Q'\lambda)$. Differentiating the real gauge change and the node factors gives errors bounded by $C(\alpha_0 + \|A\|_X)\|\lambda\|_Y$ in the weighted site force and top-row norms. Compose with the covariant site inverse eq. 3.ccclxxii with the first sign reversed. Its uniform site bound gives identity plus an error of norm less than $1/2$ on the fixed chart. This proves that $\lambda \mapsto (RD^\sharp \delta_\lambda A, \varrho_A \lambda)$ is onto. When $\varrho_A \lambda = 0$, the derivative $K_A^\flat$ of the normalized reduced rows vanishes on $\delta_\lambda A$ by covariance. The node relation changes each outward row by a factor depending only on the already retained interior rows of the next finer block, giving a triangular change of row coordinates with invertible diagonal. Hence the kernel of $K_A^\flat$ is $\ker K_A$. Gauge invariance also gives $\langle F'(A), \delta_\lambda A\rangle = 0$. Pairing the field equation with these tangents gives $\langle RD^\sharp A, RD^\sharp \delta_\lambda A\rangle = 0$. With $\varrho_A\lambda = 0$ the first entry of the site pair can be any vector in $\operatorname{ran} R$. Taking it to be $RD^\sharp A$ gives $RD^\sharp A = 0$. Hence $F'(A) = K_A^\sharp \omega$. Differentiating the physical rows adds the infinitesimal top-site rotations to the normalized derivative. The derivative of the normalized top map on gauge tangents is onto by the site pair above. Consequently a physical constraint tangent can be made a normalized reduced constraint tangent by adding a gauge tangent. Both parts are annihilated by $F'(A)$, giving stationarity on the physical constraint fibre. In the solved field equation the second difference is now $K_A^\sharp \omega - F'(0) - \Delta' A - \mathcal{V}(A)$. The regional row and force estimates bound this by $4(1 + L^3)\Theta r$ in the weighted force norm. This gives

$$\|A\|_{X,\mathbf{B}} \le 7K_5\alpha_0, \qquad |D^\mathsf{T} DA|_{(-3)} \le 28(1 + L^3)\Theta K_5 \alpha_0.$$

Restore the node values by taking the gauge equal to $v_j[A]^{-1}$ at tops of level j. On interior rows eq. 3.cccxliii gives the prescribed averages. On an outward row the gauge at its outer end is $v_{j-1}[A]^{-1}$. The one-step node factor in eq. 3.cccxliv cancels against the same factor of the straightened datum, giving the exact physical datum for both orientations. Gauge covariance carries constrained stationarity to the restored field.

Set $\alpha_2 = 7L^2 \max\{1, 4(1+L^3)\Theta\}K_5\alpha_0$. The threshold $c_{10} \le c_8, c_9$ also ensures $\alpha_2 \le \rho_{1,\mathrm{svar}}$, $C_{4,\mathrm{svar}}\alpha_2 \le 1$, $4\alpha_2 + C_{4,\mathrm{svar}}(\alpha_0+\alpha_2) \le 1/2$, and $2\alpha_0 + 3\alpha_2 \le 1/3$. The curvature and current expansions with the displayed first and second difference bounds give provisional regularity radius $2(2\alpha_0+3\alpha_2) = K_9\alpha_0$. The same bounds hold after node restoration by covariance. By the datum threshold $K_9\alpha_0 \le a_5(\rho)$. To reduce this provisional radius use the improvement in the class with full matrix divergence. On a critical field with input radius $e_0 \le a_5(\rho)$ and datum bound $\varepsilon' \le e_0$, its output radius is

$$\max\{6\varepsilon',\, 3K^\sharp\varepsilon' + 3\vartheta e_0\}, \qquad \vartheta = C_b\rho^2 e^{-\delta_*\rho/24} + C_c\rho^4 e_0.$$

The estimate at positive index uses the localized critical equation. At index zero the plaquette is prescribed, and the full-bond divergence is bounded by the six incident plaquettes of index at most one. Choose the separation floor and $a_5(\rho)$ so the two terms of ϑ are at most $1/24$ each. Since $B_{\mathrm{I}} \ge \max\{6, L^2, 12K^\sharp\}$, the output radius is at most $\max\{B_{\mathrm{I}}\varepsilon', e_0/2\}$. Iterating until the first term dominates gives radius $B_{\mathrm{I}}\varepsilon' \le B_3^{\mathrm{s}}\varepsilon'$. This last return, including its current estimate, is essential; the factor L^3 cannot be iterated as a loss of regularity.

Proposition 3.34 (The finite-depth induction)**.** Assume the one-level analytic input just stated, uniformly in the admitted geometry, and the regularity improvement and regular-orbit comparison estimates used in that input. There are radii $a_0^{\mathrm{s}} > 0$ and $a_1^{\mathrm{s}}(\rho) > 0$, independent of the depth and torus, with $B_3^{\mathrm{s}} a_1^{\mathrm{s}}(\rho) \le a_0^{\mathrm{s}}$, such that a real datum whose test holonomies are all within $0 < \varepsilon_1 \le a_1^{\mathrm{s}}(\rho)$ one has a critical configuration in $\mathfrak{U}'_k(B_3^{\mathrm{s}}\varepsilon_1)$. Any two critical configurations for that datum in $\mathfrak{U}'_k(\varepsilon_0)$, with $\varepsilon_0 \le a_0^{\mathrm{s}}$, belong to the same residual gauge orbit. ■

Proof. Take $\varepsilon' > C_\downarrow\varepsilon_1$ in the uniform smallness range, with $\varepsilon' \le 2C_\downarrow\varepsilon_1$, and first descend the datum as in eq. 3.cdxxvi– eq. 3.cdxxvii. At depth zero the datum itself specifies every inner bare bond. Its curvature is bounded by ε'; its covariant plaquette divergence is bounded by $6\varepsilon'$. Since $B_3^{\mathrm{s}} \ge 6$, this starts the upward induction.

Suppose $U^{(n-1)}$ has been constructed. On every double block read by a level-n row, all level-$(n-1)$ bonds belong to the last member of the preceding truncation. Exact locality of the one-step average therefore gives

$$\mathcal{M}^n U^{(n-1)}(c) = \mathcal{M}(V_{n-1}^{(n-1)})(c).$$

Together with eq. 3.cdxxvii, this verifies the new datum error required by the analytic step. That step produces $U^{(n)} \in \mathfrak{U}'_n(B_3^{\mathrm{s}}\varepsilon')$. The older constraints are exact by eq. 3.cdxxvi. The same bound consequently holds at every depth. At depth k the radius is at most $B_3^{\mathrm{s}}\varepsilon'$. Choose $a_1^{\mathrm{s}}(\rho)$ small enough that $2B_3^{\mathrm{s}}C_\downarrow a_1^{\mathrm{s}}(\rho)$ is below the initial radius allowed by the improvement estimate on the full sequence. Applying that estimate at the original datum radius ε_1 gives $B_3^{\mathrm{s}}\varepsilon_1$.

For uniqueness, take one regular critical field as reference. The regular-orbit comparison places any second one in its Landau chart, with zero reduced datum and field norm at most $\mathsf{B}_1\varepsilon_0$. Choose $a_0^{\mathrm{s}} \le r_\circ/\mathsf{B}_1$ and $6K_5 a_0^{\mathrm{s}} \le r_\circ$, in addition to the curvature ceilings of that chart. Both the zero field and the second field then solve the same coupled equation in its uniqueness ball. The field component of the second solution is zero. Its gauge fixes the tops, and the common prescribed datum fixes the retained seam nodes; hence it is a residual gauge. This proves orbit uniqueness. □

For the actual determining sets eq. 3.cccvi, Prop. 3.124 verifies these analytic premises using Props. 3.88 and 3.120 and the comparison and reset estimates Lems. 3.121 to 3.123. The proof retains the complete outward blocks and the inner-action boundary force. Its uniqueness conclusion

concerns all regular critical configurations in the stated radius. It does not identify an unrestricted global minimum or assert an infinite-volume or continuum limit.

3.11.23.3. Recovering the regularity radius from the datum. In the separated geometry choose a power σ of L satisfying $\sigma \geq L^2\rho_{\mathrm{c}}$, with $\mathfrak{M} \geq \mathfrak{M}_{\mathrm{c}}$ and $\rho \geq L^2\sigma$, and with at least 6ρ sites in each direction at the top level. Let U be critical and already regular at a radius a_{c}. The fixed floors $\mathfrak{M}_{\mathrm{c}}, \rho_{\mathrm{c}}$ come from the local flat inverse construction. At a bare site x let $r_U(x)$ be the maximum of $\eta^{-2}\mathsf{L}(p)^2|\partial U(p) - 1|$ and $\mathsf{L}(b)^3|J(U)(b)|$ over the plaquettes and full bonds based at x. Here L is the local layer spacing and the current in this test is formed at full bonds. For $R = 20L\sigma$ in the weighted distance, let $r_R(x)$ be the supremum of r_U over the ball and $v_R(x)$ the largest defect in the datum tests meeting it, including the pinch tests if inward rows are kept. The local estimate at a regular critical field has the form

$$r_U(x) \leq K_{\mathrm{loc}} v_R(x) + \tfrac{1}{2} r_R(x).$$

Here are the local estimates behind this inequality. If x is in the bare layer away from the next layer, the bonds in the relevant plaquettes are datum bonds. The current there is bounded by the sum of at most six such plaquette defects. Otherwise choose level k to be the layer of x, or the next layer when x is within 5σ in the units of its own layer of that next member. In the units of level k, the enlarged cube reads only layers $k-1, k$. Write Q_s for the s-neighborhood of the partition cube of side σ containing x. For the auxiliary sequence take the full torus at level zero and Q_{s_i} for $1 \leq i < k$, where

$$s_k = \sigma - \rho_{\mathrm{c}}, \qquad s_i = s_k + \sum_{i \leq l < k} (\rho_{\mathrm{c}} + \mathfrak{M}_{\mathrm{c}}) L^{l-k}.$$

The member at level k is $Q_{s_k} \cap \Omega_k$. Keep an inward row of this auxiliary sequence only when the original determining set keeps it. Its positive-level members are subordinate to the original ones, and the largest is inside $Q_{\sigma-2}$. If $v_R(x)$ is above the fixed ceiling of the datum transport gauge, the local inequality follows from $r_U(x) \leq a_{\mathrm{c}}$ by increasing K_{loc}. Use that gauge below its ceiling.

For the real local gauge on Q_σ, take the enlargement of side $3\sigma + 4L\mathfrak{r}_{\mathrm{p}}$, where $\mathfrak{r}_{\mathrm{p}}$ is the fixed cube floor. It lies in $Q_{3\sigma}$ and lifts to a single cube. The two local scales give curvature at most $L^2 r_R(x)\eta^2$, and the current comparison gives covariant divergence at most $2L^3 r_R(x)\eta^2$. The local regular-gauge estimate with these two inputs bounds the potential, its first difference and its flat second-order reads on Q_σ by $C\sigma r_R(x)$ in level-k units. Its smallness condition $C\sigma r_R(x) \leq c$ is included in the radius choice. Extend this potential by zero on the other bonds of the auxiliary torus. A constrained variation there is fixed on the bare determining bonds outside the largest positive-level member. Patch it to the original field across Q_σ. The patched curve fixes each old row. A row whose two endpoints are below its reading level in the auxiliary sequence is fixed by induction in the averaging equation. A row with an endpoint of exactly its reading level is an auxiliary constraint, and its two-block read is inside Q_σ. The old inward rows meeting the varied set, when present, are inherited auxiliary constraints at the interface of levels $k-1, k$. Every varied plaquette lies within Q_σ, so the two actions have the same derivative along the curves. This proves criticality for the extension at its own auxiliary datum. The cutoff region retains the actual current of the extension. Its local length there is the bare spacing, so the zero extension costs $C\sigma r_R(x)$ in the weighted current norm. Passing to the flat Landau slice with the prescribed node factors gives a datum bound $b_{\mathrm{f}} \leq C\sigma^2 r_R(x)$ and the flat response bound $r_{\mathrm{f}} \leq C\sigma^2 r_R(x)$.

In the inner cube the datum in that slice is smaller. The transport gauge of the datum writes each nearby row in terms of the tested plaquettes and, at a retained seam, the tested holonomies. A row based at y has size at most $C(1 + |y - x|)v_R(x)$ in the chosen scale. At the outer endpoint of a coarse row the extra straightening factor is one, since the prescribed datum gauge makes the corresponding lower contour one. At an edge row the two factors at the common seam node cancel, leaving the tested seam transport.

The flat response uses the full flat linear package of Lem. 3.36 when inward edge rows are retained. It bounds the weighted potential and its first difference at $|y-x| \le \sigma/8$ by

$$C(1+|y-x|)v_R(x) + Ce^{-c\sigma}b_{\mathrm{f}} + Cr_{\mathrm{f}}^2.$$

This is the near and far split of the datum sum. The linear distance factor is summable against the kernel, and the far rows are at distance at least $\sigma/8-2$. In the multiplier equation split the differentiated potential sum at the same inner cube. For rows within $4L+2$ of x this gives

$$|\omega(r)| \le Cv_R(x) + Ce^{-c\sigma}(b_{\mathrm{f}} + r_{\mathrm{f}}) + Cr_{\mathrm{f}}^2.$$

The actual row differential in $F'(A) = K_A^{\natural *}\omega$ reads only these nearby multipliers at the full bond. The plaquette estimate uses the potential bound on the neighboring tops. The two readouts agree with those of the original field up to gauge, and the old local length is at most L times the auxiliary length at these reads. The resulting coefficient of $r_R(x)$ is at most $C\sigma^2 e^{-c\sigma} + C\sigma^4 a_{\mathrm{c}}$. Choose σ first and then a_{c} to make this at most $1/2$, with the ceilings of the local gauge and flat inverse also imposed at that choice.

The estimate implies regularity improvement with no accumulation in the number of layers. Let

$$P(x) = \sup_{\tau} e^{-\delta d_{\mathbf{B}}(x,\tau)}|\partial V(\tau) - \mathbf{1}|, \qquad e^{\delta R} = \sqrt{2},$$

where τ ranges over the datum tests. The triangle inequality gives $v_R(x) \le \sqrt{2}P(x)$ and $P(y) \le \sqrt{2}P(x)$ for y in the ball. For $a > 0$, maximize $r_U(x)/(P(x)+a)$ over the bare sites. If S is the maximum, the local inequality at a maximizing site gives $S \le \sqrt{2}K_{\mathrm{loc}} + S/\sqrt{2}$. Letting $a \downarrow 0$ yields $r_U(x) \le 5K_{\mathrm{loc}}P(x)$. Moving from the base point of a bond or plaquette to a corner costs at most two bare steps in the weighted distance, so the same estimate holds there with an enlarged fixed constant. In particular, when every datum test is bounded by ε', the regularity radius is at most $C\varepsilon'$. The flat chart admission in this calculation is verified in Lem. 3.123; the provisional one-level output lies in its permitted radius by eq. 3.mlxxxix.

3.11.24. *Norms and the remaining finite estimates.* The natural weights in the nonlinear estimates can be stated explicitly. One field norm and force norm are

$$\|A\|_{X_1} = \max\{\|\mathsf{L}A\|_\infty, \|\mathsf{L}^2\nabla_{U_0}A\|_\infty\}, \qquad \|f\|_{\mathcal{F}} = \|\mathsf{L}^3 f\|_\infty. \tag{3.cdxxviii}$$

The force is the physical density in the fine pairing $\eta^4\sum_b(f_b, A_b)$. The datum b is a raw row logarithm, with norm $\|b\|_Y = \sup_c|b_c|$. Use the counting pairing $\sum_c(\omega_c, b_c)$ for its multiplier and $\|\omega\|_Z = \sup_c|\omega_c|$. For differentiated conclusions append the separate natural second-order and current readouts; do not replace them by the supremum of every second difference.

This convention explains a normalization in the named propagator formulas. The per-length row field is $B_Q(c) = \xi_c^{-1}b_c$ with cell pairing $\sum_c \xi_c^4(\omega_Q(c), B_Q(c))$. Equality with the raw pairing requires

$$\omega_Q(c) = \xi_c^{-3}\omega_c, \qquad \|\omega\|_Z = \|\xi_c^3\omega_Q\|_\infty. \tag{3.cdxxix}$$

It is the bilinear weighted transpose of $b = \mathsf{m}B_Q$. Similarly the per-length penalty $\sum_c \xi_c^4 a_0 \xi_c^{-2}|B_Q(c)|^2$ equals $\sum_c a_0|b_c|^2$. Thus its raw mass is a_0, while its per-length mass is $a_0\xi_c^{-2}$. The generic identity in eq. 3.cccxlii uses one consistent pairing; eq. 3.cccxlvi–eq. 3.cccxlviii use the per-length convention. Converting their multipliers and quadratic readouts uses eq. 3.cdxxix.

The requirements for a general background construction can be organized as the local inequalities below. For the proper determining sets in force, the later construction supplies the estimates needed for the physical problem on its stated domains. The strong row saddle is proved in Prop. 3.88; the actual Wilson and constraint remainders are bounded in eq. 3.mxxxv and eq. 3.mxxxviii. The site inverse and finite gauge construction are given by eq. 3.mxliv–eq. 3.mlviii. These estimates use the physical amplitudes eq. 3.mxxix, retain every outward factor, and apply about real references with the required actual curvature and current bounds. Their uniform holomorphic continuation and

weighted response are proved in Prop. 3.117 and eq. 3.mlxvii. Props. 3.120 and 3.124 then supply the regular-trial correction and the real background induction on those determining sets.

The canonical independent-current completion is fixed separately in Prop. 3.90, with its strong bounds in Prop. 3.92. These results apply to that specified operator family. For any other primitive package, the list and conditional assembly below retain its own domain, norms and complete projected comparison eq. 3.cccxxxviii; no identification follows merely from using the same operator names.

The site estimate. For the actual Q', including its outward endpoint convention, the real site correction uses the weighted inverse on the admitted separated sequence. On the primitive complex ball one needs the corresponding weighted kernel bounds for eq. 3.ccclxxii and its first differences. Prove the nonlinear gauge and node remainders there with fixed admission margins. This is the quantitative version of the completely proved projector algebra in eq. 3.ccclxviii–eq. 3.ccclxxii.

The constrained inverse. For the actual Lagrangian and all actual row and gauge terms, prove

$$\|\mathcal{S}_0^{-1}\|_{\mathcal{F}\oplus Y\longrightarrow X_1\oplus Z}\le C,\qquad \sup_y\sum_c e^{md_{\mathbf{B}}(y,y_c)}\|(\mathcal{S}_0^{-1})_{yc}\|_{\mathrm{norm}}\le C, \tag{3.cdxxx}$$

and the corresponding column and readout estimates. The normalized entry includes the physical cell weights of its source species. This is required first on the primitive real class, then by a whole-ball complex perturbation. The complete projected current and gauge comparison in eq. 3.cccxxxviii, with every term of eq. 3.cccxlvi–eq. 3.cccxlviii, is a separate identification task.

The local coefficient estimate. For the actual fine Wilson action, actual straightened constraint and actual datum factors, prove eq. 3.ccclii in these norms, with

$$c_F(r)+c_q(r)+c_{q\omega}(r)+c_{\mathrm{mix}}(r)\le C(r+\gamma_0+\epsilon_0) \tag{3.cdxxxi}$$

in the chosen linearization, or the corresponding small triangular matrix just treated. The finite coordinate remainders must be summed using their actual supports. For example bare second differences created by a group product have to be paired with their actual powers of η, or summed by parts before a kernel is applied. Counting all fine variables of a pillar as independent losses is not a proof of eq. 3.cdxxxi.

The slice improvement. The current comparison and eq. 3.ccclxxiv give the reset in the real slice under its fixed potential ceiling. The descent and ascent also require the preliminary contour alignment at seams with its single defect cost. The exact rigidity and summability eq. 3.cccxix–eq. 3.cccxx already supply the group-valued part.

The critical patch estimate. The auxiliary sequence and the flat row readouts give eq. 3.ccclxxvi and the pointwise profile on the admitted real geometry. The real cube gauge supplies the potential and second-order bounds used on that geometry. The maximum argument transfers the local inequality to the profile.

The continuation and tower estimate. Lem. 3.127 and Prop. 3.129 construct the common analytic ball and bound the ratio M/r_0^2 in eq. 3.ccclxxxvii, including the actual representative gauge and physical current. Cor. 3.130 supplies both erosion rules and every truncation. The outer and inner substitutions, with their full parameter domains and nested tower tests, are proved in Props. 3.132 and 3.135. The geometric and radius comparisons below use these estimates with their stated localization collars.

These are finite lists of specific actual inequalities and identities with their uniformities. Their proofs can share the same matrix estimates, and some can be proved in a different order. They are not all extra assumptions on every possible route. For example a direct smooth fine section can be replaced by the real coarse datum section eq. 3.cdxxv and the lower background induction. The latter avoids requiring an independent fine trial construction.

3.11.25. *The six conditional background conclusions.* Here is a precise way to assemble the reductions without promoting an estimate that has not been proved. Suppose the preceding finite

estimate list is established on the declared primitive domains, with its actual normal-form matches and fixed margins. Suppose also that the history regions satisfy their finite separation certificates, and that the one-step section uses the proved pivot support geometry. All constants below may depend on $L, \rho, \mathfrak{M}$ and the stated local geometry, but not on depth, volume, region shape, datum position or real holonomy. Then the following six conclusions hold.

3.11.25.1. Regular orbit. Every datum in the specified small regular class has one regular critical residual orbit, with

$$\sup_p \eta^{-2}\mathsf{L}(p)^2|\partial U(p) - 1| + \sup_b \mathsf{L}(b)^3|J_A(U)(b)| \le C \sup_\tau |\partial \mathbf{V}(\tau) - 1|. \tag{3.cdxxxii}$$

It has the unique comb representative outside all nodes. Existence is the datum descent, the actual induced action step and eq. 3.cdxiv, with the uniform radius reset. The induction is on the marked two-radius data class of eq. 3.cdx, so each recursive completion encounters at most one loss on a test path. The single global small base radius is chosen after that fixed $C_\downarrow$. Uniqueness is the slice argument following eq. 3.cdxv. The representative is the exact construction in eq. 3.cccix–eq. 3.cccx. At trivial complete datum the orbit is flat and is an absolute minimum of the nonnegative Wilson action. At other data the conclusion is regular criticality.

3.11.25.2. Local regularity. The field has the profile eq. 3.ccclxxix–eq. 3.ccclxxx. On a cube of side $m\xi_j$ with its prescribed enlargement inside Ω_j and shorter than half the torus, $m\epsilon \le c$ gives a real local gauge with

$$\xi_j|A| + \xi_j^2|\nabla A| + \xi_j^3|\Delta A| + \xi_j^3|\partial^\sharp \partial A| \le Cm\epsilon. \tag{3.cdxxxiii}$$

Its first differences have the Hölder bound in eq. 3.ccclxvii. Here $\Delta = -\Delta_\eta$ is the positive componentwise Laplacian; the heat generator Δ_η in eq. 3.ccclxxxi has the opposite sign. The full-current radius is required on the enlarged cube. The single real gauge construction supplies the ordinary Laplacian in eq. 3.cdxxxiii, and the covariant divergence comparison supplies its flat curl term. The constant-layer site estimate then gives the Hölder bound.

3.11.25.3. Complex continuation. For each admitted real datum center there is one holomorphic comb background on its specified physical datum ball, agreeing with the real representative. It has a Landau pair in eq. 3.cccxlv with its actual node normalization, and a possibly different comb pair. The real conjugation and admitted gauge covariance follow from uniqueness. The coupled construction, site correction and real/complex gluing prove these assertions. A global all-site bound on the comb gauge is included only when its actual readout estimate is supplied; a top bound for the Landau gauge is not silently enlarged.

3.11.25.4. Response. On the entire admitted datum ball, a unit source e at row c has the bounds

$$\begin{aligned}\xi_y|h| + \xi_y^2|\nabla h| + \xi_y^3|D^\sharp Dh| + \xi_y^3|\Delta_{U_0} h| + \xi_y^3|\delta J_A| \\ \le Ce^{-md_{\mathbf{B}}(y,y_c)}|e|.\end{aligned} \tag{3.cdxxxiv}$$

The multiplier and top node readouts have their corresponding normalized bounds. The Hölder member follows from the actual pointwise gradient and Laplacian estimates. At a noncritical independent-current pair the second-order members are the combinations eq. 3.ccclxxxii; the critical slice identity is not asserted there. eq. 3.cccxcvii, the actual kernel estimates and the local readout formulas prove these claims.

3.11.25.5. Hereditary complex domains. For sufficiently small radii (e_0, e_1), Cor. 3.130 gives tower curvature and current bounded by $C(e_0 + e_1^2)$ in their declared scales. The common complex ball and its uniform crude readout bound are proved in Lem. 3.127. At settled elements of an ambient sequence the same readouts use eq. 3.cdxix and have the ambient exponentially weighted Lipschitz bound. Outer and inner substitutions preserve the specified cores under their all-clause numerical margins. These follow from eq. 3.ccclxxxvi–eq. 3.ccclxxxix, Prop. 3.138, and eq. 3.cdiv, with the true radius factors retained.

3.11.25.6. Construction, restriction and comparison. The certified label, healed, prepared, stage, tower and joined sequences are separated. Restriction gives eq. 3.cccxciii, and the next-step background nests with its truncation. For a collared region the joined problem and exact lifted datum define its localized background. The common admitted path then gives eq. 3.cd, with its potential, gradient and second-order readouts. The comparison gauge is prescribed only at the stated tops. Separation closure, the adaptive factorization, constrained criticality, regular uniqueness and the weighted response prove this conclusion.

The numerical constants in this theorem must have a solved order of choice. One admissible order fixes the local geometry and its uniform coefficient degrees, the inverse and response constants, then the cutoff scale σ, and finally the small regularity and analytic radii. If an exponent or reserve parameter must be chosen before later geometry, the needed degree bound must be uniform in that geometry, or the whole finite feasibility list must be solved jointly. Logarithmic smallness at already fixed geometry does not prove a different choice order.

The first-step chart, classical flat inverse and kernels, and physical first-step backgrounds provide proved instances of these reductions. The site, layered, full-current and window estimates listed above remain their precise multilevel application tasks. No claim about an all-current completion, an interacting Gaussian law or a history formation bound follows from the conditional background theorem without those separate matches and estimates.

3.12. **Constrained propagators and local decay.**

3.12.1. *Propagators in a background field: exponential decay produced by the averages.* Every object produced by a renormalisation step is assembled from inverses of "Hessian of the action + gauge term + mass made of block averages". These inverses are taken around a background on a decreasing sequence of regions, in which each layer has a scale of its own. The propagator hypotheses are: they exist; they depend analytically on the background; in each layer they behave like massive Green's functions measured in the unit of that layer; they decay exponentially; and they are sums of terms that are local both in the field and in the regions. A single requirement governs the whole construction. Since the regions are supplied by the large-field analysis, none of the constants may vary with their shape or their number, nor with the level, the cutoff or the torus. Two numbers are exceptions, and neither of them enters any localised bound, rate, weight or sum of weights. (Bałaban's papers are referred to by the volume of Commun. Math. Phys. in bold. Where two papers must be told apart, the first page is added: **99**, 75 and **99**, 389; **102**, 277; **122**, 175. The volume and page references identify the published papers. Clauses 0–5 appear below; the following list defines the references to later requirements. The mechanisms in (iii) carry the letters (a)–(k).)

The numbered requirements concern six propagators, their covariances and walks, and parameter decoupling. The vector and current conclusions require the specified operator and domain estimates. § 3.13 proves its stated site, row, averaging-coefficient and physical-Hessian reductions; those reductions establish only the requirements stated there.

3.12.1.1. References to the propagator hypotheses. References to statements 6–8 mean the requirements below. The labels 1c.1–1c.10 in the strategy name stages of the conditional argument, as follows.

Conditioned covariance (statement 6).: This means the actual fluctuation precision A, its conditioning $\chi_Y \mathsf{A} \chi_Y$, and the inverse $C^{(k)}(Y)$ defined below, with the coercivity, complex-domain and boundary requirements of Input A2 and the kernel/locality requirements of Input A3 in the dependency catalogue. Their walk requirements are included in statement 5 here. Physical identification uses the complete current and gauge comparison below and the three Hessian readouts of § 3.13, not a Ward identity alone. The canonical proper covariance, including its outer constraint curvature and relative contour form, is constructed in Prop. 5.45 and § 5.13.

Walks as parameter-dependent operator data (statement 7).: For a fixed cube partition P, each supplied walk term has its specified finite parameter carrier $\mathsf{P}(\omega)$. Write $s^\omega = \prod_{\Delta\in\mathsf{P}(\omega)} s(\Delta)$ and $\mathsf{O}(s) = \sum_\omega s^\omega \mathsf{O}_\omega$. The required data include the total-incidence bound in mechanism (i), absolute locally uniform convergence on $|s(\Delta)| < e^{\bar\kappa}$, the stated weighted bounds, reality and covariance, compatibility on common lifts, and wall-component splitting when separating parameters vanish. The exceptional convergence-only bound mentioned below is part of these supplied data. These are the operator-data hypotheses following eq. 2.x in § 2.2; the substitutions, their domain condition and their alternating brackets are eq. 2.xi–eq. 2.xiii there. None of this asserts $QH(s) = 1$.

Decoupled response (statement 8 and system (I)).: The operative system (I) is eq. 2.x in § 2.2. There B' and D are raw rows; each map written $\mathsf{H}_{(1)}(s)$ means the raw-datum version $\mathsf{H}_{(1)}(s)\mathsf{m}^{-1}$ of the per-length map used here, and C_k means the raw nonlinear part $\mathcal{C}$ defined below. Use the following hypotheses there on the reduced current, holomorphy, bounds, splitting, transport and actual substitution domains. Their existence and uniqueness remain response inputs of A3. At $s = 1$, identification with the physical branch uses the fixed-reference stationarity and constraint equations in eq. 3.dcviii, the actual Lagrangian Hessian eq. 3.dcxi, and the coupled inverse in eq. 3.dcxii–eq. 3.dcxvi in § 3.14.

The coupled alternative (system in eq. 3.cdxliv).: This is the explicitly defined operator-data map below. Its coefficient bounds, radius and current requirements are additional conditional data; it is not identified with eq. 3.dcviii at arbitrary s or at an independent current. Equality of the two response constructions is used only on their common domain at $s = 1$ over the stated critical physical pair, after full operator matching and the required uniqueness have been established.

(i) The setting and the objects.

Geometry. The integer L is odd and large. The cube size of the walk expansions, M_1, and the gap number, R_1, are both powers of L, with $R_1 \geq L$. We work in level-k units, in which $\mathbb{T}^{(j)}$ has spacing $\xi_j := L^{j-k}$; moreover $\eta = \eta_k = \xi_0$. A sequence $\Omega_0 \supset \cdots \supset \Omega_k$ is called *separated* when every Ω_j is a union of M_1-cubes at level j and

$$\mathrm{dist}_\infty(\Omega_j^c, \Omega_{j+1}) > R_1 M_1 \xi_j.$$

No further condition is placed on the regions. In particular Ω_0 is arbitrary, and Dirichlet conditions are imposed outside it. *Layers* are the sets $\mathcal{L}_j = \overline{\Omega_j \setminus \Omega_{j+1}}$. The *tops* y are the sites of $\mathbb{T}^{(j)}$ lying in $\mathcal{L}_j$. Such a top has local scale $\xi_y = \xi_j$ and block $\Delta(y)$, which is the cube of side ξ_y with centre y. The *rows* c are the bonds of $\mathbb{T}^{(j)}$ that have one end point in $\mathcal{L}_j$ and the other end point either in $\mathcal{L}_j$ (the *interior* rows) or, when $j \geq 1$, outside Ω_j (the *outward* rows); for them $\xi_c = \xi_j$. The *inward* bonds, those that enter Ω_{j+1}, carry no row. The distance

$$d_{\mathbf{B}}(y, y') = \inf_{\Gamma \ni y, y'} |\Gamma|_{\mathbf{B}},$$

$$|\Gamma|_{\mathbf{B}} = \sum_{j\geq 1} \xi_j^{-1} \,\mathrm{length}(\Gamma \cap \mathcal{L}_j) + \xi_0^{-1} \,\mathrm{length}(\Gamma \setminus \Omega_1)$$

(Γ connected)

measures each layer in the unit of that layer. Outside Ω_1, and hence also outside Ω_0, length is counted in the bare unit. Therefore $d_{\mathbf{B}}$ is independent of Ω_0, and a path that leaves Ω_0 finds no cheaper unit of length out there. This distance differs from the distance (2.46) of **96**, whose contours are made up, in each layer, of bonds of the lattice of that layer. A larger class of paths is allowed here, and so $d_{\mathbf{B}}$ is the smaller of the two.

Regular pairs $(\mathbf{U}, \mathbf{J})$ consist of $\mathbf{U} = e^{i\eta A'}U$, with U real, together with an **independent** $\mathfrak{g}^c$-valued 1-form $\mathbf{J}$ that represents the current. Such a pair is required to satisfy, on $\mathcal{L}_j$,

$$|\partial U - \mathbf{1}|, |\partial \mathbf{U} - \mathbf{1}| < \alpha_0 \eta^2 \xi_j^{-2},$$
$$\xi_j |A'|,\ \xi_j^2 |\nabla_U A'| < \alpha_1,$$
$$|\mathbf{J}| < \gamma_0 \xi_j^{-3},$$

and, on every cube of side $O(M_1 \xi_j)$ contained in $\mathcal{L}_j \cup \mathcal{L}_{j+1}$, to admit a real gauge $U = e^{i\eta A}$ with $\xi_j |A|, \xi_j^2 |\nabla A| \le \alpha_0$. In this condition the bound is α_0 on the entire cube, and not $O(M_1)\alpha_0$. Pairs in which the current is a separate variable, with a radius γ_0 of its own, are due to Bałaban (**109**, p. 262, (1.10)–(1.14)). In the present setting they are formed on a sequence, with the local scales. Throughout, $J(\mathbf{U})$ is the first variation of the action of the *inner* plaquettes, namely those inside Ω_0. At every bond whose six plaquettes are all inner, it coincides with the current $D^*_{\mathbf{U}} F_{\mathbf{U}}$; when $\Omega_0 = T_\ell$, every bond is of this kind. *On shell*: the pair satisfies $\mathbf{J} = J(\mathbf{U})$ at the bonds that touch Ω_1. *Real*: $A' = 0$, and $\mathbf{J}$ is real. *Local class on* W: the same conditions, required inside W.

Operators. Relative to $\mathbf{U}$, the *straightened* j-fold average of $e^{i\eta A}\mathbf{U}$ takes, at a row c of level j, the value $\exp i\mathcal{Q}(A)(c)$. Here $\mathcal{Q} = \mathsf{m}\,(Q + C^{(2)} + \dots)$, and m is multiplication by ξ_c. Thus Q, which maps 1-forms to rows, is the linear part per unit length, and $C^{(2)}$ is the quadratic part per unit length. When the level has to be displayed, the straightened average is written $\mathcal{Q}_j^{\mathrm{st}}(\mathbf{U}; A)$. In the units of level j, its linear part is the operator $Q_j^\sharp(\mathbf{U})$ of the Notation, §3, which is built from the means over the contour families of $\mathcal{M}$. The index st stands for "straightened"; the *straight* linear average $Q_j^{\mathrm{st}}(\mathbf{U})$ of the Notation is a different operator. Consequently, in this part the unadorned letters $\mathcal{Q}$ and Q differ from those of §3 of the Notation: they denote neither the logarithm $\mathcal{Q}_j(\mathbf{U}; A)$ of $\mathcal{M}^j(e^{i\eta A}\mathbf{U})\,\mathcal{M}^j(\mathbf{U})^{-1}$ nor its linear part $Q_j(\mathbf{U})$. The straightened and the plain averages are related by *site factors* v_n; these are the node factors $v_n = v_n[A]$ of the Notation, §3, and in 1c.10 they are also called node factors. These are group-valued functions on the sites of $\mathbb{T}^{(n)}$, and they accumulate from one step to the next (statement 3: $\mathcal{M}^n(e^{i\eta A}\mathbf{U}) = \big(e^{i\mathcal{Q}_n^{\mathrm{st}}(A)}\mathcal{M}^n\mathbf{U}\big)^{v_n}$). The linear parts of the straightened and of the plain average already differ at $\mathbf{1}$, by a gauge term on the coarse lattice. For the plain averages, two facts of statement 3 fail: the identity $QD = \bar{D}Q'$, and the bound $1 + C(\dots)$ on the derivative. In that identity, at a row of level j, $\bar{D}$ is the covariant difference on $\mathbb{T}^{(j)}$ formed with $\mathcal{M}^j\mathbf{U}$, and Q' takes, at each of the two end points of the row, the j-fold average of a site function; this applies also to the outer end point of an outward row, which is a top of level $j-1$. The operator Q' maps site functions to tops. It is the linearisation of the average of a gauge transformation, taken with the same contour variables. At a row of level j, the notation $\bar{D}Q'$ uses the j-fold site average at both endpoints. At the outer endpoint of an outward row, which is a top of level $j-1$, this value is the additional transported L^4-block average of its own-level top values. Thus $\bar{D}$ means the extended endpoint operator of § 3.13, not an ordinary difference of the two own-top components. The symbol ^{T} denotes the transpose with respect to bilinear pairings, so that everything remains holomorphic. The operator a acts on rows as multiplication by $a_0\xi_c^{-2}$, where a_0 is a fixed number (equal to 1 in the sub-parts). On tops it acts as multiplication by a comparable weight $\approx \xi_y^{-2}$. We write $D = D_{\mathbf{U}}$. Finally, $\Delta^{\mathrm{W}}_{\mathbf{U}}$ is the Hessian of the action in Ω_0. In statements 3–8 it is the Hessian of the action of the inner plaquettes, which is an exactly invariant function. In statements 1, 2 it is obtained by taking the Hessian on the entire lattice and compressing it to the bonds of Ω_0.

$$G' = (\Delta_{\mathbf{U}} + Q'^{\mathsf{T}} a Q')^{-1},$$
$$R = 1 - G'Q'^{\mathsf{T}}(Q'G'^2Q'^{\mathsf{T}})^{-1}Q'G',$$

$$\mathsf{S} = 1 - DG'RD^{\mathsf{T}},$$

$$\mathsf{G}_0 = (\Delta_{\mathbf{U}}^{\mathrm{W}} + DRD^{\mathsf{T}} + Q^{\mathsf{T}}aQ)^{-1},$$
$$\mathsf{G} = (\mathsf{G}_0^{-1} - \Delta'_\pi[\mathbf{J}])^{-1},$$
$$\mathsf{G}_1 = (\mathsf{G}^{-1} - \mathsf{S}^{\mathsf{T}}\Delta^{(2)}[\mathsf{H}^{\mathsf{T}}\mathbf{J}]\mathsf{S})^{-1},$$
$$\mathsf{H}_{(1)} = \mathsf{G}_{(1)}Q^{\mathsf{T}}(Q\mathsf{G}_{(1)}Q^{\mathsf{T}})^{-1}$$

(where a bracketed index occurs, the formula holds both with that index and without it). The operators are defined in this order: G, then H from G, then G_1, then H_1 from G_1. The symbol $\Delta'_\pi[\mathbf{J}]$ denotes a specified current-linear completion whose required physical Ward identity is stated below. Its complete form is part of the operator data: linearity and that Ward identity alone do not determine its horizontal or independent-current terms. The distinct mean-constraint correction $\Delta^{(2)}$ is retained separately. Moreover, $(A, \Delta^{(2)}[\mathsf{j}]A) = 2(C^{(2)}(A), \mathsf{j})$. The *six propagators* are

$$\mathsf{G}, \mathsf{G}_1, \mathsf{H}, \mathsf{H}_1, (Q\mathsf{G}Q^{\mathsf{T}})^{-1}, (Q\mathsf{G}_1Q^{\mathsf{T}})^{-1}$$

. In addition we set $\mathfrak{G} = \mathsf{G}_1 - \mathsf{G}_1DRD^{\mathsf{T}}\mathsf{G}_1 - \mathsf{H}_1Q\mathsf{G}_1$. For step $k+1$ we work on the bonds of $\mathbb{T}^{(k)}$ that touch Ω_{k+1}, with $V = \mathcal{M}^k\mathbf{U}$. Let C_V be the elimination of the pivot bonds, and let $\mathsf{G}_V^{(2)}$ be the quadratic part of the soft axial gauge fixing. Let $\mathsf{E}^{(2)}$ be the quadratic current form of the one-step constraint, which is imposed through the plain $\mathcal{M}$ at V and whose linear part is the Q_V of the Notation, §3. Its notation includes the actual pivot multiplier. More precisely, write $\mathfrak{q}_V$ for the raw constraint logarithm and h_V for the pivot right inverse of $D\mathfrak{q}_V(0)$. In raw counting coordinates, its bilinear form contracts $D^2\mathfrak{q}_V(0)[u,v]$ with $h_V^{\mathsf{T}}\widehat{j}$, where $\widehat{j}$ is the raw coarse-bond current. The unhatted form uses the corresponding raw/per-length dual conversion. This is the curved-fibre readout derived in § 3.13; the coarse-bond current is not directly identified with a new-row multiplier. We set

$$\Delta_k = (Q\mathsf{G}_1Q^{\mathsf{T}})^{-1} - a - \mathsf{E}^{(2)}[\mathsf{H}_1^{\mathsf{T}}\mathbf{J}],$$
$$\mathsf{A} = \mathsf{C}_V^{\mathsf{T}}(\mathsf{G}_V^{(2)} + \Delta_k)\mathsf{C}_V,$$
$$C^{(k)}(Y) = (\chi_Y\mathsf{A}\chi_Y)^{-1}.$$

At the physical critical pair $(U_{k+1}, J(U_{k+1}))$ of the step, the required identification is $\mathsf{A} = \mathsf{C}^{\mathsf{T}}\Delta^{(k)}\mathsf{C}$. This identity must hold for the complete projected forms, including the pivot graph, all current and mean-constraint corrections, and the specified soft-gauge term. The absolute or relative contour-gauge convention must be checked in that comparison; a Ward identity alone does not establish the identification. Its action-value component is the quadratic term of the action of the background, regarded as a function of its datum. This is Bałaban's expansion **102**, 277, (174), together with **109**, (2.4)–(2.8), (2.11). There the derivation is carried out on the whole lattice, using Bałaban's own rows and his averages. For $\mathcal{M}$ and the straightened rows, on the sequence of a label, the expansion is obtained from the system with a multiplier of § 3.11. That multiplier coincides with the gradient of the action of the background with respect to its datum, as one sees by differentiating the constraint and pairing the result with the Euler–Lagrange equation. A single differentiation of the system yields the derivative of the multiplier. Here ω is the physical row multiplier in $J(\mathbf{U}) = Q^{\mathsf{T}}\omega$, with the declared cell-weighted transpose; it is unique on the independent datum space when Q is onto. For the critical pair, the required identified form of G_1^{-1} is the projected Lagrangian Hessian $\mathsf{S}^{\mathsf{T}}K_{\mathrm{L}}\mathsf{S}$, together with the gauge term and the row mass,

where $K_{\mathrm{L}} = \Delta^{\mathrm{W}} - \Delta^{(2)}[\omega]$. On the declared Landau slice the projections act as the identity. For the canonical completion this identity follows from Prop. 3.90; its proper outer-fibre identification, including the pivot second derivative, is proved in § 5.13. Hence this derivative is obtained by applying $(Q\mathsf{G}_1Q^{\mathsf{T}})^{-1} - a$ to the datum. When the datum moves along a curve contained in the fibre of the one-step average, it picks up a second-order term, and this term is determined by the quadratic part of the one-step constraint. Paired with the gradient, this term yields $-\mathsf{E}^{(2)}[\mathsf{H}_1^{\mathsf{T}}\mathbf{J}]$. Bałaban also gives a second expression for the first two terms of Δ_k, namely $\mathsf{H}_1^{\mathsf{T}}[\mathsf{G}_1^{-1} - DRD^{\mathsf{T}} - Q^{\mathsf{T}}aQ]\mathsf{H}_1$. It differs from them by $-\mathsf{H}_1^{\mathsf{T}}DRD^{\mathsf{T}}\mathsf{H}_1$, a term that vanishes on shell. The bounds and the positivity in statement 6 concern the form displayed above.

3.12.1.2. Positivity of the compressed fluctuation form. The direct argument in Lems. 5.43 and 5.44 and Prop. 5.45 proves the proper lower bound, complex continuation and local inverse families for the precise relative-contour form below. The following local-system comparison describes an alternative positivity mechanism. Consider an admitted real layered pair in statement 6 with the complex potential slot equal to zero and with real current. In this argument the local pieces have width $\mathfrak{M}$ on the fluctuation scale, with $\mathfrak{M} \geq M^{\mathrm{pcs}}$, $R_1 \geq L$, and $R_1\mathfrak{M}$ at least the floor of the local propagator construction. The torus side in level-k units is at least $2L\mathfrak{M}$. Take Y to be the free-bond set for a subfamily of the retained top blocks in the conditioning geometry. The form $T_Y = \chi_Y \mathsf{A} \chi_Y$ acts on the free bonds in Y, after pivot elimination. To compare it with a positive form, use a partition $\sum_\kappa h_\kappa^2 = 1$ on those bonds, with each cutoff supported inside a larger piece on which the local system is defined. In each piece, continue the field in a gauge with a small potential and keep the three current slots, including the two multiplier readouts $\mathsf{H}^{\mathsf{T}}\mathbf{J}$ and $\mathsf{H}_1^{\mathsf{T}}\mathbf{J}$. These readouts obey the smallness bounds in the units of their rows by the weighted operator estimates. Perturbation of the flat system gives the inverse C_κ in the fluctuation slot with $cI \leq C_\kappa \leq pI$, where $c, p > 0$ are independent of the piece. The comparison is made for the completed local system, including the pivot graph and gauge block.

Write $P = \sum_\kappa h_\kappa C_\kappa h_\kappa$, with restriction and extension by zero in each summand. Then $cI \leq P \leq pI$. To compute PT_Y, take a free field B, set $f = T_Y B$, and complete B to the solution Φ of the coupled equations with right-hand side f in the fluctuation slot and zero in the other slots. The uniform auxiliary inverse and pivot bounds give $\|\Phi\|_\infty \leq C\|B\|_\infty$ in local units. The local and global systems agree on inputs supported in the intermediate piece, with output in the larger piece. Choose $\widetilde{h}_\kappa$ supported in that intermediate piece and equal to one on the cutoff support and its interaction neighborhood. The local system applied to $h_\kappa\Phi$ has right-hand side $h_\kappa f$ in the fluctuation slot plus the cutoff commutator applied to $\widetilde{h}_\kappa\Phi$. Solving the local equations and summing their free-field slots yields $PT_Y = I - E$. The commutator costs $C/\mathfrak{M}$ in the scale-weighted source norm, and bounded overlap of the cutoffs gives $\|E\|_{\infty\to\infty} \leq C/\mathfrak{M} \leq 1/8$.

This last bound controls the eigenvalues of PT_Y. Since PT_Y is similar to the real symmetric matrix $P^{1/2}T_YP^{1/2}$, that matrix is at least $7I/8$. Thus $T_Y \geq 7I/(8p)$, and the inverse on the free bonds has norm at most $8p/7$. On the axial slice the same calculation uses the free fields vanishing on the box trees. The reconstructed fields are supported on the free bonds together with their pivot bonds. The bounded norm of the pivot lift converts the free-field lower bound into the lower bound in the norm of the reconstructed field.

The walk terms for the covariance of the compressed form are written against counting measure on its free bonds. Their local comparison uses the traces of the regions and of Y on the carrier, and the regular pair on the enlarged pieces used in the two local systems. For the history induction the forms to be integrated must be identified with this compressed form, or compared with it with an error smaller than its lower bound. In particular, selecting part of a walk sum does not preserve its positivity by this argument. To extend the lower bound to the complex integration cores one must bound the change in the complete form on the specified cores.

Walks. A *cell* is a union of $O(1)$ cubes of side $O(M_1\xi_j)$ lying in two consecutive layers. In a *walk* $\omega = (X_0, \dots, X_m)$, any two consecutive cells overlap. In a *tree walk*, each X_i overlaps an earlier

cell, called its parent, and the cells are enumerated depth first. With arbitrary parent maps, one sequence of length m is counted as many as $m!$ times. The *hull* $[\![\omega]\!]$ enlarges the walk by $O(M_1)$ local units and is not cut off at Ω_0. The *carrier* is $[\omega] = [\![\omega]\!] \cap \Omega_0$. Finally, $d_{\mathbf{B}}(\omega; y, y')$ is the smallest weighted length of a tree that passes through y, y' and meets the cells $X_1, \dots, X_m$. The tree is not required to meet X_0.

Several letters have a different meaning in the sub-parts 1c.1, 1c.6 and 1c.10, as follows. The cube size of the walks is denoted $\mathfrak{M}$ in 1c.1. In 1c.10 the cubes $\square$ that carry parameters (statement 7), whose side is ℓ_{P}, are denoted Δ. Also there, Γ_j denotes the set of rows of level j. In 1c.10, Q stands for $\mathsf{m}Q$, and slanted H, H_1 stand for $\mathsf{Hm}^{-1}, \mathsf{H}_1\mathsf{m}^{-1}$. Within 1c.6, which treats averaging operators at complex configurations together with the gauge identities on which the propagators rest, the operator $Q_k^{\mathrm{st}}(\mathbf{U}) = \eta\, \mathbf{Q}(W_{k-1}) \cdots \mathbf{Q}(W_0)$, where $\mathbf{Q}(W)$ denotes the linear part of a single step, stands everywhere for the linear part of the straightened average, namely the $Q_k^{\sharp}(\mathbf{U})$ of §3 of the Notation; it is not the straight average defined in that section of the Notation.

In comparison with the Notation:

- R_1 denotes a number (as in **116**, p. 3) and not a region R_t.
- A cell means a cell of a walk, as opposed to a level-k cell of §9.
- The hull of a walk differs from the hull in a coarser partition.
- $\mathfrak{G}$ denotes an operator, not the gauge-fixing factor $\mathfrak{G}_k$.
- A is the fluctuation operator, which is written K in §5 of the Notation.
- $\Delta(y)$ is the block $B^j(y)$, regarded as a cube.
- $s(\square)$ is a parameter, not a depth.
- $\bar\kappa$ is the exponent in the radius of the parameters, the same $\bar\kappa$ as in the order of the constants fixed in the Notation. **116** and 1c.10 write this exponent as κ_1; that κ_1 is not the κ_1 of the Notation, which is the rate at which the large-field factor decays.
- $\gamma, \gamma^{\mathrm{pos}}$ are lower bounds, not ceilings on couplings.
- γ_0 is the radius of the current, which is also written α_0 in §11.
- λ denotes a site function (an infinitesimal gauge transformation); in statement 8 and in mechanisms (j), (k), however, it denotes a multiplier, that is, a function on rows.
- X denotes a localisation domain in statement 0, X_i is a cell, X in (I) is a function on rows, and X_χ is a gauge direction.
- A' is the complex factor of the triple $(U, A', \mathbf{J})$; the one exception is 1c.10, where, in the system of clause 1 of the Theorem (the decoupled response at complex parameters), it stands for the unknown $H_1(s)B' + \mathbf{A}$.
- S denotes, in statement 6, a set of coarse cubes and, in eq. 3.cdxliv, an operator; S denotes the operator $1 - DG'RD^{\mathsf{T}}$.

In 1c.10 the following further conventions hold:

- θ_0 denotes the decay rate with respect to $d_{\mathbf{B}}$; it is not one of the members of the sequence θ of §6.
- $\mathsf{r} = v[\mathbf{H}]$ is a function on the nodes with values in G, and not an isometry.
- β and $\beta_\natural$ denote a small real datum, not the bare inverse coupling.
- $\omega(\cdot)$ is the map that sends a field to its multiplier; it is not a walk.
- $\mathsf{E}_1 = G_1 DRD^{\mathsf{T}} G_1$ denotes an operator rather than an event.
- $P_1(s)$ is the operator built from the walk data of $D(1-R)D^{\mathsf{T}}$, and neither a region nor a momentum.

(ii) The principal statements. All constants depend only on L (and on Hölder exponents). There are two exceptions, and neither enters any localised bound, rate, weight or sum of weights. The first is the bound of statement 7, which serves only for convergence. The second is the entrywise bound of mechanism (i), which makes the family normal. The numbers γ, γ^{pos}, δ_0, δ_*, δ' are positive constants of this kind.

In statement 2 the side of the torus, measured in top units, is at least a small fixed multiple of R_1M_1; in the sentence of that statement which concerns a single lattice, it is at least C. From statement 4 onwards the side is at least CM_1. In 5, the single assignment of terms valid for all tori needs room for three cubes of side $O(M_1)$ in each direction. Statements 7, 8 need room for three cubes of side ℓ_{P}. These are lower bounds on the volume, and no constant depends on the volume except the bound of statement 7 just mentioned.

In what follows:

- $x \in \Delta(y)$, and the sources f lie near $\Delta(y')$;
- $\mathsf{e} = e^{-\delta_0 d_{\mathbf{B}}(y,y')}$, up to a fixed fraction of the rate;
- $\|\cdot\|_\varepsilon$ denotes a Hölder seminorm;
- kernels are taken with respect to the counting measure;
- on 1-forms, the covariant Laplacian is $\Delta_{\mathbf{U}} = \sum_\nu \nabla_\nu^{\mathsf{T}} \nabla_\nu$, where ∇_ν are the covariant differences of the components;
- $\Delta = \Delta_{\mathbf{1}}$ is the full vector Laplacian $\partial^*\partial + \partial\partial^*$, with $\partial = D_{\mathbf{1}}$. It acts componentwise and is not the $\Delta = \Delta_U^{\mathrm{W}}$ of the Notation, §5.

0. The domains of analyticity are contained in the classes. Consider a pair in the domain of an activity on $X \in \mathcal{D}_j$. Such a pair satisfies $|\partial U - \mathbf{1}|, |\partial \mathbf{U} - \mathbf{1}| < \alpha_0\eta^2$, $|A'|, |\nabla_U A'| < \alpha_1$ and $|\mathbf{J}| < \alpha_0$, and on cubes of side $O(LM)$ it admits real gauges with $|A|, |\nabla A| < O(LM)\alpha_0$. It is a regular pair for the tower of regions obtained from X by erosion (1b.8), and the radii with which it is regular are

$$(O(LM)\,\alpha_0,\, \alpha_1,\, \alpha_0).$$

Let a label be produced by steps in which each region Ω_n, $n \geq 1$, is a union of LM-cubes of level n. By a *layered domain* we mean a domain defined by the layered bounds of §4.17.1.1, *Structures*, whose radii do not exceed the running radii of the level of each layer. Only the following of these bounds enter. On the layer $\mathcal{L}_n$ of the label, $n \geq 1$, one has $|\partial U - \mathbf{1}|, |\partial \mathbf{U} - \mathbf{1}| < \alpha_{0,n}\eta^2\xi_n^{-2}$, $|\mathbf{J}| < \alpha_{0,n}\xi_n^{-3}$ and $\xi_n|A'|, \xi_n^2|\nabla_U A'| < \alpha_{1,n}$. The cubes of level n of the domain are the closed cubes of side $CM\xi_n$ that are contained in $\mathcal{L}_n \cup \mathcal{L}_{n+1}$ and meet Ω_{n+1}^c; on the part in X of each of them there is a real gauge with $\xi_n|A|, \xi_n^2|\nabla A| < CM\alpha_{0,n}$. Then on $X \cap \Omega_1$ a pair of a layered domain belongs to the local class of the *label sequence*, which is the sequence formed by the Ω_n of the label. The radii are $O(M)\max_n \alpha_{0,n}$ and $\max_n \alpha_{1,n}$, together with $\max_n \alpha_{0,n}$ for the current. In that class the gauge clause is derived for those cubes of level-n size which meet $\mathcal{L}_n$. For $n = 0$, on the cubes inside $\mathcal{L}_1$, it is derived from the gauge of a cube of level 1, which can be used at the index 0 since $\xi_0 < \xi_1$. The same remark applies to a cube of level-n size inside $\mathcal{L}_{n+1}$, because some cube of level $n+1$ of the domain contains it. This smaller cube is contained in Ω_{n+1}, intersects Ω_{n+2}^c, and its side is below $M\xi_{n+1}$. The derivation of the clause on the cubes meeting $\mathcal{L}_n$ uses no other property of a cube; hence repeating the same steps with the grids of level $n+1$ produces the larger cube. The factors $O(LM)$, $O(M)$ are the cost of the gauge clause, since on a cube of side $O(M)$ a gauge has $|A| \leq O(M)\alpha_0$. The field strengths are fixed after M.

1. The flat theorem. Let $\mathbf{U} = \mathbf{1}$, $\mathbf{J} = 0$, and let Q, Q' be the straight averages taken over the centred blocks. Then on every separated sequence

$$|\mathsf{G}_0 f|, |\nabla \mathsf{G}_0 f|, |\mathsf{G}_0 \nabla^* f|, |\Delta \mathsf{G}_0 f|\,(x) \leq C[\xi_y^2, \xi_y, \xi_y, 1]\,\mathsf{e}\,|f|,$$
$$|\nabla \mathsf{G}_0 \nabla^* f(x)| \leq C_\varepsilon\,\mathsf{e}\,(\xi_{y'}^\varepsilon \|f\|_\varepsilon + |f|),$$

together with matching bounds in Hölder and L^2 norms. The same bounds hold for G', and

$$|(Q'G'^2Q'^*)^{-1}(y,y')| \leq C\xi_y^{-4}\mathsf{e},$$

$$|(Q\mathsf{G}_0Q^*)^{-1}(c,c')| \le C\xi_c^{-2}\mathsf{e},$$
$$|\mathsf{H}(b,c)|, |\nabla\mathsf{H}(b,c)| \le C[1,\xi_y^{-1}]\mathsf{e},$$

$$Q\mathsf{G}_0Q^* \ge \gamma\,\xi_c^2,$$
$$\langle B, [(Q\mathsf{G}_0Q^*)^{-1} - a]B\rangle \;\ge\; c\,L^{-5}\|B\|^2$$

for every B with three properties: it lives on the bonds of $\mathbb{T}^{(k)}$ that touch a union of L-blocks lying well inside Ω_k; its straight one-step average vanishes; and it vanishes on the axial trees of the blocks. Each block has one such tree. It consists of the contours joining the site $y \in \mathbb{T}^{(k+1)}$ of the block to each of its points x, along which the coordinates are changed successively, always in the same fixed order. The gauge so defined is the strict axial gauge, which is a hard gauge fixing. It is not the block axial gauge (Notation, §3), where the means $V(y,x)$ over contour families are all equal to $\mathbf{1}$. For the plain one-step constraint, in that gauge or on trees, the lower bound is proved again in 1c.8. If the gauge condition is dropped, the form has null directions.

2. Real backgrounds with Bałaban's average. Let Q, Q' be formed with one contour per site and moved to centred blocks by a translation. Let the Hessian be the compressed one. Let U be real, with local gauges and with small plaquettes; for G_0 this includes the plaquettes that stick out of Ω_0. Then $\Delta_U + Q'^*aQ'$, $Q'G'^2Q'^*$ and G_0^{-1} are positive. The operators $G', \nabla G', \mathsf{G}_0, \nabla\mathsf{G}_0, (Q'G'^2Q'^*)^{-1}$ satisfy the bounds of 1 for every Ω_0, including a collar of Ω_1 and a concentric cube. On a single lattice, and for U with $|\partial U - \mathbf{1}|, |D_U^*\partial U| < \alpha\eta^2$, where α is small, also $Q\mathsf{G}_0Q^* \ge \gamma > 0$, and $\mathsf{G}_0Q^*(Q\mathsf{G}_0Q^*)^{-1}$ is a right inverse of the linearised constraint; this right inverse and its gradient decay like $e^{-\delta_*|y-y'|}$. The rows of $\mathcal{M}$ agree with these rows up to a transport and an error $O(\alpha_0)$ in the row and column norms, uniformly in the level. Statements 3–8 concern different operators, built from the rows of $\mathcal{M}$ and the Hessian of the inner plaquettes. At $\mathbf{1}$ the two kinds of rows coincide.

3. The averages and the gauge identities. The operators Q, Q' are local and holomorphic in $\mathbf{U}$. Their row sums are $\le 1 + C(\alpha_0 + \alpha_1)$ and their entries are $\le C(\eta/\xi_c)^4$, independently of the number of levels. At each row the non-linear average is holomorphic in (A', A) on a polydisc $\sup|A'|, \sup|A| < r_L$, where r_L is determined by L and measured in units of the row's level. Fix a bond of $\mathbb{T}^{(k)}$, and write $\delta/\delta A_b = \eta^{-4}\partial/\partial A(b)$. Let $\mathcal{Q}_n^{\mathrm{st}}$ be the n-fold straightened average, and let v_n be the accumulated site factors belonging to it. Then on this polydisc

$$\Big|\frac{\delta\mathcal{Q}(A)(c)}{\delta A_b}\Big| \le 1 + C(\alpha_0 + \sup|A'| + \sup|A|),$$
$$\Big|\frac{\delta(\mathcal{Q} - \mathsf{m}Q)(A)(c)}{\delta A_b}\Big| \le C\sup|A|,$$
$$\mathcal{M}^n(e^{i\eta A}\mathbf{U}) = \big(e^{i\mathcal{Q}_n^{\mathrm{st}}(A)}\mathcal{M}^n\mathbf{U}\big)^{v_n}.$$

Let $\bar{D}$ be the covariant difference of $\mathcal{M}^j\mathbf{U}$ on $\mathbb{T}^{(j)}$. At a row of level j, let $Q'\lambda$ denote the j-fold average taken at both ends of the row. For an outward row, the outer end is a top of level $j-1$, not a top of level j. Then

$$QD\lambda = \bar{D}Q'\lambda,$$
$$\Delta_{\mathbf{U}}^{\mathrm{W}} - \Delta'_\pi[J(\mathbf{U})] = \mathsf{S}^{\mathsf{T}}\Delta_{\mathbf{U}}^{\mathrm{W}}\mathsf{S},$$
$$\mathsf{G}_{(1)}DR = DG'R + \mathsf{G}_{(1)}\Delta'_\pi[\mathbf{J} - J(\mathbf{U})]DG'R.$$

On shell, the defect is zero, $RD^{\mathsf{T}}\mathsf{H}_{(1)} = 0$, and $\mathsf{H}B$ is a critical point of $\frac{1}{2}(A, \Delta_{\mathbf{U}}^{\mathrm{W}} A)$ on $\{QA = B,\ RD^{\mathsf{T}}A = 0\}$, with critical value $\frac{1}{2}(B, [(Q\mathsf{G}Q^{\mathsf{T}})^{-1} - a]B)$.

4. The six propagators at regular pairs. The ceiling on the radii $\alpha_0, \alpha_1, \gamma_0$ is fixed before M_1 and is **independent of** M_1. At every regular pair all the inverses exist, they are holomorphic in $(\mathbf{U}, \mathbf{J})$, and they are real at real pairs. At real pairs $\mathsf{G}_0, \mathsf{G}, \mathsf{G}_1 > 0$, both on shell and off shell. The six propagators and $(Q'G'^2Q'^{\mathsf{T}})^{-1}$ satisfy the upper bounds of 1 with covariant differences, and G and G_1 satisfy those of G_0. The exception is the bound on $\Delta_{\mathbf{U}}\mathsf{G}_{(1)}$, and the Hölder quotients are taken only over $|x - x'| \le \xi_y$. For G' at complex pairs the bounds reduce to the supremum bounds on $G'f$ and $DG'f$. Moreover $|D(1-R)D^{\mathsf{T}}(b, b')| \le C(\eta/\xi_{y'})^4 \xi_y^{-2} \mathsf{e}$.

5. Walk expansions. Let O be any of the following operators:

- one of the six propagators;
- $1 - R$ or one of its derivatives;
- $\mathfrak{G}$;
- Bałaban's $H_0, \tilde{G}$, namely $\mathsf{H}\mathsf{m}^{-1}$ and $\mathsf{G} - \mathsf{H}Q\mathsf{G}$ at $\mathbf{J} = 0$;
- $C^{(k)}(Y)$ or $\chi_Y \mathsf{A} \chi_Y$, these two taken at the pairs that are regular for the longer sequence $(\Omega_j)_{j \le k+1}$, where M_1 is larger and the ceiling on the radii is smaller than in 4.

For $\tilde{G}$ the indices are the walks together with the pairs of walks in which the second walk starts at a cell that a row joins to some cell of the first walk, its cells being placed after those of the first. In the display, $|\omega|$ is then the total length of the two walks, and the step that joins them contributes no small factor. Each such operator is then a sum $\sum_\omega \mathsf{O}_\omega$, where, in the norms in which O is bounded,

$$\|\mathsf{O}_\omega\| \le (\text{bound of } \mathsf{O}) \cdot (C M_1^{-1/2})^{|\omega|} M_1^{-|\omega|/2},$$

$$d_{\mathbf{B}}(y, y') \text{ replaced by } d_{\mathbf{B}}(\omega; y, y').$$

The first factor makes the sum over the walks converge. The second factor is left over, and it absorbs the factor $|\omega| + 1$ of mechanism (i). The bounds of O are as follows:

- For $\mathfrak{G}$ and $\tilde{G}$ there are exactly four: the bounds on $|\mathsf{O}f|$, $|\nabla \mathsf{O}f|$, $|\mathsf{O}\nabla^{\mathsf{T}} f|$ and on the Hölder seminorm of $\nabla \mathsf{O}f$ that 4 provides for G, G_1. For $\tilde{G}$ they hold with a smaller fraction of δ_0.
- For $1 - R$ and for its derivatives $D(1-R)$, $(1-R)D^{\mathsf{T}}$, $D(1-R)D^{\mathsf{T}}$, the relevant bounds are the kernel bounds $C(\eta/\xi_{y'})^4 [1, \xi_y^{-1}, \xi_y^{-1}, \xi_y^{-2}]\, \mathsf{e}$. The last of these is displayed in 4.
- For $\chi_Y \mathsf{A} \chi_Y$, the bound is the kernel bound that 6 states for $C^{(k)}(Y)$.

Each O_ω has the following properties:

- it is holomorphic on the local class on $[\omega]$;
- its dependence on the regions is through their traces on $[\![\omega]\!]$ alone;
- it is gauge covariant and real at real pairs;
- it is **the same function** for any two sequences, tori or cutoffs that a *shift*, namely a translation in $M_1 \xi_k \mathbb{Z}^4$, relates on the hull of (i), *Walks*, which is the set just named; in the Notation, §5, this hull is called the surroundings of ω. For $C^{(k)}(Y)$, $\chi_Y \mathsf{A} \chi_Y$ the translation is in $M_1 \xi_{k+1} \mathbb{Z}^4$ and must also carry Ω_{k+1} and Y.

The operators are covariant under every isometry that preserves $\mathbb{T}^{(k)}$ and the regions, using the induced action on each of their input and output spaces. At a reversed bare bond b this action sends $A(b)$ to $-\operatorname{Ad}(\mathbf{U}(b)^{-1})A(b)$. At a reversed row or coarse bond c of level n, it instead sends $B(c)$ to $-\operatorname{Ad}(V_n(c)^{-1})B(c)$, where $V_n(c) = (\mathcal{M}^n \mathbf{U})(c)$ is the actual level-n average; in particular, the covariance and fluctuation operators on level k use V_k. Site slots are transported without an orientation factor. These formulas act on the independent positively oriented tangent coordinates. The skew extension $\nu(\bar{c}) = -\nu(c)$ within a fixed choice of orientation remains a separate convention. Thus an operator from one slot to another transforms as $\mathsf{r}_{\mathrm{out}} \mathsf{O} \mathsf{r}_{\mathrm{in}}^{-1}$. For a term evaluated at a pair

given only on its carrier, every nonzero kernel entry has the complete averaging reads needed to form both orientation factors. The transformed kernel is zero at zero entries; filling undefined averages outside those reads by arbitrary elements of G^c does not change it. The maps preserve the complex bilinear pairings: $\mathrm{Ad}(g)^{\mathsf{T}} = \mathrm{Ad}(g^{-1})$, and the isometry preserves each row's level and hence its cell weight. Accordingly the same transformation law applies to the declared transposes, with either physical or counting row measure, without an additional density factor. At complex pairs this is a bilinear identity, not a claim that the action preserves the norm. For $C^{(k)}(Y)$, $\chi_Y \mathsf{A} \chi_Y$ the isometry must also preserve $\mathbb{T}^{(k+1)}$ and Ω_{k+1}, and Y is carried along. Pivot bonds go to pivot bonds, since each pivot bond is the middle bond of its path. For single terms the covariance holds only under those isometries which in addition preserve the M_1-cubes of the top level. For $C^{(k)}(Y)$, $\chi_Y \mathsf{A} \chi_Y$ that level is $k+1$, and in the strict axial gauge the isometry must also preserve the axial trees. This covariance holds at the pairs whose image again lies in the class.

(iii) The strategy.

The chain. The parts have the following content.

- 1c.1 (the operators and the statements about them) fixes the operators, the classes and the form of the statements. It counts the walks and derives statement 0. It also shows that the identification of A at the step reduces to Bałaban's expansion of the background action.
- 1c.2 (the flat case, I) states the flat theorem and compares it clause by clause with the published statements. It also contains the exact algebra at $\mathbf{1}$: existence, identities with boundary terms, and the independence of R and H from Ω_0.
- In 1c.3 (the second flat case) the one-scale operator is treated uniformly in the spacing; then come G', $(Q'G'^2Q'^*)^{-1}$ and R.
- In 1c.4 (the flat case, III) the local two-scale operators are treated, followed by G_0, $(Q\mathsf{G}_0Q^*)^{-1}$ and H. With this, statement 1 is complete.
- 1c.5 (Bałaban's theorems in a background) yields statement 2. On the whole lattice it comes from the published theorems; on sequences it comes from the flat case, by a shortened form of mechanism (f).
- 1c.6 (the averaging operators at complex pairs; the algebraic identities) yields statement 3.
- 1c.7 (the six propagators) uses mechanisms (f), (g) to derive, from the flat bounds and 1c.6, statement 4 and the expansions of 5.
- In 1c.8 (the covariance; positivity) these two mechanisms are applied to a larger system. This yields statement 6, except for the expansion of A over sets of coarse cubes.
- In 1c.9 (walk expansions as data) an expansion is regarded as a datum enjoying the short list of properties of 7. Statement 7 is deduced from these properties together with the geometry. Moreover, 1c.9 *makes* terms that are real, covariant and identical on all tori with room; these properties do not follow from the list.
- 1c.10 (the decoupled response) takes the operators as data and solves the systems (I), eq. 3.cdxliv. Next it inserts the local maps and operators of 1c.6–1c.9; for $\mathfrak{G}$ and $D(1-R)D^{\mathsf{T}}$ the inserted data are those named at the end of 7. Last, it treats the case $s \equiv 1$.

The order of § 3.11 and § 3.12.1, which involves no circle. None of statements 1–7 mentions a background of § 3.11, since the classes are defined by inequalities. The results are obtained in the following order:

- the geometry and the real calculus of $\mathcal{M}$ (1b.1–1b.2);
- the flat case;
- the lemmas of 1b.3 that are geometric or algebraic (folding, cells and rows, the algebra of Q', Q, R, sums over tops, weights for a general metric), and none of them uses any bound on a propagator;
- 1c.5;

- the rest of 1b.3; then existence, regularity (which provides the backgrounds of § 3.11 with their local gauges) and continuation (1b.4–1b.6);
- 1c.6–1c.9. Their inputs are the flat case, the alignment of the blocks in 1c.5, and 1b.1–1b.2, together with, besides these, geometric facts in which neither a propagator nor a background of § 3.11 enters (meets of sequences; the covariance of $\mathcal{M}$ with respect to the isometries of the lattice);
- the decay of the response, and the membership in the classes of the backgrounds of § 3.11 (1b.7–1b.9);
- finally, the identification at $s \equiv 1$.

Mechanisms.

(a) **The metric matches the mass.** The form satisfies $\langle \lambda, (\Delta + Q'^{*} a Q')\lambda\rangle \geq \gamma \sum_j \xi_j^{-2} \|\lambda\|^2_{\mathcal{L}_j}$, and on each layer $d_{\mathbf{B}}$ has slope ξ_j^{-1}. A single conjugation by $e^{\varsigma\varphi}$, with φ Lipschitz with respect to $d_{\mathbf{B}}$ (Combes–Thomas), therefore serves for all layers at once. It costs $O(\varsigma L^2)$, and this cost stays below γ under a ceiling on the rate, $\varsigma \leq c\gamma L^{-2}$, where L is chosen first. Every layer that has to be traversed in full costs the gap, that is, the separation of the boundaries of consecutive regions, which exceeds $R_1 M_1$ when measured in the unit of that layer; thus $d_{\mathbf{B}}(y, y') \geq R_1 M_1 (|j - j'| - 1)_+$. Let a rate $\tau > 0$ and a power $q \geq 0$ be given, and choose the product $R_1 M_1$ after them so that $\tau R_1 M_1 \geq C(1+q)\log L$. Then

$$\sum_{y'} e^{-\tau d_{\mathbf{B}}(y,y')} \leq C(\tau, L),$$

$$(\xi_{y'}/\xi_y)^q \leq L^q e^{\tau d_{\mathbf{B}}(y,y')} :$$

the factor $e^{-c\tau R_1 M_1}$ for each level outweighs the growth L^4 in the number of sites. Conjugation and walk expansions do different work. Conjugation yields decay of the inverse as a whole, and it requires no cube size to be large; its rate is a fraction of the spectral gap, which is the lower bound γ of the form. A walk expansion gives, in addition, a sum of terms, each of which depends on the background and on the regions only near its own walk. This property is what statements 5–8, the comparison of tori and § 4.5 make use of. Both methods are used. Conjugation serves for the scalar, one-scale and local operators and for the inverses on tops and rows. Walks serve for the assembly, namely of G_0 in (d) and of the propagators in a background in (f). In **95**, p. 36, Bałaban describes conjugation as "probably the simplest proof" of the decay; he builds a walk representation instead, since "such representations will be our basic tool in investigation of more complicated operators".

(b) **No Dirichlet condition on a lattice finer than the blocks.** Because of the gap that separates Ω_0^c from Ω_1, $\partial\Omega_0$ lies in $\mathcal{L}_0$. On that layer $Q = Q' = 1$ and the gauge term is zero, and the local operator $G_\square$, which inverts the form on a cube $\square$ (see (d)), obeys $a_0 \leq \eta^2 G_\square^{-1} \leq a_0 + 16$. Finite range together with a mass comparable with the norm gives decay for an arbitrary set of bonds. The following examples show that this placement of the boundary matters. Let G be a one-scale operator (spacing η, unit blocks) whose order is ≥ 1, with Dirichlet conditions imposed outside a union of *whole* blocks, so that the lattice is finer than the blocks and no block is cut. Two examples, a flat face and a re-entrant edge, rule out constants uniform in the order, by powers of η^{-1}. This applies to the L^2 bounds on second differences, to the bounds on ΔG, to those on ∇G and to its Hölder norm. It applies equally to the pointwise bound and to the Hölder bound involving $\nabla G \nabla^*$, taken in the form of statement 1, the powers being those that occur for ∇G and for its Hölder norm. Indeed, on the region every bounded f supported in a block can be written as $\nabla^* F$ with $F = \nabla \Delta^{-1} f$, where Δ^{-1} denotes the free inverse on $\eta\mathbb{Z}^4$ (on a torus, the inverse on functions of mean zero, after f has been modified on a block lying outside the region); moreover $|F|, \|F\|_\varepsilon \leq C_\varepsilon \sup|f|$ uniformly in η, and the sum over the blocks is controlled by the exponential

factor in the bound. For the L^2 bound involving $\nabla G \nabla^*$, by contrast, the two examples rule out no uniform constant. On a separated sequence no operator of this kind arises.

(c) **One scale, two scales.** Uniformity in η comes from two sources. The first is the representation $(\Delta+1)^{-1} = \int_0^\infty e^{-t} e^{-t\Delta} dt$, combined with heat-kernel bounds that hold both below and above $t = \eta^2$. The second is a factorisation of $\partial(1-R)\partial^*$ through the unit lattice. At a seam one makes an exact change of gauge $A = A_2 + H_j B - \partial H_j' \vartheta$. Here $A_2 \in \ker Q_j$, and B is a 1-form on the coarse lattice whose values on the axial trees of the L-blocks of the coarse region are zero. Further, ϑ is a site function on the coarse lattice, supported in the coarse region, whose mean over every one of those blocks is zero; for these two classes the representation is unique. Finally, H_j, H_j' are the one-scale minimisers, with H_j' the minimiser of $\|\Delta\lambda\|^2$ rather than of $\|\partial\lambda\|^2$. This change of gauge splits the form orthogonally into three parts: a form in A_2, a form in B and a form in $\vartheta - \vartheta_1$, where ϑ_1 is linear in A_2 and B. If the coarse region is all of the torus, the two-scale representation of the inverse of the form so obtained becomes a recursion $G_j \to G_{j+1}$, where G_j denotes the one-scale propagator of order j. It is applied for a single step and is never iterated. In the scalar theory, recursions of this kind add up to a series over the scales, and they served as the method of proof of regularity (**89**, (2.34)). Here G_j occurs multiplied by other operators. Iteration then leads to long products of operators whose gauge conditions are not the same at different scales (a remark of Bałaban, **96**, pp. 246–247). For gauge propagators, accordingly, no series over the scales is employed; instead the one-scale G_j has to be known simultaneously for all j (1c.3). Three spectral gaps on the unit lattice take the place of a small parameter. The sharp one is stated for B on a unit lattice that vanishes on the axial trees. In it, Q_1 and ∂_1 are the straight one-step average and the exterior derivative; the $Q_1(\mathbf{1})$ of the Notation, §3, also contains site terms. The sharp gap reads

$$L^2 \sum_c |(Q_1 B)(c)|^2 + \sum_p |(\partial_1 B)(p)|^2 \geq c L^{-5} \|B\|^2.$$

(d) **Many scales at 1.** No expansion of G' is required. For $u = G'(f + \nabla^* F)$ the conjugation of (a) yields

$$\|\xi^{-1} e^{\varsigma\varphi} u\| + \|e^{\varsigma\varphi} \nabla u\| \leq C\gamma^{-1} (\|\xi e^{\varsigma\varphi} f\| + \|e^{\varsigma\varphi} F\|)$$

, where ξ denotes multiplication by the local scale. From this one passes to local L^2 norms, and then to interior estimates at the scale ξ_y, with the mass term treated as a source. The walk expansions are obtained afterwards, as data. For G_0 we take $\sum_\square h_\square^2 = 1$, with $\zeta_\square = 1$ near $\operatorname{supp} h_\square$, and we let $G_\square$ be the inverse, on the periodised cube $\square$, of the form of (c), taken with one scale or with two. For the cubes of level 0 that extend beyond Ω_0, $G_\square$ is instead the operator of (b). For a cube of level ≥ 1 the periodic two-scale model is retained, irrespective of where Ω_0^c and the finer layers lie; this is legitimate since across the two seams to $\mathcal{L}_j \cup \mathcal{L}_{j+1}$ the function $h_\square$ is cut off. With $P = 1 - R$ and $\mathcal{P} = \partial P \partial^*$ one has

$$\mathsf{G}_0^{-1} \sum_\square h_\square G_\square h_\square = 1 - \mathcal{R},$$

$$\mathcal{P} h - h \mathcal{P}_\square = \zeta [\mathcal{P}_\square, h] + \zeta(\mathcal{P} - \mathcal{P}_\square) h + (1-\zeta)\mathcal{P} h :$$

of all these operators, only the non-local $\mathcal{P}$ cannot be transplanted. Each commutator costs M_1^{-1}, because $|\nabla h| \leq C(M_1 \xi_j)^{-1}$ stands against $|\nabla G_\square| \leq C\xi_j$. The change of domain costs e^{-cM_1}; this follows from resolvent identities on the two domains, recombined by means of $1 - P = R$. The tail is likewise exponentially small, and it is turned into a step $\square \to \square'$ by means of $\sum h_{\square'}^2 = 1$. The factor M_1^{-1} for each step outweighs the number $C(\tau, L)$ of neighbours.

Lower bounds independent of the number of levels underlie the inverses on tops and rows. The bound $Q'G'^2Q'^* \geq \gamma\xi_y^4$ follows by duality with test functions ψ_y on the blocks, with $Q'\psi_y = \delta_y$, whose second differences are $\leq C\xi_y^{-2}$, across the faces as well. The bound $Q\mathsf{G}_0Q^* \geq \gamma\xi_c^2$, with γ independent of L, follows from a right inverse E for all rows of all levels at once. This right inverse has scale-invariant energy, $\|\nabla\mathsf{E}B\|^2 \leq C\|\mathsf{m}^{-1}B\|^2$. The construction below gives the finite energy lift for the cornered-comb rows. Applying its estimate to the actual averaged rows requires the row comparison and the indicated pairing change. In 2, where there is a single lattice, the test forms are placed on the face separating the two blocks of a bond; there the share $\theta_0 > \frac{1}{2}$ of its own chains outweighs $1 - \theta_0$. Neither matrix is bounded below by a number independent of the scales ξ. They are therefore rescaled, to $\Sigma = \xi^{-2}Q'G'^2Q'^*\xi^{-2}$ or $\xi^{-1}Q\mathsf{G}_0Q^*\xi^{-1}$. A matrix $\Sigma \geq \gamma$ with $|\Sigma| \leq Ce^{-\tau d_{\mathbf{B}}}$ then satisfies $|\Sigma^{-1}| \leq 2\gamma^{-1}e^{-\tau' d_{\mathbf{B}}}$, where τ' is small compared with the spectral gap γ (Combes–Thomas, Schur). Thus both inverses decay without any expansion, and H decays column by column. A sequence is compared with the same sequence cut down around a cube. The cut-down sequence is again separated and coincides with the given one on the doubled cube, and its $Q\mathsf{G}_0Q^*$ provides the local operators that enter the walk expansion of $(Q\mathsf{G}_0Q^*)^{-1}$. The comparison uses Green's identity with a cut-off, by way of $(\partial^*\partial + Q^*aQ)\,\mathsf{G}_0Q^* = Q^*$, and the gauge term vanishes on the columns.

3.12.1.3. An energy-bounded lift of all determining rows. The row estimate used to invert the coarse Schur operator has a finite construction. It is useful to retain the distinction between the cornered-comb rows used in this construction and the differential of the averaged nonlinear constraint. Write $Q_{\mathrm{c}}^+ = (Q_j^{\mathrm{c}}|_{\widehat{\Gamma}_j})_j$ for the former, with all inward rows retained in $\widehat{\Gamma}_j$. Its output is a raw row logarithm, with the counting pairing $\sum_c\langle\omega(c), b(c)\rangle$. In particular, $Q_0^{\mathrm{c}}A = \eta A$. Fine fields have the pairing $\eta^4\sum_b\langle A(b), A'(b)\rangle$. The rows here are the linear parts of the iterated cornered-comb average, with the endpoint factors kept in its nonlinear factorization. They are not the response operator of the critical background.

Assume $L \geq 13$, the separated aligned geometry of eq. 3.ccciii–eq. 3.ccciv, with gap at least $L^2\xi_j$, and a real background satisfying

$$|\partial U(p) - 1| \leq \alpha\eta^2\mathsf{L}(p)^{-2}.$$

The required smallness threshold for α depends on L, but not on the depth. In the construction below all norms of row matrices are the counting ℓ^2 norms.

For a positive row c of level $j \geq 1$, choose its endpoint y_c in the level-j layer. Put $N = L^j$, $n = (N-1)/2$, and $w = \lfloor N/8\rfloor$. In integer coordinates P_ν measured from the lowest corner of $B^j(y_c)$, set

$$\begin{aligned} h(P) &= (w - |P - n|)_+, \\ \varphi_\pm(P) &= (w - |P - (n \pm w)|)_+, \\ g^+(P) &= (n+w)\varphi_+(P) - (n-w)\varphi_-(P), \\ g^-(P) &= (n+w+1)\varphi_-(P) - (n-w+1)\varphi_+(P). \end{aligned}$$

The sign is positive when $y_c = c_-$, and negative otherwise. For a bare bond b in the direction μ of c, define

$$\psi_c(b) = \frac{N^3}{2\eta w^9} g^{\pm}(P_\mu(b_-)) \prod_{\nu\neq\mu} h(P_\nu(b_-)),$$

and set it equal to zero on the other bonds. Transport a row vector to b_- along the cornered comb in this cell; for a negative row first transport it along the straight segment to that corner. The resulting test form is denoted by $Z_c e$. At level zero put $Z_c e = \eta^{-1}e$ on c, and zero elsewhere. Set $Z\omega = \sum_c Z_c\omega(c)$ and $\Theta = Q_{\mathrm{c}}^+ Z$.

The profiles are supported a positive fraction of the cell width away from its faces. Extending them by zero introduces no jump across a cell face. The identities

$$\sum_P h(P) = w^2,$$
$$\sum_P g^+(P)(P+1) = \sum_P g^-(P)(N-1-P) = 2Nw^3,$$
$$\sum_P g^+(P)(N-1-P) = \sum_P g^-(P)(P+1) = 0$$

follow by summing each triangular profile about its center. These are the two moments needed for the positive and negative rows at one site. The chain multiplicities in the cornered comb are $P+1$ and $N-1-P$, respectively. Thus at a flat field the test forms are biorthogonal to the rows at the same level.

For a small-curvature field, comparing each chain transport with the cornered comb changes this calculation by $O_L(\alpha)$. There are at most sixteen nonzero entries in each row and eight in each column of the same-level error. Decreasing the curvature threshold gives

$$\Theta = D_0 + N_0, \qquad \|D_0 - 1\| \le \frac{1}{48}, \qquad \|N_0\| \le \frac{288}{L} < 23, \qquad N_0^2 = 0. \tag{3.cdxxxv}$$

Here D_0 preserves the level and N_0 raises it by one. To check the last two assertions, a level-j test form can be read at a higher level only by an outward row of level $j+1$. Its entry has size at most $36L^{-3}$; at most $8L^4$ entries occur in one row and at most eight in one column. The Schur test gives $288/L$. Two consecutive upward transitions would place Ω_{j+2} within $(1+(L-1)/2+L)\xi_{j+1} < L^2\xi_{j+1}$ of Ω_{j+1}^c, contrary to separation. Downward transitions vanish because the supports avoid the outer sheet of each cell. This proves the asserted form and nilpotence.

Proposition 3.35 (A lift in the energy norm)**.** For sufficiently small α, there is a right inverse $Z^\sharp$ of Q_{c}^+ satisfying

$$Q_{\mathrm{c}}^+ Z^\sharp = 1, \qquad \mathcal{N}(Z^\sharp\omega) \le 48^2 c_Z \|\omega\|_2^2, \qquad c_Z = 21 \cdot 18^{12}.$$

Here

$$\mathcal{N}(A) = \|DA\|_{2,\sim}^2 + \|D^*A\|_2^2 + \|\mathsf{L}^{-1}A\|_2^2 + \|Q_{\mathrm{c}}^+ A\|_2^2.$$

The first term is the usual inner-plaquette energy together with $\eta^2 \sum_p (\sum_{b\subset\partial p} |A(b)|)^2$ over plaquettes which meet an inner bond and are not inner plaquettes. All constants are uniform in the depth and admitted torus. ∎

Proof. Since $N_0^2 = 0$, the exact factorization is

$$\Theta = (1+N_0)\{1 + (1-N_0)(D_0-1)\}.$$

The perturbation in braces has norm at most $24/48 = 1/2$. Its Neumann inverse therefore has norm at most two, and $\|\Theta^{-1}\| \le 48$. Notice that the inverse is

$$\Theta^{-1} = \{1 + (1-N_0)(D_0-1)\}^{-1}(1-N_0).$$

The same-level error must be included at a curved field.

For completeness, the energy estimate is local. The profile bounds and the curvature comparison give

$$|Z_c e| \le \tfrac{1}{2} 18^5 \xi_j^{-1} |e|, \qquad |\nabla_U Z_c e| \le 18^6 \xi_j^{-2} |e|.$$

A cell contains N^4 sites and has physical volume $\eta^4 N^4 = \xi_j^4$. At most two rows of each direction are assigned to one cell. The curl, divergence and weighted field terms consequently contribute at most $20 \cdot 18^{12} + 2(18^5/2)^2$ times the squared row norm. The level-zero terms obey the smaller bounds 24, 16 and 1. Disjoint cell cores prevent sums over different levels in this calculation.

Finally $\|Q_{\mathrm{c}}^{+}Z\omega\|_2^2 = \|\Theta\omega\|_2^2 \le 625\|\omega\|_2^2$. Adding the estimates gives $\mathcal{N}(Z\omega) \le c_Z\|\omega\|_2^2$. Take $Z^\sharp = Z\Theta^{-1}$. □

This lift also gives the lower bound for the coarse Gram operator. Suppose the real positive operator G_0 is defined by the Wilson Hessian, its specified gauge term and the retained row penalty, and suppose its form obeys

$$\langle A, G_0^{-1}A\rangle \le C_E\mathcal{N}(A).$$

For the inner Wilson Hessian one can take $C_E = 1 + 19C_{4,\mathrm{svar}}$, where $C_{4,\mathrm{svar}}$ is the constant in its local curvature-remainder estimate. With $\gamma_Q = (48^2 C_E c_Z)^{-1}$, Cauchy–Schwarz gives

$$\begin{aligned}\|\omega\|_2^2 &= \langle G_0^{-1}Z^\sharp\omega, G_0(Q_{\mathrm{c}}^{+})^*\omega\rangle \\ &\le \gamma_Q^{-1/2}\|\omega\|_2\langle\omega, Q_{\mathrm{c}}^{+}G_0(Q_{\mathrm{c}}^{+})^*\omega\rangle^{1/2}.\end{aligned}$$

Thus $Q_{\mathrm{c}}^{+}G_0(Q_{\mathrm{c}}^{+})^* \ge \gamma_Q$. This conclusion uses positivity of the specified fine operator; the right inverse by itself does not prove that positivity.

Removing inward rows is restriction in the counting row space. The lift and the Gram estimate restrict with the same constants. Their use for the averaged constraint additionally requires the comparison of its rows and endpoint transports with the cornered-comb rows. Their use for a current-corrected inverse requires the corresponding form comparison. Neither comparison is an identification of this lift with the derivative of the nonlinear background map.

For the scale convention in this section, the row pairing is weighted by m^4, where $\mathsf{m}(c) = \xi_c$. If $\widehat{Q}$ is the raw operator and $Q = \mathsf{m}^{-1}\widehat{Q}$, then $Q^* = \widehat{Q}^{\mathsf{T}}\mathsf{m}^3$, with $\widehat{Q}^{\mathsf{T}}$ taken in the counting row pairing. Thus multiplication by m^2, which identifies the weighted row Hilbert space with the counting row space, conjugates QG_0Q^* to $\mathsf{m}(\widehat{Q}G_0\widehat{Q}^{\mathsf{T}})\mathsf{m}$. This is the source of the two factors of the local spacing in the target Gram lower bound. The constants from the energy comparison must also have the uniformity required for the intended application.

3.12.1.4. From comb rows to the averaging constraint. The row lift above applies first to a specified linear family. We describe the change to the straightened mean constraint, including its error at the reference field. Throughout this comparison the reference configuration U_0 is real, the regions satisfy the separated-layer hypotheses, and all local boxes used by an average are admitted boxes. Constants depend on L, and the smallness and separation thresholds are fixed independently of the number of layers.

Write Q_{c}^{+} for the raw cornered-comb rows on all retained positively oriented bonds and Q_{c} for their restriction to the interior and outward bonds. The pairing of raw rows is counting measure. The fine-field pairing has weight η^4, and the site pairing on tops has weight ξ_y^4. In these conventions the comparison at level j reads

$$Q_{\mathrm{m},j} = T_j(Q_{\mathrm{c},j} + E_j), \qquad Q'_{\mathrm{m},j} = T'_j(Q'_{\mathrm{c},j} + E'_j). \tag{3.cdxxxvi}$$

Here $T_j\omega(c) = \mathrm{Ad}(t_j(c_-))\omega(c)$ and $T'_j\mu(y) = \mathrm{Ad}(t_j(y))\mu(y)$, with transports of U_0 in the appropriate local boxes. They preserve the indicated real pairings. The field-row error vanishes outside the double block under c, and

$$\sum_b |E_j(c,b)| \le \kappa_F\alpha_0\xi_j, \qquad \sum_{c\in\Gamma_j^{+}} |E_j(c,b)| \le \kappa_F\alpha_0\eta^4\xi_j^{-3}, \tag{3.cdxxxvii}$$

$$|E'_j\lambda(y)| \le \kappa_F\alpha_0 \max_{B^j(y)}|\lambda|.$$

At level zero these errors vanish. At higher levels, the curvature bound on the double block is $L^2\alpha_0 L^{-2j}$. The local comparison of the two averages gives the first bound and the corresponding bound for each kernel entry. A fine bond belongs to at most eight such rows at a fixed level, which gives the second bound. In level-j units the field is $\xi_j A$, so the row and column bounds become $\kappa_F\alpha_0$ and $\kappa_F\alpha_0(\eta/\xi_j)^4$, respectively.

The positive fine operator used for the comb Gram estimate is

$$G_{\mathrm{c}}^{-1} = \Delta_{U_0}^{\mathrm{W}} + B + DR_{\mathrm{c}}D^* + Q_{\mathrm{c}}^*Q_{\mathrm{c}}, \qquad R_{\mathrm{c}} = \mathrm{proj}_{\Delta_{U_0}\ker Q_{\mathrm{c}}'}. \tag{3.cdxxxviii}$$

The boundary operator B is positive and symmetric, its kernel joins only bonds of a common non-inner plaquette, and its row sums are at most $12\eta^{-2}$. The projection in eq. 3.cdxxxviii is taken in the fine site pairing. The scale-weighted comb propagator estimates give

$$M_{\mathrm{c}} = Q_{\mathrm{c}}G_{\mathrm{c}}(Q_{\mathrm{c}})^* \geq \gamma, \qquad H_{\mathrm{c}} = G_{\mathrm{c}}(Q_{\mathrm{c}})^*M_{\mathrm{c}}^{-1}, \qquad Q_{\mathrm{c}}H_{\mathrm{c}} = 1, \tag{3.cdxxxix}$$

and the scale-weighted bounds

$$\|H_{\mathrm{c}}\beta\|_X \leq K_1\|\beta\|_\infty, \qquad \|H_{\mathrm{c}}^*f\|_\infty \leq K_1|f|_{(-3)}.$$

These are estimates for the operator in eq. 3.cdxxxviii. In the nonlinear estimates below, $|f|_{(-s)} = \sup \mathsf{L}^s|f|$ uses the scale assigned to the fine bond or plaquette, and $\|A\|_X = \max\{|A|_{(-1)}, |\nabla A|_{(-2)}\}$. The version using the scale of the top of a cell is equivalent with factors at most L^s. Enlarge K_1 by these fixed factors when using the linear estimates in these norms.

Let $\mathcal{Q}^\natural(A)$ be the logarithmic straightened mean on the interior and outward rows, with $K_A = (\mathcal{Q}^\natural)'(A)$. With the corresponding fixed transport T, one has

$$T^{-1}\mathcal{Q}^\natural(A) = Q_{\mathrm{c}}A + C(A), \qquad T^{-1}K_A = Q_{\mathrm{c}} + C'(A), \qquad C'(0) = E. \tag{3.cdxl}$$

In particular, the remainder contains a linear term at a curved reference field.

Here are the quantitative estimates in these row coordinates. Let c_4, C_2 be the local logarithm and mean kernel constants, let $\kappa_{F,\mathrm{slin}}$ be the constant in the corresponding local comparison, and put

$$C_3^\natural = 104/c_4, \qquad \epsilon = \kappa_{F,\mathrm{slin}}L^2\alpha_0 + 4(C_2+1)Lr, \qquad \epsilon^* = \kappa_{F,\mathrm{slin}}L^2\alpha_0 + C_3^\natural Lr.$$

For $|A|_{(-1)}, |A_i|_{(-1)} \leq r \leq c_4/(4L)$,

$$\|C(A)\|_\infty \leq L\epsilon|A|_{(-1)}, \qquad \|C'(A)a\|_\infty \leq L\epsilon|a|_{(-1)}, \tag{3.cdxli}$$

$$|C'(A)^*\omega|_{(-3)} \leq 4L^3\epsilon^*\|\omega\|_\infty, \qquad |(C'(A_1)^* - C'(A_2)^*)\omega|_{(-3)} \leq 2L^4C_3^\natural|A_1 - A_2|_{(-1)}\|\omega\|_\infty.$$

The first line also gives the Lipschitz bound for C. For the transpose estimates, a fine bond of scale ξ_n occurs only in rows of levels $n-1, n, n+1$; their weights sum to at most $(L^3+2)\xi_n^{-3}$. The derivatives of the local mean kernel bound the column sum. Applying Cauchy's estimate in the local field ball to that column norm gives the last bound in eq. 3.cdxli. In particular these estimates do not introduce a factor equal to the depth.

The right inverse now transfers on the small chart. If $K_1L\epsilon \leq 1/2$, then

$$T^{-1}K_AH_{\mathrm{c}} = 1 + C'(A)H_{\mathrm{c}}, \qquad \|C'(A)H_{\mathrm{c}}\|_{\infty\to\infty} \leq 1/2.$$

Its Neumann inverse therefore gives

$$H_A = H_{\mathrm{c}}(1 + C'(A)H_{\mathrm{c}})^{-1}T^{-1}, \qquad K_AH_A = 1, \qquad \|H_A\beta\|_X \leq 2K_1\|\beta\|_\infty. \tag{3.cdxlii}$$

The dual calculation controls the multiplier. If $q = 4K_1L^3\epsilon^* \leq 1/8$, then

$$S_A = 1 + H_{\mathrm{c}}^*C'(A)^*, \qquad \|S_A^{-1}\|_{\infty\to\infty} \leq 8/7, \qquad H_{\mathrm{c}}^*(T^{-1}K_A)^* = S_A.$$

Consequently, whenever $F'(A) + DR_{\mathrm{c}}D^*A = K_A^*\omega$, its multiplier is uniquely determined by

$$T^{-1}\omega = S_A^{-1}H_{\mathrm{c}}^*(F'(A) + DR_{\mathrm{c}}D^*A). \tag{3.cdxliii}$$

This argument does not assume a bound for the multiplier before solving for it. Here $F(A)$ is the inner Wilson action evaluated at $e^{i\eta A}U_0$.

There is a further coordinate change when the datum is written with its endpoint gauges. The seam coordinate change Ξ gives $K_A^\flat = D\Xi\, K_A$. For the actual reduced datum, write $n(A) = x(A)^{v[A]}$. Its derivative is

$$dn[A]a = [dx[A]a]^{v[A]} + \mathrm{rot}_{n(A)}(\mu), \qquad \mu = i^{-1}(dv[A]a)v[A]^{-1}.$$

Gauge covariance gives $dn[A]\delta_\lambda A = \mathrm{rot}_{n(A)}(\lambda|_{\Lambda_*})$, where $\delta_\lambda A$ is the infinitesimal bare gauge variation and rot denotes the infinitesimal action on the datum. To attain a prescribed tangent datum, first choose a using the surjectivity of the straightened rows and then choose $\lambda = \mu$ on the tops. The vector $a - \delta_\lambda A$ attains the datum. This proves surjectivity of the finite-dimensional datum map. A uniform bound for its right inverse additionally uses the estimates for this gauge extension.

The first line of eq. 3.cdxli holds for complex increments around the fixed real reference field. The transpose bounds hold with an additional factor two, using the complex bilinear transpose. Extension of a real linear estimate to complex vectors is distinct from allowing the reference field and the independent current to vary on the full complex domain of the propagator statements.

Thus the local averaging constraint has a bounded right inverse on its specified chart. To obtain the target Gram estimate for the corrected rows and current-completed fine operator, one must still match the row coordinates and pairings, establish the energy bound for the resulting lift, and compare that fine quadratic form with eq. 3.cdxxxviii. The construction in eq. 3.dcv addresses the actual row energy; the row comparison above supplies its source interpretation when the averaging conventions agree. Neither surjectivity in the supremum norm nor eq. 3.cdxxxix alone performs the remaining quadratic-form comparison.

(e) **Gauge algebra without Gaussian integrals.** On a pure gauge, take the derivative of the covariance of the straightened average; the site factors then convert point values into block means: $QD = \bar{D}Q'$. Consequently the rows annihilate $D\ker Q'$. Combine this with the invariance of the action to second order, which is exact for the inner plaquettes; this accounts for that Hessian. The result is $\mathsf{G}^{-1}D\lambda = D\Delta_{\mathbf{U}}\lambda - \Delta'_\pi[\mathbf{J} - J(\mathbf{U})]D\lambda$ on $\ker Q'$. The propagators are taken at pairs whose current is an independent variable carrying a bound of its own, as in the spaces of **109**, p. 262. The reason is that bounds on the plaquettes, on the potential and on the first differences do not control $J(U)$ uniformly in the level: a staggered field satisfies all of them with $|J(U)| \geq \alpha\eta^{-1}$. In **99**, 389, by contrast, $J = J(U)$, and a condition on second differences is imposed in addition ((3.36), (3.38)). The price of a free current is the defect in 3. Uniformity in the level holds for the following reason. Row norms and column norms are both submultiplicative, and for a single step they lie near L and L^{-3}. The relative errors $O(\alpha_0(L^n\eta)^2 + \alpha_1 L^n\eta)$ of the steps form geometric series that are dominated by the top level.

3.12.1.5. Matching the local factors of the background propagator. For the native propagator construction use the same candidate cubes, trace-local bump rule and rules for modifying the cover in the two nests. Let $G_0 = \sum_\square h_\square G_\square h_\square$ be the native vector parametrix. Divide each candidate bump by the square root of the sum of all retained and inserted bump squares at that point, so that $\sum_\square h_\square^2 = 1$. Use local inverses whose levels agree with the global levels on the tested stencils. For a level-j cube this agreement holds when its twice-enlarged cube lies in $\Omega_j \setminus \Omega_{j+2}$. Separation supplies the inner margin. At the outer face one has to check the same levels or use the corresponding boundary model. Write D for the covariant site derivative and P for the projection occurring in the gauge term. Write $\Delta_a G_0 = I - R$. The four summands of R at a cube are

$$K(h_\square)G_\square h_\square, \qquad (1-\zeta_\square)DPD^* h_\square G_\square h_\square,$$
$$\zeta_\square(DPD^* - DP_\square D^*)h_\square G_\square h_\square, \qquad \zeta_\square[DP_\square D^*, h_\square]G_\square h_\square.$$

Here $K(h_\square)$ is the local differential and averaging commutator. The last term uses the local projection and the first difference of the bump. In the two occurrences of the global projection substitute

$$P = G'Q'^*(Q'G'^2Q'^*)^{-1}Q'G'.$$

For G', the scalar parametrix with the same square partition gives the series of local inverse and commutator factors. For the site Gram inverse, glue its local inverses. The resulting error consists of a tail outside the cut, a difference of scalar propagator squares and a local commutator. Insert the scalar expansion with the cover modified at the cut. The difference of squares is expanded as $(A-B)A + B(A-B)$, with the corresponding local scalar propagators A, B. In the vector error

with $\zeta_\square$, the term containing no small commutator or separated supports cancels against the local projection term. To get this cancellation, replace the inserted bumps by $\zeta_\square$, compare the modified local inverses with the original ones, and commute the cutoffs to the right. The errors have a cutoff difference, a localized inverse difference or a commutator. The term left after these operations uses $\zeta_\square h_\square = h_\square$. Consequently $G_0 \sum_{m\ge 0} R^m$, with these substitutions, has only local inverse, projection and commutator factors [B85c, (3.87)–(3.108)].

For comparison on a common region, fix one list of possible words before imposing either nest. Take as the nominal footprint the union of the constituent cubes with five layers of padding at their own scales. Admission of the word also reads the geometric decisions that modify the cover. In top units the index rule reads the region data less than $2M$ beyond the footprint, since it tests the neighboring cube in deciding which cover to use. Enlargement by $2M$ is also sufficient for the coefficients, including the bumps and the full field reads. If the outer averaging and derivative factors read entirely inside the footprint, the field reads require only the original footprint. Use this enlarged region for comparison. Equality of the two nests and their region data there gives the same cover decisions, local sequences and cutoffs. The local operators are therefore the same functions of the common background reads. At the same background on those reads their values are equal. Thus all the words whose enlarged reads lie in the common region cancel, term by term. Under the native regularity and separation assumptions the absolute walk majorant permits this cancellation inside the sum. It estimates the remaining terms by the first escape from the common region, with the geometric padding subtracted before measuring the escape. An operator formed with an additional region restriction uses its required margin to that region's boundary. For the history comparison, one neighboring cell supplies this geometric padding when $\check{R}_s \ge 2$. The trace data must record the full nest inside each component meeting the filed domain. The clean neighboring cells have trivial trace when they belong to the regular region of every nest in force. Where the padding reaches a different component, the comparison uses its nest and region trace on the cells met by the padding. For an application to a switched or compressed inverse one must also match its actual masks and the data read by its additional vertices.

(f) **Unfolding and parametrix.** With auxiliary unknowns

$$\Psi = (A; v, w, \sigma; p, q, r; \nu)$$

, the operators R, Δ'_π, $\mathsf{S}^{\mathsf{T}}\Delta^{(2)}\mathsf{S}$ and the constraint are combined into a single system $\mathbb{K}$ of finite range. The inverse of this system has the propagators as blocks. Let $\varkappa$ be an M_1-cube; these cubes have side M_1 in the local unit and tile Ω_0, whereas the $\square$ of (b), (d) are the cubes of the flat expansions. On a regular interior piece, in the gauge of the class, $\mathbb{K}_\varkappa$ equals the flat system plus $O(\alpha_0 + \alpha_1 + \gamma_0)$, and this perturbation need only be small compared with flat constants. A piece meeting the true bare boundary instead uses the direct massive inverses of the actual compressed Wilson Hessian and the covariant site Laplacian. In bare units the real operators $1 + \eta^2\Delta_Y(U)$ and $1 + \eta^2\Delta_U^\circ$ have uniform positive lower bounds, respectively $1/2$ and 1, and uniformly bounded finite-range kernels. A small complex perturbation preserves their inverses and exponential decay; local elimination then supplies the remaining slots. This boundary construction uses the actual incident inner plaquettes and requires no gauge across the boundary. Let $\theta_\varkappa$ be a partition of unity, let the cut-offs $\tilde{h}_\varkappa = 1$ near $\operatorname{supp}\theta_\varkappa$ be such that $\mathbb{K} = \mathbb{K}_\varkappa$ on $\operatorname{supp}\tilde{h}_\varkappa$, and let δ denote the rate of the local inverses. Then

$$\mathbb{K}\sum_\varkappa \tilde{h}_\varkappa \mathbb{K}_\varkappa^{-1}\theta_\varkappa = 1 - \sum_\varkappa \mathbb{R}_\varkappa,$$

$$\mathbb{R}_\varkappa = -[\mathbb{K}_\varkappa, \tilde{h}_\varkappa]\mathbb{K}_\varkappa^{-1}\theta_\varkappa = O\big(M_1^{-1}e^{-c\delta M_1/L}\big),$$

where the power comes from the commutator, and the exponential from how far $\operatorname{supp}\theta_\varkappa$ lies from $\operatorname{supp}\nabla\tilde h_\varkappa$. This bound outweighs the $O(1)$ neighbours. Three features keep the perturbation and the commutators from losing a derivative: scaling weights, one component of the source that admits a divergence, and the absence of any derivative on p.

(g) **Trees.** The system $\mathbb{K}$ depends affinely on the non-local coefficient $\mathsf{H}^{\mathsf{T}}\mathbf{J}$. The part of walk length zero stays in the local operators. The remainder, of size $O(\gamma_0 M_1^{-1}e^{-cM_1/L})$, forms a vertex that carries a walk of H. Thus vertices are small because of M_1 and not because of the field, and each term is indexed by a trunk with branches. When the cells are listed depth first, the number of such trees grows geometrically: for each first cell, there are C^m tree walks of length m starting from it. Both this count and the size of M_1 needed for the sum over trees to converge coincide with the ones in 1c.9. In 1c.7 and 1c.8 a branch is listed as soon as its cut is reached, and the trunk is resumed afterwards. For the data of 1c.9 the listing first continues at every cell along the trunk (within a branch, along the branch). So the whole trunk comes first, and then the branches come in the reverse order of their cuts, beginning with the last cut and ending with the first. Each of the two orders is a depth-first order. The order of listing changes neither the cells nor their parents, and so it changes neither the hull, nor the tree length, nor the bounds.

(h) **Multiplier and positivity.** Adding the equation "QA = fluctuation field" brings in $(Q\mathsf{G}_1Q^{\mathsf{T}})^{-1}$ as a Lagrange multiplier. Consequently $C^{(k)}(Y)$ occurs as a block in the inverse of a system of finite range. In the flat case, positivity follows from $\sum_{p'}|\bar\partial QA(p')|^2 \le \eta^4\sum_p|\partial A(p)|^2$, with $\bar\partial$ taken on $\mathbb{T}^{(k)}$, together with a definite form on double blocks. In a background, a homotopy to $\mathbf{1}$ preserves $C_\varkappa > 0$ for the local inverses. The eigenvalues z of $\chi_Y\mathsf{A}\chi_Y\sum h_\varkappa C_\varkappa h_\varkappa$ satisfy $|1-z|\le CM_1^{-1}$.

(i) **Length against parameters.** A tree of length t comes close to at most $2^4\max\{1, Ct/\ell_{\mathsf{P}}\}$ cubes $\square$ of the partition of side ℓ_{P} in statement 7; these are not the cubes $\square$ of (b), (d). Hence $\bar\kappa\#\mathsf{P}(\omega) \le 2^4\bar\kappa + (C\bar\kappa/\ell_{\mathsf{P}})|\Gamma|_{\mathbf{B}}$ for every tree Γ admitted in $d_{\mathbf{B}}(\omega; y, y')$, provided that X_0, which Γ need not meet, lies within $O(1)$ top units of y (no other term enters a functional near y, since the left argument of the kernel of O_ω touches X_0). Consequently, for $|s(\square)| \le e^{\bar\kappa}$ and $\delta \ge C\bar\kappa/\ell_{\mathsf{P}}$,

$$|s^\omega|\, e^{-\delta d_{\mathbf{B}}(\omega;y,y')} \le e^{2^4\bar\kappa}\, e^{-(\delta - C\bar\kappa/\ell_{\mathsf{P}})d_{\mathbf{B}}(y,y')}.$$

Each cube beyond the first 2^4 adds to the tree a length $\ge c\ell_{\mathsf{P}}$. Since ℓ_{P} is chosen last, $e^{-c\delta\ell_{\mathsf{P}}}$ outweighs $e^{\bar\kappa}$. The factor $e^{2^4\bar\kappa}$ is left over and cannot be avoided, as a cell at a corner of the grid shows. The displayed bound uses only the total-incidence count: $|s^\omega| \le e^{\bar\kappa\#\mathsf{P}(\omega)}$, followed by $d_{\mathbf{B}}(\omega; y, y') \ge d_{\mathbf{B}}(y, y')$. Its parameter loss is the stated reduction of the spatial decay rate. The estimate is Bałaban's (**116**, p. 5, after (1.11)); in his setting as well, the exponential by itself does the paying, and $e^{16\bar\kappa}$ remains. He keeps the factor $M_1^{-|\omega|/2}$ in reserve together with the exponential (p. 3, after (1.7)). This factor is not used up on the parameters, and here it is still at our disposal for the factor $|\omega|+1$ that occurs below. Since the uncut hull, which is his localisation domain, is connected, $\mathsf{P}(\omega)$ is connected through walls; this yields the splitting. The carrier is needed because the fields are given only on Ω_0, and it need not be connected when $\Omega_0 \ne T_\ell$.

The properties of single terms are produced by construction; they are not deduced. The sum is itself covariant and real. Therefore the Haar mean of the terms, made symmetric under the conjugation fixing the real pairs, is once more an expansion of the sum. By convexity it satisfies the same bounds, provided that the family of bounds is invariant under the real gauge transformations and under this conjugation; the family of localised bounds has this invariance. A single assignment for all tori is obtained in three steps: a mean over translations; a push-forward from covering tori; and a passage to the limit by Montel's theorem, along a subsequence fixed once, at the given top level and units. In the push-forward, a walk wrapping around the small torus gains at most $|\omega|+1$ blocks; the weight therefore loses a factor $|\omega|+1$, and nothing else is lost. The family is made

normal by an entrywise bound, which is one and the same number for all tori with room. This number is allowed to depend on the level, since the entries of $(Q\mathsf{G}Q^{\mathsf{T}})^{-1}$ are $O(\eta^{-2})$, and none of the norms, rates, weights or sums of weights involves it. If a family of terms is already carried by all shifts and compatible with all coverings, it is not changed.

3.12.1.6. The coupled map eq. 3.cdxliv. The datum in this map is the raw row logarithm B'. The fine pairing retains its physical cell weights, while the raw row pairing is counting measure. At $s=1$, define $\hat{Q}=\mathsf{m}Q$, $H=\mathsf{H}\mathsf{m}^{-1}$, $S=(\hat{Q}\mathsf{G}\hat{Q}^{\mathsf{T}})^{-1}$, $H_0=\mathsf{G}_0\hat{Q}^{\mathsf{T}}(\hat{Q}\mathsf{G}_0\hat{Q}^{\mathsf{T}})^{-1}$, and $\tilde{G}=\mathsf{G}_0-H_0\hat{Q}\mathsf{G}_0$. Here S acts on raw rows and is distinct from the fine projector S. The multiplication operator a is fixed by $\hat{Q}^{\mathsf{T}}\mathsf{a}\hat{Q}=Q^{\mathsf{T}}aQ$; for the row volumes ξ_c^4 and $a(c)=a_0\xi_c^{-2}$, it is $a_0 I$. All transposes in these formulas use the indicated two pairings.

Let $F(T)=A_{\Omega_0}(e^{i\eta T}\mathbf{U})$, using its regular holomorphic continuation, and define $\mathcal{C}(T)=\mathcal{Q}(T)-\hat{Q}T$ and $\mathcal{N}(T)=F'(T)-F'(0)-\Delta_{\mathbf{U}}^{\mathrm{W}}T$. Both remainders vanish to second order at zero on their actual admitted balls. The independent $\mathbf{J}$ is not set equal to $F'(0)$. The transpose of $\mathcal{C}'_T$ maps a raw row multiplier λ to a fine force. For $s\neq 1$, the four maps $H_0(s),\tilde{G}(s),H(s),S(s)$ are their specified walk-data sums, not inverses recomputed using identities that may fail after decoupling.

The map on a fine potential T and raw row multiplier λ is

$$\begin{aligned} T &= H_0(s)[B'-\mathcal{C}(T)] \\ &\quad -\tilde{G}(s)[\mathcal{N}(T)-{\mathcal{C}'_T}^{\mathsf{T}}\lambda], \\ \lambda &= H(s)^{\mathsf{T}}\mathbf{J}+[S(s)-\mathsf{a}][B'-\mathcal{C}(T)] \\ &\quad +H(s)^{\mathsf{T}}[\mathcal{N}(T)-{\mathcal{C}'_T}^{\mathsf{T}}\lambda]. \end{aligned} \tag{3.cdxliv}$$

Thus $H_0,\tilde{G}$ are the zero-current slots, whereas H,S use the current-dependent propagator. The centred multiplier variable is $\lambda-H(s)^{\mathsf{T}}\mathbf{J}$. With these raw-row pairings, the physical multiplier in the identified case is $\mathsf{m}^{-3}\lambda$. Prop. 3.177 proves convergence and uniqueness on the full first-order regular-pair domain and enlarged parameter discs, with the additional independent-current smallness required by this coupled system. Its decorated maps are the actual carrier sums of Lem. 3.172.

(j) **Operators as data.** The principle goes back to Bałaban, who observes that in the equations for the response "we can replace the propagators by arbitrary operators having the same regularity properties and satisfying the same bounds" (**116**, p. 3, (1.5)). In its published form, however, the second equation relies on the identities $RD^{\mathsf{T}}\mathsf{H}=0$ and $\mathsf{G}^{-1}\mathsf{H}=Q^{\mathsf{T}}(Q\mathsf{G}Q^{\mathsf{T}})^{-1}$, and therefore on their consequences $Q\mathsf{H}=1$ and $\Delta_\pi\mathsf{H}=Q^{\mathsf{T}}[(Q\mathsf{G}Q^{\mathsf{T}})^{-1}-a]$ ($\Delta_\pi=\Delta_{\mathbf{U}}^{\mathrm{W}}-\Delta'_\pi$). None of these is available for the sums $\sum_\omega s^\omega\mathsf{O}_\omega$: on the cubes around a row where s vanishes, every term is absent, so that $Q\mathsf{H}(s)$ equals 0 there and not 1. The first identity, moreover, holds only for the pairs on shell, even at $s\equiv 1$. Consequently no identity enters the argument. The identities are applied earlier, where they hold. With their help the gradient of the non-quadratic part of the action is put into a shape from which its second-order term $\Delta_\pi\mathsf{H}$ is absent, and this expression *defines* W_s for every s and every pair (it is a gradient only at $s\equiv 1$ and on shell). From then on only bounds are used, in the norms

$$\|A\|_\varpi=\sup_y \varpi(y)\max\{\xi_y|A|,\,\xi_y^2|\nabla_{\mathbf{U}}A|\},$$

$$|f|_\varpi^\sharp=\sup_y \varpi(y)\,\xi_y^3|f|,$$

$$\varpi(y)\le e^{\theta d_{\mathbf{B}}(y,y')}\varpi(y'):$$

the first measures a potential together with its first derivative, the second a force. The operator $\mathfrak{G}(s)$ takes the second norm back to the first, with norm $\hat{\mathsf{b}} \sim e^{2^4\bar{\kappa}}$, which is the size of every one of the operators; this closes the fixed-point argument.

3.12.1.7. The reduced force on the complex ball. Use raw row coordinates in this calculation. Write $\widehat{Q} = \mathsf{m}Q$ and let H_s be the walk sum for the raw lift $\mathsf{H}\mathsf{m}^{-1}$. Let S_s be the row inverse sum in these coordinates. At $s = 1$ it equals $(\widehat{Q}\mathsf{G}\widehat{Q}^{\mathsf{T}})^{-1}$, where the transpose uses the raw row pairing. If λ is a raw multiplier, the multiplier in the row-volume pairing is $\mathsf{m}^{-3}\lambda$. Indeed the row amplitude is multiplied by m and the row volume is m^4, so the corresponding per-length transpose is $\widehat{Q}^{\mathsf{T}}\mathsf{m}^3$. Put $P_s = S_s - \mathsf{a}$ with the row mass a used in eq. 3.cdxliv.

Let $\mathcal{C}_2$ be the quadratic part of the raw remainder $\mathcal{C}$. Given an auxiliary potential T, solve

$$X(T) = \mathcal{C}(T - H_sX(T)), \qquad Y(T) = T - H_sX(T), \qquad E_T = (\mathrm{d}X(T))^{\mathsf{T}}.$$

The bounded local row map and the quadratic estimate on $\mathcal{C}$ make this a contraction in X on a ball of radius Cr^2 when $\|T\| \le r \le c/\hat{\mathsf{b}}$. Indeed the Lipschitz constant is $C\hat{\mathsf{b}}r$, and $\|Y(T)\| \le 2r$ after decreasing c. Differentiating the equation for X gives

$$E_T = {\mathcal{C}'_{Y(T)}}^{\mathsf{T}}(1 + H_s^{\mathsf{T}}{\mathcal{C}'_{Y(T)}}^{\mathsf{T}})^{-1}.$$

In particular X starts with $\mathcal{C}_2(T)$. In the following formulas $\mathcal{V}$ is the quadratic remainder of the action gradient, restricted to the force bonds of the local calculation as in $\mathcal{N}$ above. Write $\phi = H_s^{\mathsf{T}}\mathbf{J}$. The formula used with the walk data is

$$\begin{aligned}\mathsf{W}_s(T) = \; & -(E_T - (\mathrm{d}\mathcal{C}_2(T))^{\mathsf{T}})\phi - \widehat{Q}^{\mathsf{T}}P_sX(T) \\ & - E_TP_s\widehat{Q}T + E_TP_sX(T) + \mathcal{V}(Y(T)) - E_TH_s^{\mathsf{T}}\mathcal{V}(Y(T)).\end{aligned} \tag{3.cdxlv}$$

For the reduction take the full carrier at $s = 1$, with the on-shell identity $RD^{\mathsf{T}}H_{s=1} = 0$. Use $\Delta_\pi H_{s=1} = \widehat{Q}^{\mathsf{T}}P_{s=1}$, where $H_{s=1}$ is the raw lift from G. Thus $H_{s=1}^{\mathsf{T}}\Delta_\pi H_{s=1} = P_{s=1}$. The terms in the differentiated reduced action come from

$$-(\phi, X - \mathcal{C}_2(T)) - (\widehat{Q}T, P_{s=1}X) + \tfrac{1}{2}(X, P_{s=1}X) + V_0(Y), \qquad V_0' = \mathcal{V}$$

on the full physical domain. Symmetry of $P_{s=1}$ gives the fourth term in eq. 3.cdxlv, and the chain rule for Y gives its last two terms. For general s eq. 3.cdxlv is evaluated directly using the designated operator sums.

For the estimate, the two small arguments T_i have $\|T_i\| \le r$. Set $d = \|T_1 - T_2\|_\varpi$. In the raw row norm the fixed point and its derivative satisfy

$$|X_i| \le Cr^2, \quad |X_1 - X_2|_\varpi \le Crd, \quad |E_{T_i}\psi|_\varpi^\sharp \le Cr|\psi|_\varpi, \quad |(E_{T_1} - E_{T_2})\psi|_\varpi^\sharp \le Cd|\psi|.$$

Here $|\cdot|$ on rows is the unweighted supremum and $|\cdot|_\varpi$ uses the weight at the assigned top. The first two bounds follow from the row contraction. The two derivative bounds use the local estimate for the transpose of the average differential and the resolvent identity for $1 + H_s^{\mathsf{T}}{\mathcal{C}'_Y}^{\mathsf{T}}$. Each difference in the resolvent identity contains one difference of $\mathcal{C}'_Y$, bounded by Cd with its weight on that factor. Both resolvents are bounded on the same ball since $C\hat{\mathsf{b}}r$ is small.

The second and third terms of eq. 3.cdxlv have differences bounded by $C\hat{\mathsf{b}}rd$. In the fourth the additional small factor r comes from E_T acting on the quadratic X, or from X when the difference falls on E_T. The fifth term is bounded by Crd by the local action remainder estimate and $\|Y(T_1) - Y(T_2)\|_\varpi \le 2d$. For the sixth, the undifferenced action remainder is $O(r^2)$, its difference is $O(rd)$, and H_s^{T} costs $C\hat{\mathsf{b}}$. These contributions are therefore bounded by $C\hat{\mathsf{b}}r^2d$.

For the first term let $r_0 = c/\hat{\mathsf{b}}$ be the radius of the full holomorphic ball and assume $0 < r < r_0$. Put $N(T) = E_T - (\mathrm{d}\mathcal{C}_2(T))^{\mathsf{T}}$. The function $g(z) = (N(zT_1) - N(zT_2))\phi$ is holomorphic on $|z| < r_0/r$, with $g(0) = g'(0) = 0$, because $\mathcal{C}_2$ is the quadratic term of X. The derivative difference bound gives

$|g(z)|_{\varpi}^{\sharp} \le C|z|d\,|\phi|$. Apply Schwarz's lemma to $g(z)/z$, after pairing with a dual functional of norm one, and take the supremum over the dual unit ball. This gives

$$|g(1)|_{\varpi}^{\sharp} \le C(r/r_0)d\,|\phi| \le C\hat{\mathsf{b}}^{\,2}\gamma_0 rd.$$

The resulting bound is $C\hat{\mathsf{b}}(1+\gamma_0\hat{\mathsf{b}})rd$. The coefficient and operator bounds here are on the local class used for the walk sums, with the force bonds, row supports, and the neighboring plaquettes inside its enlarged carrier. In applying this calculation to a history, membership of the actual restricted fields in that common class must still be checked.

The Lipschitz constant of the fixed-point map is $\hat{\mathsf{b}}\cdot\hat{\mathsf{b}}^2\cdot\hat{\mathsf{b}}\sup|B'|$, with contributions from $\mathfrak{G}$, W_s and H_1, and this is why the radius is $\hat{\mathsf{b}}^{-4}$. Decay amounts to choosing the weight $\varpi = e^{\theta d_{\mathbf{B}}(\cdot,y')}$. When $s \not\equiv 1$, bounds of first order on the operators do not yield a bound on $\Delta_{\mathbf{U}}\mathbf{H}$ independent of the level; an oscillating kernel belonging to the class of data is an example. The reduced current takes its place. It is built from the multiplier, and in it the second-order part of the gradient occurs only in paired form, $(D^{\mathsf{T}}DA, \mathsf{H}e_c) = (DA, D\mathsf{H}e_c)$, where e_c is an element of $\mathfrak{g}^c$ placed at the row c. As a result, only first-order norms occur.

3.12.1.8. Restriction of the response. A surviving walk has its full parameter support in one wall component of $\{s \neq 0\}$. It gives the same summand when all parameters outside that component are set to zero. For the nonlinear part, use the two nested collars in the definition of the local class. The potential and datum slots of the walk operators are supported inside the first collar boundary, at distance greater than the reach of the local average and force from the other components. Thus an iterate supported there has its averages, action remainder and transposed differential computed from data in the enlarged collar. The next iterate is again supported in the same slots. Starting at zero, the iteration for the union is the sum of the component iterations. Uniform contraction proves the same identity for the limits and allows comparison of settings by checking the walk terms and the local coefficients on these collars. A match of the decay rates alone would not identify the two responses.

For identification with the actual background, use all parameters equal to one at a real critical reference with its actual current. The reduced datum is obtained from the physical datum by the seam and node factors of the straightened average. Let C_{b} bound that map, r_{b} be its chart radius, r_B the radius of the holomorphic background chart, and ε_{D} the response datum radius at $s = 1$. Take the physical datum in the ball of radius $\min\{r_B, r_{\mathsf{b}}, \varepsilon_{\mathrm{D}}/C_{\mathsf{b}}\}$. The reference pair must belong to the common regular class at the admitted response radii. The holomorphic background in the normalized node gauge must lie in the response uniqueness ball and solve the constraint and slice equations there. The multiplier argument below and uniqueness identify it with the response to the reduced datum. On the constant sequence the two datum coordinates agree. The identification on a history requires the same determining rows and the same current correction in both constructions.

3.12.1.9. The coupled response in raw row coordinates. For eq. 3.cdxliv the walk sums in the four slots are $H_0(s), \tilde{G}(s), H(s)^{\mathsf{T}}$, and $S(s) - \mathsf{a}$. The mass subtraction is a local diagonal term and does not carry a decoupling parameter. In the estimate of these slots, the potentials and the row outputs of a datum at y' carry the factor $\xi_y/\xi_{y'}$. The potential from a force supported over y' carries $(\xi_y/\xi_{y'})^3$. The two bounds have the same exponential decay in $d_{\mathbf{B}}(y, y')$ and hold for partial sums. To see how the normalization enters, the datum at y' is a raw row logarithm, whereas the output potential and its first difference are measured in the units at y. Transpose the H-kernel with its fine pairing and the counting row pairing before estimating the multiplier slot. To absorb a ratio of power $p \le 3$, use the distance lower bound $\rho(|j - j'| - 1)_+$ for tops on levels j, j', with $\rho = R_1\mathfrak{M}$. Then the ratio costs at most $L^p e^{p(\log L)d_{\mathbf{B}}/\rho}$. For the kernel rate $3\dot{\delta}_0/16$, the separation floor $\dot{\delta}_0\rho \ge 512\log L$ leaves decay at rate $11\dot{\delta}_0/64$. Summing with the admissible weights at smaller rates gives the common operator bound $\hat{\mathsf{b}}$ of order $e^{16\bar{\kappa}}$. The carrier construction uses parameter cubes of side at least $88\,\mathsf{r}_{\mathrm{w}}\mathfrak{M}$, where r_{w} bounds the number of cubes in a walk cell, with at least three parameter cubes in each direction. The side is also chosen so that its product with $\dot{\delta}_0$ is at

least $4352\bar{\kappa}$. These are floors on the regular pair and walk construction, which is used throughout the contraction.

Put $\lambda_0 = H(s)^{\mathsf{T}}\mathbf{J}$ and $\nu = \lambda - \lambda_0$. For $|B'|_\infty \le r$ consider the ball of radius $R = 2\hat{\mathsf{b}}r$ in $\max\{\|T\|, |\nu|_\infty\}$. On this ball let Δ be the maximum of the weighted differences of T and ν at two points. The differences of the two quadratic remainders $\mathcal{C}, \mathcal{N}$ are bounded by $CR\Delta$. For the remaining term take the difference of ${\mathcal{C}'_T}^{\mathsf{T}}(\lambda_0 + \nu)$ by putting the weight on the changed factor. A difference in T costs $C(|\lambda_0|_\infty + R)\Delta$, and a difference in ν costs $CR\Delta$. Since $|\lambda_0|_\infty \le \hat{\mathsf{b}}\gamma_0$, the Lipschitz constant of the map is bounded by

$$C\hat{\mathsf{b}}(R + \hat{\mathsf{b}}\gamma_0).$$

Choose both r and γ_0 at most a sufficiently small constant times $\hat{\mathsf{b}}^{-2}$. The map has Lipschitz constant at most $1/2$, and its value at zero has norm at most $\hat{\mathsf{b}}r$. It therefore preserves the ball. Iteration gives the holomorphic solution, with the same contraction estimates in the weighted norms. Subtracting the equations at two data then bounds their solution difference by $2\hat{\mathsf{b}}|B'_1 - B'_2|_\varpi$. The choice of weight centred at the changed row gives the decay.

These estimates concern the reduced system on the interior and outward rows. The identification at parameters one is proved below at a real critical reference with its own current.

(k) **From the slice to a multiplier.** Let $s \equiv 1$, and fix a critical real U_0 such that $(U_0, J(U_0))$ is a regular pair whose radii lie below the ceiling. Then (I) is equivalent to the constraint, the Landau condition and $\mathsf{z} := F'(\mathbf{H}) - K_{\mathbf{H}}^{\mathsf{T}}\lambda \in DR(\text{site functions})$, where λ is the multiplier formed from $\mathbf{H}$. In other words, (I) amounts to stationarity on the gauge slice alone. If B' is real and close to 0, then $\mathbf{H}(B')$ is real and lies in a neighbourhood of 0 whose size is not uniform. On that neighbourhood the invariance of the action and the factorisation in 3 provide gauge directions X_χ with $(F'(\mathbf{H}), X_\chi) = 0$ and $K_{\mathbf{H}}X_\chi = 0$, and the $RD^{\mathsf{T}}X_\chi$ fill out the range of R. Therefore $\mathsf{z} = 0$ on this neighbourhood, and by the identity theorem also on the whole polydisc, so the neighbourhood enters no constant. The factorisation of the averages holds only up to site factors and, at rows that leave their layer, up to seam factors; this is the reason for the row datum.

3.12.1.10. The reduced response over a real critical reference. For the remainder of this argument put $s = \mathbf{1}$ and take the real regular pair (U_0, J) with $J = J_{\Omega_0}(U_0) = \hat{Q}^{\mathsf{T}}\lambda_0$. Use the closed row set: the outer end of an outward row has its full block of interior rows at the preceding level. The transposes use the fine weighted pairing and the counting row pairing. Put $\mathcal{Q}(T) = \hat{Q}T + \mathcal{C}(T)$ and $K_T = \hat{Q} + \mathcal{C}'_T$. If $F(T)$ is the action of the inner plaquettes at $e^{i\xi T}U_0$, then $F'(T) = J + \Delta T + \mathcal{V}(T)$, with the same Hessian and current convention as in the propagators. Here $\mathcal{V}$ is the nonlinear force remainder.

Define $\mathsf{z} = F'(T) - K_T^{\mathsf{T}}\lambda$ and $\phi = RD^{\mathsf{T}}T$. Write r_1, r_2 for the left sides minus the right sides of the two reduced equations, evaluated at $B' = \mathcal{Q}(T)$. Their exact expressions are

$$r_1 = \widetilde{G}(\mathsf{z} + D\phi), \qquad r_2 = \mathsf{L}G'\phi - H^{\mathsf{T}}(\mathsf{z} + D\phi). \tag{3.cdxlvi}$$

Indeed $\widetilde{G}\hat{Q}^{\mathsf{T}} = 0$ and $T = H_0\hat{Q}T + \widetilde{G}G_0^{-1}T$, where $G_0^{-1}T = \Delta T + D\phi + \hat{Q}^{\mathsf{T}}\mathsf{a}\hat{Q}T$. This gives r_1. For r_2 use $\hat{Q}H = 1$ and

$$H^{\mathsf{T}}\Delta T = (\hat{S} - \mathsf{a})\hat{Q}T + H^{\mathsf{T}}\Delta'_\pi T - H^{\mathsf{T}}D\phi.$$

To identify the middle term, set $\Upsilon = G'RD^{\mathsf{T}}$. The quadratic form of Δ'_π has terms bilinear in $(A, \Upsilon A)$ or quadratic in ΥA. In the polarization at $(H\beta, T)$ only the term with $(H\beta, \Upsilon T)$ remains, because $RD^{\mathsf{T}}H = 0$ at the real current. If $\mathfrak{b}(v, A)$ denotes this bilinear part with the arguments in that order, define $\langle \beta, \mathsf{L}v\rangle = \mathfrak{b}(v, H\beta)$. This gives $H^{\mathsf{T}}\Delta'_\pi T = \mathsf{L}G'\phi$. Also $H^{\mathsf{T}}J = \lambda_0$.

For the reduced solution the first equation gives $\hat{Q}T = B' - \mathcal{C}(T)$. Since the kernel of $\widetilde{G}$ is $\operatorname{ran}\hat{Q}^{\mathsf{T}}$, the two vanishing defects in eq. 3.cdxlvi give

$$F'(T) + D\phi = K_T^{\mathsf{T}}\lambda + \hat{Q}^{\mathsf{T}}\mathsf{L}G'\phi. \tag{3.cdxlvii}$$

For real B' near zero, let $X_\chi(T)$ be the variation of T by the real gauge $e^{i\tau\chi}$. The accompanying node variation is $\varrho(T;\chi)$, obtained by undoing the averaging factors of the two fields. The straightened constraint varies by $\ell^\natural_{B'}[\varrho(T;\chi)]$, the infinitesimal row action with its outward endpoint transport. At $T=0$ the maps X_χ and ϱ are $-D\chi$ and $Q'\chi$. The map

$$\chi \longmapsto (\varrho(T;\chi), RD^{\mathsf T} X_\chi(T))$$

is invertible near zero. At zero this follows from the onto site average and the inverse of $RD^{\mathsf T}D$ on $\ker Q'$. The finite-dimensional inverse persists on an open real neighborhood. Choose χ with first component zero and second component ϕ. Then $K_T X_\chi = 0$ and $(F'(T), X_\chi)_\xi = 0$ by gauge invariance. Pairing eq. 3.cdxlvii with X_χ gives

$$(\phi,\phi)_\xi = -\langle \mathsf{L} G'\phi, \mathcal{C}'_T X_\chi\rangle.$$

At fixed finite volume the right side is bounded by $C\|T\|(\phi,\phi)_\xi$, since $\mathcal{C}'_0 = 0$ and $\|X_\chi\| \le C\|\phi\|$. Thus $\phi = 0$ near the real origin. Holomorphy extends this identity to the entire reduced datum ball, so $F'(T) = K_T^{\mathsf T}\lambda$ there. This argument uses no uniform size for the real neighborhood. In the reverse direction a solution of the three equations has both defects zero. A sufficiently small T puts its multiplier in the same uniqueness ball: the second equation bounds $|\lambda-\lambda_0|$ by $C\hat{\mathsf{b}}\|T\|(1+|\lambda_0|+|\lambda-\lambda_0|)$, where the last term is absorbed. This gives the comparison on a common smaller uniform radius.

To return to physical data, the factorization of $\mathcal{Q}$ gives the plain datum $(e^{iB'^\natural}V_0)^{v[T]}$, where $V_0 = M_{\mathbf{B}}(U_0)$. At an outward row the right endpoint factor is $\theta_z(B')^{-1}$ if the outer endpoint is $z = c_+$, and the left factor is $\theta_z(B')$ if $z = c_-$. This is the mean formed from the interior rows in the block at z. Use the inverse conversion of the physical logarithm to B' on the common smaller chart. To check criticality on the physical fibre, pair λ with $\ell^\natural_{B'}[\sigma]$. At small real B' the map of gauge variations above supplies every node value σ. The pairing is zero since it equals $(F'(T), X_\chi)_\xi$. Holomorphy extends its vanishing to the datum ball. On a differentiable curve of real fields with fixed physical datum, the derivative of the reduced datum is a node variation of this form, obtained by differentiating the factors $v[T]$ with the physical datum held fixed. The derivative of the action on the curve therefore vanishes. After undoing $v[T]$ at the nodes this gives a critical field at the specified physical datum. Where the response lies in the regularity class, uniqueness of the real orbit identifies it with the continued regular background in the normalized slice. For the decoupled response at an independent current we use the reduced system and its analytic estimates. The identification with a physical critical orbit uses the real critical reference and the closed rows as above.

Constants are chosen in the following order, each large or small enough relative to those chosen before it. First comes L, and with it, as a single group, the numbers determined by L alone: the flat constants and the flat rate, the lower thresholds that the flat case imposes on M_1 and on R_1M_1, the radius of the local perturbation theory, the rates δ_0, δ_*, δ', and the ceiling on $\alpha_0, \alpha_1, \gamma_0$. Next come M_1 and R_1M_1; the ceiling does not depend on them, and they do not depend on the ceiling. Then comes $\bar\kappa$. It does not depend on M_1, R_1, and they do not depend on it, so it may just as well be chosen before them. After that come $\ell_{\mathsf P}$, the radius in B', and the second ceiling on γ_0, which concerns eq. 3.cdxliv. The final choices are M and the field strengths of the construction, taken so small that $O(LM)\alpha_0$ is below the ceiling. Two numbers are exceptions: among the bounds of statement 7, the one bound that is used for convergence alone; and, in mechanism (i), the entrywise bound by which the family is normal. Neither of them appears in a localised bound, a rate, a weight or a sum of weights. With the exception of these two, every constant, rate and ceiling, and the radius in B', is independent of k, K, ℓ, of the sequence (in particular of Ω_0), of Y and of the pair, and also of M_1, R_1 once these are large enough. The sizes $\ell_{\mathsf P}$ and M, and the side of the coarse cubes of 6, are each at least a multiple of M_1. The field strengths are small compared with

$(LM)^{-1}$. Where statement 8 makes the identification with the response of § 3.11, the datum of the background is small compared with M_1^{-1}.

3.12.2. *The additional reduced rows at a retained inward seam.* This paragraph supplies the linear inverse for the optional convention that retains inward bonds. The determining sets in eq. 3.cccvi still use only interior and outward rows. At each additional seam node choose one retained inward bond as its tying bond, oriented towards that node. The tying equation fixes its node factor. The remaining independent equations are the quotients of the other retained inward bonds by this tying bond. Call these the edge rows. If only one inward bond is retained at a node, it adds a node factor but no edge row.

Write K_{p} for the differential of the proper reduced rows and K_{e} for that of these edge rows, all in raw dimensionless logarithmic coordinates. Both row spaces have counting measure. In this paragraph K^* denotes the transpose for that counting measure and the physical fine pairing $\eta^4 \sum_b \langle A(b), A'(b)\rangle$. In particular it is not the physical top transpose with its row-length weight omitted. Let $a_q(A)$ be the iterated reduced logarithm at level q in the reference chart, and extend it to reversed bonds by $\widehat{a}_q(\bar{b}) = -\operatorname{Ad}(W_q(b)^{-1})a_q(b)$, where $W_q = \mathcal{M}^q U_0$. For an edge $e = (b_i(x), b_1(x))$, put $V_0(e) = W_q(b_i(x))W_q(b_1(x))^{-1}$. Differentiation of its quotient gives the exact formula

$$K_{\mathrm{e}} A(e) = \widehat{\dot{a}_q[A]}(b_i(x)) - \operatorname{Ad}(V_0(e))\widehat{\dot{a}_q[A]}(b_1(x)). \tag{3.cdxlviii}$$

Put $\mathfrak{M} = M_1$. The auxiliary peeled sequence has $\Omega'_0 = \Omega_0$; for $q \geq 1$, Ω'_q is the union of the aligned $\mathfrak{M}\xi_q$-cubes in Ω_q whose sup distance from Ω_q^c is at least $\mathfrak{M}\xi_q$. Its determining set contains only proper rows. A full torus is unchanged, and empty members are allowed. Use the same large separation floors for both sequences. The elementary consequences are

$$\Omega_{q+1} \subset \Omega'_q \subset \Omega_q, \qquad \xi'(z) \leq \xi(z) \leq L\xi'(z).$$

Indeed a discarded cube touches the old boundary and has width $\mathfrak{M}\xi_q$. Separation puts the next member beyond this discarded strip; erosion of that next member adds $\mathfrak{M}\xi_{q+1}$ to its distance from the old boundary, so the original separation is preserved. A site loses at most one level. Each peeled pillar is contained in its old pillar.

Lemma 3.36 (Uniform edge Schur inverse)**.** Let U_0 be real. Assume that $(U_0, J(U_0))$ is a real regular pair on the original sequence and that $(U_0, 0)$ is a real regular pair on the peeled sequence, in the preceding definition with $A' = 0$ and $\alpha_0 = \alpha_1 = \gamma_0 = \alpha$. Require the local-gauge bounds on every complete box used in the proper-row inverse estimates, with a common sufficiently small radius α. These are two primitive admissions: the original pair uses the actual physical current, and the peeled pair uses independent current zero. The original physical-current premise ensures positivity of the zero-independent-current completed Wilson form. Both admissions hold at the flat reference. The separation floor may be increased by a fixed number depending only on the inverse constants and L.

Let $G_{\mathrm{p}} = T^{-1}$ be the original positive completed Wilson inverse, in raw row normalization, and set

$$\begin{aligned} T &= \Delta_{U_0}^{\mathrm{W}} + DRD^\sharp + K_{\mathrm{p}}^* K_{\mathrm{p}}, \\ H_{\mathrm{p}} &= G_{\mathrm{p}} K_{\mathrm{p}}^* (K_{\mathrm{p}} G_{\mathrm{p}} K_{\mathrm{p}}^*)^{-1}, \qquad C_{\mathrm{p}} = G_{\mathrm{p}} - H_{\mathrm{p}} K_{\mathrm{p}} G_{\mathrm{p}}, \\ M_{\mathrm{e}} &= K_{\mathrm{e}} C_{\mathrm{p}} K_{\mathrm{e}}^*. \end{aligned}$$

There are $c, C, s > 0$, independent of depth, mesh, volume and the subset of inward bonds retained, such that

$$cI \leq M_{\mathrm{e}} \leq CI, \qquad |M_{\mathrm{e}}^{-1}(e, e')| \leq Ce^{-sd(y_e, y_{e'})}.$$

Here y_e is the outer top of the nontying bond of e, and d is the original weighted distance. If there are no edge rows, the edge space is zero and the following corrections are zero. Otherwise define

$$\begin{aligned} H_{\mathrm{all}}(b_{\mathrm{p}}, b_{\mathrm{e}}) &= H_{\mathrm{p}} b_{\mathrm{p}} + C_{\mathrm{p}} K_{\mathrm{e}}^{*} M_{\mathrm{e}}^{-1} (b_{\mathrm{e}} - K_{\mathrm{e}} H_{\mathrm{p}} b_{\mathrm{p}}), \\ C_{\mathrm{all}} &= C_{\mathrm{p}} - C_{\mathrm{p}} K_{\mathrm{e}}^{*} M_{\mathrm{e}}^{-1} K_{\mathrm{e}} C_{\mathrm{p}}. \end{aligned} \tag{3.cdxlix}$$

With $K = (K_{\mathrm{p}}, K_{\mathrm{e}})$ and $\mathcal{X} = \Delta_{U_0}^{\mathrm{W}} + DRD^{\sharp}$, these maps satisfy

$$K H_{\mathrm{all}} = 1, \quad K C_{\mathrm{all}} = 0, \quad C_{\mathrm{all}} \mathcal{X} = 1 - H_{\mathrm{all}} K, \quad \ker C_{\mathrm{all}} = \operatorname{ran} K^{*}.$$

They have the same raw-datum-to-field and force-to-field bounds as the proper package, with a smaller positive exponential rate. More precisely, use the cell field norm $\|A\|_y = \max\{\xi_y |A|_y, \xi_y^2 |\nabla_{U_0} A|_y\}$ and force norm $|f|_y^{\sharp} = \xi_y^3 |f|_y$. Here the maxima are over bonds or difference sites assigned to the pillar of y, and $|b|_y$ is the maximum of the Euclidean raw row norms at that top, taken as zero if there is no row. Complete fixed enlargements in local estimates have bounded overlap. Then

$$\begin{aligned} \|H_{\mathrm{all}} b\|_y &\le C \sum_z e^{-s d(y,z)} |b|_z, \\ \|C_{\mathrm{all}} f\|_y &\le C \sum_z e^{-s d(y,z)} |f|_z^{\sharp}. \end{aligned}$$

The localized gradient Hölder bounds hold for each fixed $0 < \beta < 1$, with constants additionally depending on β. This is a linear package for the completed Wilson Hessian; it is not an identification with a current-corrected background response. ∎

Proof. Let H_{p}' be the proper raw-row lift on the peeled sequence. Use the Euclidean Lie algebra norm induced by the real trace pairing and put $\|A\|_{\mathcal{E}}^2 = \sum_y \|A\|_y^2$. The proper exponential estimates and the bounded weighted metric volume imply

$$\|H_{\mathrm{p}} b\|_{\mathcal{E}} \le C \|b\|_2, \quad \|H_{\mathrm{p}}' b'\|_{\mathcal{E}'} \le C \|b'\|_2, \quad \|A\|_{\mathcal{E}} \le L^2 \|A\|_{\mathcal{E}'}.$$

The last inequality follows by replacing the maximum on an old pillar by the sum of squares on its disjoint peeled subpillars. All constants in this proof are fixed before the depth is chosen.

We construct a test for each edge row. Write $b_i(x) = (y_i, x)$, with $x = y_i + \sigma \xi_q e_\mu$, and let $B(X)$ be the level-$(q+1)$ block containing x. The bonds

$$f_0 = (y_i, x), \quad f_1 = (x, x + \sigma \xi_q e_\mu), \quad f_2 = (x + \sigma \xi_q e_\mu, x + 2\sigma \xi_q e_\mu)$$

are proper interior rows of the peeled sequence. In fact this entire block is in the strip removed from Ω_{q+1}, while it and y_i lie in Ω_q'. On their common line transport a vector v from y_i to the initial point of each bond, and assign the oriented values $(1, -2, 1)v$ in these transported frames. On a reversed bond use the covariant minus sign. Denote this pattern by $J_e v$. Different edge rows have disjoint pattern supports: inward bonds at a common seam node have distinct directions, and parallel inward bonds on the same block line are separated by at least $L - 1$ bonds. Since $L \ge 13$, the three-bond patterns cannot meet. None uses a tying bond. Thus

$$\|Jb\|_2^2 = 6 \|b\|_2^2, \qquad Jb = \sum_e J_e b(e).$$

The cancellation at the next scale is essential. Along a line, the L-step paths starting in the first endpoint block meet the pattern in the sets $\{0\}, \{0,1\}, \{0,1,2\}$. Their sums are $1, -1, 0$, the first two occurring once. For the next coarse bond the nonzero sums are $-1, 1$, again once each. At a flat reference each pair cancels exactly in the L^{-4}-normalized straight-path average. At a curved reference the two transports differ by a loop in the same double block. The loop comparison bounds that difference by $C_L \alpha$. Let $\mathbf{Q}_q = D_a F_{W_q}(0)$, where F_W is the straightened one-step logarithm of eq. 3.dxc. It is the derivative in the chain rule for the reduced logarithms a_{q+1}. At a flat reference, differentiating the two endpoint factors in that formula cancels the internal contour derivatives

of the plain mean. The remaining map is the covariant straight-path average. For curvature $O(\alpha)$, differentiate the same endpoint factors, local logarithms and defining mean equation on the complete double block. In its real comb gauge their coefficients and the inverse derivative of the mean equation differ from their flat values by $O_L(\alpha)$, using the logarithm series on its fixed smaller ball. Unitary covariance restores the original frames. Thus $\mathbf{Q}_q$ differs from the covariant straight-path map by $C_L\alpha$ in its fixed finite row and column sums. The one-step row has at most $8L^4$ input bonds, and each input belongs to at most eight double blocks. These are one-step counts, with no dependence on q.

Set $A_b = H'_{\mathrm{p}} Jb$. The iterated reduced logarithms for the two sequences agree on every common complete read, by induction in the averaging equation. Hence

$$K_{\mathrm{e}} A_b = b, \qquad \|K_{\mathrm{p}} A_b\|_2 \le C_L\alpha \|b\|_2, \qquad \|A_b\|_{\mathcal{E}} \le C\|b\|_2.$$

For the first identity, eq. 3.cdxlviii reads the assigned value on b_i and zero on the tying bond. An old proper row shared by the peeled sequence reads zero. Every other old proper row has its full predecessor double block among the peeled interior rows, so the preceding cancellation and the chain rule give the second inequality. Bounded double-block overlap gives both Schur sums needed for that ℓ^2 estimate.

Correct into the proper kernel by $A = A_b - H_{\mathrm{p}} K_{\mathrm{p}} A_b$. The actual local row bounds give

$$K_{\mathrm{p}} A = 0, \qquad \|A\|_{\mathcal{E}} \le C_A\|b\|_2, \qquad \|K_{\mathrm{e}} A - b\|_2 \le C_{\mathrm{e}}\alpha\|b\|_2.$$

Choose $C_{\mathrm{e}}\alpha \le 1/2$. On this proper kernel,

$$(A, TA)_\eta \le C_T \|A\|_{\mathcal{E}}^2.$$

To check this bound, the row penalty vanishes, R is an orthogonal projection, the curl and divergence use finitely many neighboring differences, and the Wilson-minus-curl remainder is bounded by $C_L\alpha\xi_y^{-2}|A|$. The physical number of bonds in a pillar is $O(\xi_y^4)$; this cancels the four powers in the squared first-difference bound. Neighboring layers differ by at most L.

Since T is positive, its constrained inverse satisfies

$$(f, C_{\mathrm{p}} f)_\eta = \sup_{K_{\mathrm{p}} u = 0} \{2(f,u)_\eta - (u, Tu)_\eta\}.$$

Put $f = K_{\mathrm{e}}^* b$, test with $u = tA$, and use $\langle b, K_{\mathrm{e}} A\rangle \ge \|b\|_2^2/2$. Taking $t = (2C_T C_A^2)^{-1}$ proves

$$\langle b, M_{\mathrm{e}} b\rangle \ge (4C_T C_A^2)^{-1} \|b\|_2^2.$$

The upper bound and an exponentially decreasing raw kernel for M_{e} follow by composing the proper constrained inverse with the two actual local edge maps. Their counting transposes have the physical fine density; no mesh-counting factor is introduced.

For completeness, fix an edge e_0 and conjugate this raw matrix by multiplication by $\exp(s \min\{d(y_e, y_{e_0}), N\})$. The distance is one-Lipschitz in itself. Let $a > 0$ be the kernel rate already obtained. For $0 < s \le a/4$, the exponential kernel bound and the metric sum at the fixed rate $a/2$ bound the row and column sums of the conjugation error by Cs, uniformly in N. The constant C is fixed once the separation exceeds the floor for this rate. Choose $s \le \min\{a/4, c/(2C)\}$. The conjugated inverse has norm at most $2/c$. Apply it to a unit coordinate at e_0 and let N increase. This proves the displayed decay of M_{e}^{-1}. Now increase the separation floor also to bound the metric exponential sums at this smaller rate, using the same constants already fixed above. Only a fixed number of edge species occur at a top.

Direct multiplication in eq. 3.cdxlix proves the first three identities. Positivity on $\ker K$ identifies C_{all} as its constrained inverse, giving $\ker C_{\mathrm{all}} = \operatorname{ran} K^*$. Composition of the exponential kernels proves the two cell bounds after one further fixed decrease of the rate. For the localized gradient Hölder estimate, write each correction as $C_{\mathrm{p}} f$ and apply the proper estimate to this force; its bound follows from the same convolution. This uses no derivative of a row datum. All maps are real at

real coefficients. On a common smaller admitted complex tube their bilinear matrix formulas are holomorphic; the uniform weighted perturbation estimates for the proper inverse and local rows preserve the edge gap by Neumann series. At the flat reference the loop error is zero and both primitive admissions are automatic. The resulting flat package therefore includes any retained inward edge rows in the local regularity argument. □

3.12.2.1. The derivative at a retained-inward critical background. Suppose additionally that U_0 is a real critical reference for these reduced rows. Write $q(A)$ for their raw nonlinear logarithm, so $q'(0) = K$, and write F for the inner Wilson action in this chart. In this paragraph put $H = H_{\mathrm{all}}$, $C = C_{\mathrm{all}}$ and $Z = DRD^\sharp$. The nonlinear system to be solved is

$$F'(A) + ZA = q'(A)^*\omega, \qquad q(A) = b.$$

The gauge term is retained until the physical-fibre argument. Since $KH = 1$, the multiplier at the reference is unique and

$$F'(0) = K^*\omega_0, \qquad \omega_0 = H^*F'(0), \qquad |\omega_0|_\infty \le C_0\alpha.$$

Here and below the constants are uniform over the admitted data. The last bound uses the physical current admission and the absolute column estimate: in a cell the pairing has scale $\xi_y^{-1}\xi_y^{-3}\xi_y^4 = 1$.

Define B by

$$(v, Bu)_\eta = \langle \omega_0, q''(0)[u, v]\rangle.$$

The local two-leg bounds for the actual logarithms, with both leg sums and the fine density, give $|Bu|_{(-3)} \le C_1|\omega_0|_\infty\|u\|_1$. Differentiating both factors of an edge quotient gives the same bound; only a fixed number of inward bonds share a tying bond. The differential of the system at $(0, \omega_0)$ is

$$\mathcal{L}(u, \nu) = ((\mathcal{X} - B)u - K^*\nu, Ku).$$

For a force f and raw datum b, its inverse has field part

$$u = (1 - CB)^{-1}(Cf + Hb), \qquad \nu = H^*((\mathcal{X} - B)u - f).$$

Applying C proves the first formula. Conversely it gives $Ku = b$, and the first-row residual belongs to $\ker C = \mathrm{ran}\, K^*$; applying H^* then gives the unique multiplier in the second formula. Decrease α so that $\|CB\|_{1\to1} \le 1/2$, also in a fixed smaller exponentially weighted norm.

The weak multiplier estimate uses the unchanged site maps of the proper package. The proper exponential bounds for $P = 1 - R$ on site functions and for $DPD^\sharp$ remain valid. Write d for the covariant bond-to-plaquette curl, reserving D for the site-to-bond derivative. The divergence maps a field controlled in $\|\cdot\|_1$ to a site function with its two powers of local length. In $\langle e, H^*\mathrm{d}^\sharp \mathrm{d}u\rangle = (\mathrm{d}He, \mathrm{d}u)_\eta$ move one difference to each field; for the gauge term use $\langle e, H^*DRD^\sharp u\rangle = (D^\sharp He, RD^\sharp u)_\eta$ and $R = 1 - P$. The cell counts cancel the four inverse powers of length. The Wilson-minus-curl term uses its local force bound. Together with the column bound for H^*f, this proves

$$\max\{\|u\|_1, |\nu|_\infty\} \le C_I \max\{|f|_{(-3)}, |b|_\infty\}.$$

The same argument with the weight on the changed factor proves the weighted version, with a fixed smaller rate.

Here is an explicit contraction using this inverse. Write $\omega = \omega_0 + \nu$, $X = (A, \nu)$, $\|X\| = \max\{\|A\|_1, |\nu|_\infty\}$, and put

$$N_1(X) = F'(A) + ZA - q'(A)^*(\omega_0 + \nu) - [(\mathcal{X} - B)A - K^*\nu],$$
$$N_2(X) = q(A) - KA.$$

Both remainders and their first derivatives vanish at zero. The local Taylor and transpose bounds give, on $\|X_i\| \le r$ in the common chart,

$$\max\{|N_1(X_2) - N_1(X_1)|_{(-3)}, |N_2(X_2) - N_2(X_1)|_\infty\} \le C_N r\|X_2 - X_1\|.$$

The mixed term is $-(q'(A)-K)^*\nu$; its difference has one small factor and one difference. The part paired with ω_0 uses the second difference of q'. Choose r below the common row and action chart radii and so that $C_I C_N r \le 1/4$. For $|b|_\infty < r/(2C_I)$, the map

$$X \longmapsto \mathcal{L}^{-1}(-N_1(X), b - N_2(X))$$

maps the closed r-ball into itself and contracts by at most $1/4$. Iteration gives its unique solution there, holomorphic on the open datum ball and real for real data. Weighted differences have the same bound after absorption. All constants and radii were fixed before the depth and the retained subset were chosen.

Physical identification uses the same original and peeled admissions, the actual node and seam datum conversion, and the common smaller chart described above. The real gauge-variation argument removes ZA near the origin and identifies criticality on the physical fibre; its analytic identities extend over the connected datum ball. The compared physical branch must lie in this response uniqueness ball and in the admitted regularity class. Uniqueness of its real critical orbit then gives the normalized branch identification. Thus the optional continuation uses the corrected derivative $\mathcal{L}$ and the stated admissions throughout.

3.13. **Layered precision and current terms.** The precision of a constrained fluctuation is obtained only after three different operations. One forms an operator on the fine field, reads its induced action on the coarse datum, and then restricts that coarse action to the next actual fibre. Gauge and current terms enter at all three places. A positive matrix at one of them does not identify the others.

We retain this order. The fine site and field operators, their row lift and their constraint-curvature terms are typed separately. Their complete physical match is an identity of projected forms, with the actual soft gauge. The alternative explicitly defined relative-current first-step extension gives another coherent starting point. It supplies its stated first-step estimates; using that definition at later levels requires its own consistency and closure.

The reductions below use the domain and background sections. In particular, all transposes are bilinear weighted transposes on complex domains, while real lower bounds use Hermitian quadratic forms. The primitive domains are specified before the unknown critical field. No arbitrary independent current is replaced by the physical action current.

3.13.1. *Cell norms retain the ultraviolet scale.* Work on a finite compatible torus, with a separated aligned sequence and the spacings of § 3.11. Let $\Delta(y)$ be the pillar of a top y, of side ξ_y. Outside the action region one can add bare cells and extend the local scale to η; a compressed operator is zero on that added space. The point scale $\xi(x)$ is the scale of its pillar. Use the exact path metric

$$d(x,z) = \inf_{\gamma: x \to z} \int_\gamma \frac{ds_\infty}{\xi(s)}. \tag{3.cdl}$$

The half-open convention only assigns a measure-zero cell boundary; paths and their infima can be approximated on either side. The corresponding lattice metric is comparable after the fixed collar constants have been inserted.

For each field species s, declare a positive amplitude $a_s(y)$ and use $\|f\|_{s,y} = a_s(y)^{-1}\|f\|_{\infty,\Delta(y)}$. For example a physical potential has amplitude ξ_y^{-1}, a physical force density ξ_y^{-3}, and a raw datum logarithm amplitude one. The site gauge parameter also has amplitude one. A raw multiplier uses counting measure and amplitude one; its per-length density has amplitude ξ_y^{-3}. The conversion is the weighted dual conversion of the domain section.

If P_y is restriction to a cell, define the normalized cell entry of an operator $K : t \to s$ by

$$k_{st}(y,z) = \|P_y K P_z\|_{\ell^\infty(t,z)\to\ell^\infty(s,y)}. \tag{3.cdli}$$

All physical cell measures in the action of K are included before taking this norm. It is a block operator norm, not a pointwise bound on the continuum kernel. A Green kernel with its fine

Coulomb singularity can have a bounded cell norm. Replacing it by a pointwise kernel bound independent of η would be a stronger and generally false assertion.

For compatible species, the cell partition and triangle inequality give

$$(k\ell)_{su}(y,z) \le \sum_w k_{st}(y,w)\ell_{tu}(w,z). \tag{3.cdlii}$$

This follows first for finite lattices by inserting $\sum_w P_w = 1$. In an infinite-volume application the same formula holds when the row sums below give absolute convergence. Thus a two-sided exponential cell norm is an algebra norm, without discarding the fine singularity inside a block.

3.13.2. *The growth of a ball in the layer metric.* The layer metric is not assumed to have polynomial volume growth. A small-cell region can contain many more pillars than a nearby large-cell region. Separation controls that growth quantitatively.

Suppose x has layer index j and z has index i. Any path between them crosses each complete intervening layer. For a layer r, a crossing from Ω_{r+1} to Ω_r^c has an arc whose interior lies in $\Omega_r \setminus \Omega_{r+1}$. The separation makes its physical length greater than $\rho\xi_r$. On that arc the metric density is ξ_r^{-1}, so its length in eq. 3.cdl is at least ρ. Arcs belonging to distinct layers have disjoint interiors. Consequently

$$d(x,z) \ge \rho(|i-j|-1)_+. \tag{3.cdliii}$$

One layer is lost because an endpoint can already lie next to its neighboring layer. The same proof applies to an intermediate point of a path, so a path of metric length at most $R+1$ starting in layer j never uses a scale larger than

$$\xi_{\max} \le L\xi_j L^{(R+1)/\rho}. \tag{3.cdliv}$$

If the top index would exceed the depth, this is simply an overestimate.

Its physical length is at most $(R+1)\xi_{\max}$. Every pillar center in the metric R-ball therefore has a lift in the physical sup-norm ball of radius

$$H_R = L(R+1)\xi_j L^{(R+1)/\rho}. \tag{3.cdlv}$$

For each fixed level i the centers lie on its grid of spacing ξ_i. The number of grid points in that physical ball is at most $C(1+H_R/\xi_i)^4$. eq. 3.cdliii restricts the possible indices to $|i-j| \le 1+(R+1)/\rho$. Using the smallest such ξ_i in the grid count and then summing the possible levels gives

$$\#\{z : d(y,z) \le R\} \le C_L(1+R)^5 \exp\left(\frac{8\log L}{\rho}R\right). \tag{3.cdlvi}$$

Indeed $H_R/\xi_i \le C_L(R+1)L^{2(R+1)/\rho}$; its fourth power gives the exponential in eq. 3.cdlvi, and the number of levels costs one more polynomial power. Since $\rho \ge 1$, the harmless factors $L^{8/\rho}$ and the bound on the number of levels can be included in C_L uniformly in ρ.

The argument works on a torus without a nonwrapping-ball assumption. For every reached center choose the lift reached by its path. Distinct periodic centers give distinct lifted grid points. Counting all grid points in the cover ball is therefore an upper bound, even if that ball crosses many fundamental domains. Restricting the allowed regions only decreases the number counted.

An entry bound of the form

$$k_{st}(y,z) \le C\left(\frac{\xi_y}{\xi_z}\right)^p e^{-md(y,z)} \tag{3.cdlvii}$$

now implies a weighted row and column sum, provided the rate pays for scale growth. By eq. 3.cdliii the scale ratio on an annulus of metric radius R is at most $L^{|p|}e^{|p|(\log L)(R+1)/\rho}$. Break the space into unit annuli and use eq. 3.cdlvi. Thus

$$\sup_y \sum_z e^{\delta d(y,z)}k_{st}(y,z) + \sup_z \sum_y e^{\delta d(y,z)}k_{st}(y,z) \le C' \tag{3.cdlviii}$$

whenever

$$m-\delta>\frac{(8+|p|)\log L}{\rho}. \tag{3.cdlix}$$

For the column sum use the same ball argument centered at z; the absolute scale exponent is unchanged. The convergent scalar sum is bounded by $C\sum_{n\ge0}(n+2)^5e^{-[m-\delta-(8+|p|)\log L/\rho]n}$. This proves the claim with its precise uniformity.

If the amplitude normalization has already removed the scale ratio, take $p=0$. For several species use the largest of their finitely many exponents. An exponential bound with an arbitrarily small m does not automatically imply eq. 3.cdlviii. The geometry and rate must satisfy eq. 3.cdlix, or a stronger actual row estimate must be proved directly. This is a numerical condition in the order of choice of separation and kernel rates.

3.13.3. *The exponential-chart Ward identity.* We derive a complete current-linear normal form. This also states exactly what a separately specified current completion would have to match. For this calculation use raw bond logarithms and counting pairings. Equivalently use physical potentials and their dual fine cell weights, with the conversions stated below.

Let $F_U(a)=A_{\Omega_0}(e^{ia}U)$, with all plaquettes of this action inner to its gauge-invariant active graph, and put $j_U=DF_U(0)$, $\mathscr{D}_U=D^2F_U(0)$. For a site function λ, define the raw infinitesimal gauge generator by

$$(D_U\lambda)(b)=\lambda(b_-)-\mathrm{Ad}(U_b)\lambda(b_+). \tag{3.cdlx}$$

This equation fixes the sign of D_U in this section. A convention with the opposite covariant difference changes both occurrences consistently. The site Laplacian $D_U^\sharp D_U$ is unchanged.

At a nonzero reference logarithm a the gauge generator in that same logarithmic coordinate is

$$\mathfrak{d}_U(a)\lambda=\mathcal{E}_a^{-1}\{\lambda(b_-)-\mathrm{Ad}(e^{ia_b}U_b)\lambda(b_+)\},\qquad \mathcal{E}_ah=\int_0^1\mathrm{Ad}(e^{ita})h\,dt. \tag{3.cdlxi}$$

The equality follows by differentiating $e^{it\lambda_-}e^{ia_b}U_be^{-it\lambda_+}$ and multiplying by its inverse on the right. The factor $1/i$ in the right-logarithmic derivative is included in $\mathcal{E}_a$. The integral formula follows by differentiating the exponential series, or by integrating its constant-coefficient differential equation. It is holomorphic on the admitted logarithm chart.

The derivative at zero is

$$D\mathfrak{d}_U(0)[v]\lambda=-\frac{i}{2}[v_b,\lambda(b_-)+\mathrm{Ad}(U_b)\lambda(b_+)]. \tag{3.cdlxii}$$

Indeed $D\mathcal{E}_0[v]h=(i/2)[v,h]$, while differentiating the endpoint transport contributes $-i[v,\mathrm{Ad}(U_b)\lambda_+]$. Subtracting the derivative of $\mathcal{E}_a$ acting on $\lambda_--\mathrm{Ad}(U_b)\lambda_+$ gives exactly eq. 3.cdlxii, with a plus between the two endpoint site values inside its commutator.

Gauge invariance implies $DF_U(a)[\mathfrak{d}_U(a)\lambda]=0$. Differentiating once at zero proves

$$D_U^\sharp j_U=0,\qquad \mathscr{D}_UD_U=\mathcal{W}_U[j_U], \tag{3.cdlxiii}$$

where the explicit linear-current operator is

$$(\mathcal{W}_U[J]\lambda)(b)=\frac{i}{2}[\lambda(b_-)+\mathrm{Ad}(U_b)\lambda(b_+),J_b]. \tag{3.cdlxiv}$$

To verify its order and sign, cyclicity gives $\langle J,(i/2)[v,S]\rangle=\langle v,(i/2)[S,J]\rangle$. Together with eq. 3.cdlxii this is the differentiated invariance identity. The formula uses the actual action current. No constrained criticality has been assumed.

The operator $\mathcal{W}_U[J]$ is defined for an independent J by eq. 3.cdlxiv. It is local and linear in that current. It does not differentiate J. For an arbitrary independent current, $D_U^\sharp J$ need not vanish, and $D_U^\sharp\mathcal{W}_U[J]$ need not be symmetric. Those physical identities cannot be inserted in an off-current definition.

If the spacing is η, the physical generator is $D_U^{\mathrm{phys}} = \eta^{-1} D_U$. The raw and physical currents satisfy $j_{\mathrm{raw}} = \eta^3 J_{\mathrm{phys}}$, and the physical Hessian operator is $\eta^{-2}\mathscr{D}_{\mathrm{raw}}$ with respect to the η^4 pairing. Thus

$$\mathscr{D}_{\mathrm{phys}} D_U^{\mathrm{phys}} = \mathcal{W}_U[J_{\mathrm{phys}}]. \tag{3.cdlxv}$$

There is no extra inverse power of η in $\mathcal{W}_U[J_{\mathrm{phys}}]$. Both sides have the dimension of a force density applied to a dimensionless site gauge.

For the operator formulas from this point onward restore the physical cell pairings and write D_U for D_U^{phys}. Write j_U for the physical current density and $\mathscr{D}_U$ for the physical Hessian operator. Their conversion is exactly the one in eq. 3.cdlxv. The formula in eq. 3.cdlxiv is unchanged. In bare units $\eta = 1$ all these conventions coincide.

3.13.4. *An explicit symmetric current correction.* Use the site operators of the background section and set

$$\Lambda = G' R D_U^\sharp, \qquad \mathsf{S} = 1 - D_U \Lambda. \tag{3.cdlxvi}$$

On their admitted domain the proved projector identities give $\mathsf{S} D_U G' R = 0$. Define the following specific symmetric current-linear form:

$$\begin{aligned} \mathcal{B}_U[J] = {} & \mathcal{W}_U[J]\Lambda + \Lambda^\sharp \mathcal{W}_U[J]^\sharp \\ & - \tfrac{1}{2}\Lambda^\sharp \{ D_U^\sharp \mathcal{W}_U[J] + \mathcal{W}_U[J]^\sharp D_U \} \Lambda. \end{aligned} \tag{3.cdlxvii}$$

This is a definition on the whole independent-current domain. Its symmetry is visible term by term. For the physical current, eq. 3.cdlxiii and symmetry of $\mathscr{D}_U$ imply $D_U^\sharp \mathcal{W}_U[j_U] = D_U^\sharp \mathscr{D}_U D_U$, which is symmetric. Expanding $(1 - D_U\Lambda)^\sharp \mathscr{D}_U (1 - D_U\Lambda)$ therefore proves

$$\mathscr{D}_U - \mathcal{B}_U[j_U] = \mathsf{S}^\sharp \mathscr{D}_U \mathsf{S}. \tag{3.cdlxviii}$$

This is an exact identity at every admitted real or complex field with its physical current. It requires no inner minimization.

The apparent derivative of J in the middle term of eq. 3.cdlxvii is never needed for a norm estimate. Its bilinear form can be written

$$\begin{aligned} \langle u, \mathcal{B}_U[J] v \rangle = {} & \langle u, \mathcal{W}_U[J]\Lambda v \rangle + \langle \mathcal{W}_U[J]\Lambda u, v \rangle \\ & - \tfrac{1}{2}\langle D_U \Lambda u, \mathcal{W}_U[J]\Lambda v \rangle - \tfrac{1}{2}\langle \mathcal{W}_U[J]\Lambda u, D_U \Lambda v \rangle. \end{aligned} \tag{3.cdlxix}$$

Derivatives are kept on Λ. Thus bounded current, a site inverse bound and its differentiated field readouts are the actual ingredients in a current perturbation estimate. Replacing this form by a pointwise bound on $D_U^\sharp \mathcal{W}_U[J]$ would introduce an unassumed derivative of the current.

3.13.4.1. Comparison with the named gauge-restoration form. Use the same active graph, background, site inverse and projection in the two definitions. The named form uses the covariant difference $D_{\mathrm{n}} = -D_U$. This leaves the site operators unchanged and gives its gauge read $G' R D_{\mathrm{n}}^\sharp A = -\Lambda A$. Write $w = \Lambda A$ and $w_+ = \mathrm{Ad}(U_b) w(b_+)$, $w_- = w(b_-)$ on a bond. With the spacing ξ, $D_U w = \xi^{-1}(w_- - w_+)$. Substitution of the gauge read $-w$ in the named quadratic form gives the bond expression

$$i[A, w_- + w_+] - i\xi^{-1}[w_-, w_+],$$

paired with J in the physical cell pairing.

The diagonal of eq. 3.cdlxvii is $2\langle A, \mathcal{W}_U[J] w \rangle - \langle D_U w, \mathcal{W}_U[J] w \rangle$. Cyclicity in the first pairing gives $i[A, w_- + w_+]$. In the second, use $[w_- - w_+, w_- + w_+] = 2[w_-, w_+]$. Thus its bond expression is the same. Polarization proves $\mathcal{B}_U[J] = \Delta'_\pi[U, J]$ for every independent current on the common domain. In particular the equality uses the named quadratic form itself. The physical Ward identity is used separately when $J = j_U$.

The site output w lies in $\ker Q'$. At each site of the bare layer outside Ω_1 the site row is the identity, so w vanishes there. The displayed commutators therefore use the current only on the

inner bonds with an endpoint in Ω_1. This is the read set of the gauge-restoration term, before adding the separate constraint-curvature subtraction.

For the explicit choice eq. 3.cdlxvii, $R = 0$ implies $\Lambda = 0$ and $\mathcal{B}_U[J] = 0$ for every J. For an unspecified completion this conclusion does not follow merely from zero-fold averaging maps. The physical identity in eq. 3.cdlxviii and the choice of an off-current extension are different statements.

In particular $\mathcal{B}_U[j_U]$ is a gauge-Ward correction, not the full constrained-action curvature correction even on the physical graph. For horizontal vectors u, v with $\Lambda u = \Lambda v = 0$, its bilinear form is zero. The Lagrangian Hessian still contains $-\langle \omega, D^2 q[u, v]\rangle$. The distinct subtraction in eq. 3.cdlxxvi is precisely where that mean-constraint term belongs after its actual multiplier has been identified. No gap for a constrained fluctuation is transferred from the Ward identity alone.

3.13.5. *The off-current gauge defect is computable.* The preceding explicit correction has useful identities even before inverse estimates. Use the actual row intertwining $QD_U = \bar{D}Q'$, on the specified site and row spaces. This is an input identity to be checked for the actual straightened rows, including all outward endpoint values. Set

$$\widehat{G}[J]^{-1} = \mathscr{D}_U - \mathcal{B}_U[J] + D_U R D_U^\sharp + Q^\sharp a Q, \qquad \delta J = J - j_U. \tag{3.cdlxx}$$

Every assertion about an inverse is restricted to its admitted invertibility domain. The identities $\mathsf{S} D_U G' R = 0$, $Q' G' R = 0$ and $\Delta G' R = R$, with $\Delta = D_U^\sharp D_U$, give

$$\widehat{G}[J]^{-1} D_U G' R = D_U R - \mathcal{B}_U[\delta J] D_U G' R. \tag{3.cdlxxi}$$

For the action part use eq. 3.cdlxviii, whose right side annihilates $D_U G' R$. The gauge part is $D_U R \Delta G' R = D_U R$. The row mass is zero because $Q D_U G' R = \bar{D} Q' G' R = 0$. Linearity of $\mathcal{B}$ supplies the remaining current difference. Multiplying by the inverse proves

$$\widehat{G}[J] D_U R = D_U G' R + \widehat{G}[J] \mathcal{B}_U[\delta J] D_U G' R. \tag{3.cdlxxii}$$

Thus the failure of the physical gauge identity is exactly linear in the independent-current defect before inversion, and has the displayed resolvent dependence after inversion.

If $Q\widehat{G}[J]Q^\sharp$ is invertible, define

$$\widehat{H}[J] = \widehat{G}[J] Q^\sharp (Q \widehat{G}[J] Q^\sharp)^{-1}. \tag{3.cdlxxiii}$$

Transposing eq. 3.cdlxxii and using $R G' Q'^\sharp = 0$ proves

$$R D_U^\sharp \widehat{H}[J] = R G' D_U^\sharp \mathcal{B}_U[\delta J] \widehat{H}[J]. \tag{3.cdlxxiv}$$

The first term after transposition vanishes because $D_U^\sharp Q^\sharp = Q'^\sharp \bar{D}^\sharp$. At $J = j_U$ the right side is zero. An arbitrary independent current does not obey that slice condition. Norm estimates for its defect use the actual site and field kernels and the form in eq. 3.cdlxix.

There is an equally explicit second variant. Let $\mathcal{C}_U^{(2)}$ be the homogeneous quadratic part per unit length of the actual nonlinear straightened average, and normalize its current form by

$$\langle v, \Delta^{(2)}[\omega] v\rangle = 2\langle \omega, \mathcal{C}_U^{(2)}(v)\rangle. \tag{3.cdlxxv}$$

Define it bilinearly by polarization, and set

$$\widehat{G}_1[J]^{-1} = \widehat{G}[J]^{-1} - \mathsf{S}^\sharp \Delta^{(2)}[\widehat{H}[J]^\sharp J] \mathsf{S}. \tag{3.cdlxxvi}$$

The added form annihilates $D_U G' R$ on its right, by $\mathsf{S} D_U G' R = 0$. Therefore eq. 3.cdlxxi–eq. 3.cdlxxii hold with $\widehat{G}_1$ in place of $\widehat{G}$. Its row lift has the corresponding slice-defect identity. The $\widehat{H}$ inside eq. 3.cdlxxvi is formed from the first variant; replacing it by the new row lift would change the definition.

These identities do not prove invertibility or bounds. They do prove the correct physical cancellations once those estimates hold. They therefore apply to the named current completion on the

common primitive domain. If a different extension is chosen, its own defect must be calculated from its definition.

3.13.6. *An inner action and a compression have different Ward terms.* For an inner-plaquette action the gauge calculation in eq. 3.cdlxiii is exact on its active graph. A different operation first takes the Hessian of a larger action and then compresses it. Let χ be restriction of fine fields to a set of bonds, and let χ_0 restrict sites. Writing D_{loc} for a proposed local gauge generator, the defect of commuting compression and gauge variation is

$$E_D = \chi D_U \chi_0^\sharp - D_{\mathrm{loc}}. \tag{3.cdlxxvii}$$

Even if $E_D = 0$, the full Hessian can couple through removed bonds. The compressed Ward identity reads

$$\begin{aligned}(\chi \mathscr{D}_U \chi^\sharp) D_{\mathrm{loc}} = \chi \mathcal{W}_U[j_U]\chi_0^\sharp \\ - \chi \mathscr{D}_U (1 - \chi^\sharp\chi) D_U \chi_0^\sharp - \chi \mathscr{D}_U \chi^\sharp E_D.\end{aligned} \tag{3.cdlxxviii}$$

This follows by substituting eq. 3.cdlxxvii, inserting $1 = \chi^\sharp\chi + (1 - \chi^\sharp\chi)$, and applying eq. 3.cdlxiii. The extra terms are supported near the boundary when the full operator is local; with an exponentially local operator they have the corresponding boundary tails. They are not part of the physical interior current unless the action has actually been changed to the inner action.

There is a parallel distinction for lower bounds. Compressing a positive form to free coordinates by zero extension preserves its gap:

$$A \geq cI \quad \Longrightarrow \quad \chi A \chi^\sharp \geq cI. \tag{3.cdlxxix}$$

Rebuilding its Laplacian, row averages or block means on the clipped region is another operator. For example take a unit physical block with fine spacing η, its discrete Laplacian and its full-block constant projection. Their sum has a fixed physical gap after a fixed normalization. Keep one fine site, drop all crossing Laplacian edges as in a Neumann cut, and retain only the compressed full-block mean. The remaining eigenvalue is the fine-volume fraction η^4, which tends to zero. In the true Dirichlet compression the crossing-edge energy remains; this example does not contradict eq. 3.cdlxxix.

Thus every local inverse theorem specifies the order: form the actual operator with its declared rows and gauge, then compress to its free region. A local construction with modified rows instead supplies its complete boundary comparison and its own gap proof. A collar can make those differences small at the rows that are used; it does not erase them as identities.

3.13.7. *The site readout at an outward row.* The site average used in the Landau projector has one value at each top, taken at that top's assigned level. The endpoint readout of a row is a different list when the row is outward. We now give their exact relation.

Let $\mathsf{T}_j(y,x)$ be the product of the admitted internal mean transports from a level-j center y down its pillar to a bare site x. For a top of level j define

$$(Q'_{\mathrm{pill}}\lambda)(y) = L^{-4j} \sum_{x \in B^j(y)} \mathrm{Ad}(\mathsf{T}_j(y,x))\lambda(x). \tag{3.cdlxxx}$$

These pillars are disjoint. There is therefore an explicit right inverse on node fields:

$$(E_{\mathrm{pill}}\psi)(x) = \mathrm{Ad}(\mathsf{T}_j(y,x))^{-1}\psi(y) \quad (x \in B^j(y)), \qquad Q'_{\mathrm{pill}}E_{\mathrm{pill}} = 1. \tag{3.cdlxxxi}$$

This proves rank without an elliptic estimate. For real transports the right inverse has supremum norm one. With fine site measure η^4 and top measure ξ_y^4, it is also an isometry in L^2. Indeed a pillar contains L^{4j} bare sites, so $\eta^4 L^{4j} = \xi_y^4$. The invariant bilinear color pairing gives

$$Q'_{\mathrm{pill}} = E_{\mathrm{pill}}^\sharp, \qquad Q'_{\mathrm{pill}}(Q'_{\mathrm{pill}})^\sharp = 1. \tag{3.cdlxxxii}$$

The algebraic identities hold for admitted complex transports as well. Their Hermitian norm bounds then include the actual condition numbers of those transports. A counting kernel must include the ratio ξ_y^4/η^4 in the transpose; an ordinary unweighted array transpose would not be eq. 3.cdlxxxii.

For any level-j center z, write $Q'_j\lambda(z)$ for its full j-fold transported site average, whether or not its assigned top level is j. If z is the outer endpoint of a determining level-j row, its assigned level is $j-1$. The entire block $B^j(z)$ lies in that outer layer. Decompose it into its L^4 level-$(j-1)$ pillars. The product definition of the transport gives

$$Q'_j\lambda(z) = L^{-4} \sum_{w\in B(z)\cap\mathbb{T}^{(j-1)}} \mathrm{Ad}(T_{z,w}(\mathcal{M}^{j-1}U))(Q'_{\mathrm{pill}}\lambda)(w). \tag{3.cdlxxxiii}$$

To verify the coefficient, each smaller average has weight $L^{-4(j-1)}$; multiplying it by L^{-4} gives L^{-4j}. The two transport factors multiply in their path order. This proves eq. 3.cdlxxxiii exactly, without an asymptotic or small-field approximation.

Define $\mathcal{E}_{j,z}\psi$ to be $\psi(z)$ at an assigned level-j top, and to be the finite average on the right of eq. 3.cdlxxxiii at an outer endpoint. Then define the extended coarse difference by

$$(\bar{D}_{\mathrm{ext}}\psi)(c) = \xi_c^{-1}\{\mathcal{E}_{j,c_-}\psi - \mathrm{Ad}((\mathcal{M}^jU)(c))\mathcal{E}_{j,c_+}\psi\}, \qquad c\in\Gamma_j. \tag{3.cdlxxxiv}$$

For an interior row it is the ordinary covariant difference of its two top values. For an outward row it first averages the outer finer tops. There is no need to duplicate that site as a new independent top in the site Gram matrix.

Here is a direct verification of the field intertwining. Under an infinitesimal gauge $e^{it\lambda}$ the derivative of the level-j node factor is

$$\frac{1}{i}\frac{d}{dt}v_j[tD_U^{\mathrm{phys}}\lambda](y)\Big|_{t=0} = \lambda(y) - Q'_j\lambda(y). \tag{3.cdlxxxv}$$

At one step the change in each relative contour has derivative $\lambda(y) - \mathrm{Ad}(T_{y,x})\lambda(x)$. The implicit mean at the identity has differential the arithmetic mean of its inputs, so this gives the one-step formula. Iterating and using the product rule for the accumulated node factors gives eq. 3.cdlxxxv, with the hierarchical site average in eq. 3.cdlxxx.

Differentiate the actual straightening identity $\mathcal{M}^j(e^{i\eta A}U) = v_j[A]\,e^{iq_j^{\mathrm{st}}(A)}\mathcal{M}^jU\,v_j[A]^{-1}$ on a row. The plain coarse variation is $\lambda(c_-) - \mathrm{Ad}(\mathcal{M}^jU(c))\lambda(c_+)$. Subtract the two node derivatives eq. 3.cdlxxxv, with their endpoint transports. The remaining variation is

$$Dq_j^{\mathrm{st}}(0)\,D_U^{\mathrm{phys}}\lambda = Q'_j\lambda(c_-) - \mathrm{Ad}(\mathcal{M}^jU(c))Q'_j\lambda(c_+). \tag{3.cdlxxxvi}$$

Divide by ξ_c to obtain the per-length row Q. Using eq. 3.cdlxxxiii proves the fully typed identity

$$QD_U^{\mathrm{phys}} = \bar{D}_{\mathrm{ext}}Q'_{\mathrm{pill}}. \tag{3.cdlxxxvii}$$

This supplies the intertwining needed in eq. 3.cdlxx–eq. 3.cdlxxiv. There $\bar{D}$ means this extended row difference and Q' means the own-pillar site map. Using a single unextended value of the outer top would give the wrong formula.

Each endpoint extension reads at most L^4 tops in one adjacent layer. Its real row sum is at most one, since the transports are unitary and the weights add to one. A finer top occurs in one such outer block and at most eight incident coarse rows. Thus its two-sided normalized cell counts are bounded at fixed L, without a factor depending on the depth. For complex pairs the same statement uses the actual bounded transport condition numbers. The latter are atomic domain estimates; the algebraic intertwining does not prove them.

3.13.8. *Finite real existence of the site operators.* There is also a real finite positivity statement independent of a quantitative inverse bound. Assume the actual mean transports are admitted and unitary, and that every active fine site lies in a connected pillar with its top. Let a be strictly positive on the top space. Then

$$L_{\mathrm{site}} = D_U^\sharp D_U + (Q'_{\mathrm{pill}})^\sharp a Q'_{\mathrm{pill}} \quad \text{is strictly positive.} \tag{3.cdlxxxviii}$$

To prove it, a vector of zero Hermitian energy must obey $D_U\lambda = 0$ and $Q'_{\mathrm{pill}}\lambda = 0$. Split into Hermitian real and imaginary parts; it suffices to treat real λ. The first identity means that $e^{it\lambda(x)}$ leaves every active bond unchanged:

$$e^{it\lambda(b_-)} U_b e^{-it\lambda(b_+)} = U_b. \tag{3.cdlxxxix}$$

Gauge covariance of each actual mean transport therefore gives $\mathrm{Ad}(\mathsf{T}_j(y,x))\lambda(x) = \lambda(y)$. Average over the pillar: $Q'_{\mathrm{pill}}\lambda(y) = \lambda(y)$. Its zero value makes $\lambda(y) = 0$. Parallel transport along the active graph from the top to every site makes $\lambda = 0$. This proves eq. 3.cdlxxxviii.

It follows that $G' = L_{\mathrm{site}}^{-1}$ exists on every finite real problem of this type. The site Gram matrix

$$Q'_{\mathrm{pill}} G'^2 (Q'_{\mathrm{pill}})^\sharp \tag{3.cdxc}$$

is strictly positive as well. For a nonzero node vector ψ, surjectivity makes $(Q'_{\mathrm{pill}})^\sharp\psi \neq 0$; invertibility of G' then makes its squared norm positive. Thus the formulas for R and S are genuine finite real matrices before their uniform bounds are established.

No volume-uniform or scale-weighted lower bound has been deduced from this nullspace argument. That bound needs the quantitative site Poincaré and local-gauge estimates. Nor does eq. 3.cdlxxxviii prove positivity of the fine Wilson Hessian or of its independent-current completion. The distinctions between finite invertibility, uniform coercivity and exponentially local readouts remain necessary.

3.13.9. *Transport control on one pillar.* The site gap has a quantitative proof from the actual averages. Let a pillar have side $\xi = n\eta$, where $n = L^j$, and assume

$$|\partial U(p) - 1| \le \epsilon\, \eta^2 \xi^{-2} \tag{3.cdxci}$$

on its determining neighborhood. The fixed path neighborhood has an embedded rectangular lift. If an extra fine collar is needed, the regularity bounds in the adjacent layer give the same inequality with a fixed L-dependent factor. We include that factor in the constants below.

Take the fine coordinate comb from the pillar center and put $g(x) = U(\Gamma_{y,x})$. For adjacent $x, x + \eta e_\mu$, the loop made by the two root combs and that bond is filled by strips of width one fine cell. Commuting the extra μ-step through the later coordinate segments uses at most Cn plaquettes, not Cn^2. The unitary Stokes product inequality therefore gives

$$|U^g(b) - 1| \le C\epsilon/n \quad \text{on internal fine bonds.} \tag{3.cdxcii}$$

Here $g(y) = 1$. Every curvature norm is unchanged. The gauge need not be close to one, and its derivatives are not estimated in this step.

Write $\xi_r = L^r\eta$, and let a_r be the supremum of $|\mathcal{M}^r(U^g)(c) - 1|$ on the level-r internal edges used in the hierarchical transport. Let ϖ_r be the corresponding coarse plaquette bound. The determining neighborhoods remain in the rectangular pillar neighborhood: each parent block is a union of its child blocks, and each contour stays in its assigned block. The real curvature iteration proved in the background section gives

$$\varpi_r \le C_L \epsilon (\xi_r/\xi)^2. \tag{3.cdxciii}$$

The same finite comparison shows that one actual averaged edge differs from its central straight transport by at most $C_L\varpi_r$. Indeed every closed logarithm in its definition is a comparison loop

with that central transport. The unitary strip estimate bounds those logarithms, and then their exponential average. The central route has L edges, so

$$a_{r+1} \le L a_r + C_L \varpi_r. \tag{3.cdxciv}$$

The coefficient of a_r is exactly L, by the unitary product inequality.

Iterating eq. 3.cdxciv, using $a_0 \le C\epsilon\eta/\xi$, gives

$$\begin{aligned} a_r &\le L^r a_0 + C_L \epsilon \sum_{s<r} L^{r-1-s} (\xi_s/\xi)^2 \\ &\le C_L \epsilon\, \xi_r/\xi. \end{aligned} \tag{3.cdxcv}$$

For the sum, insert $\xi_s = \eta L^s$; its geometric factor is bounded by a constant times $(\xi_r/\xi)^2$, which is no larger than ξ_r/ξ. The constants do not multiply with the number of levels.

The internal mean on level r is a finite smooth mean of paths of $O(L)$ edges. On its regular near-identity chart it differs from one by at most $C_L a_r$. The hierarchical transport has one such factor at each level below j. All are unitary, hence

$$|\mathsf{T}_j(U^g; y, x) - 1| \le C_L \sum_{r<j} a_r \le C_L \epsilon \quad (x \in B^j(y)). \tag{3.cdxcvi}$$

The last sum uses $\sum_{r<j} \xi_r/\xi \le 1/(L-1)$. The fixed smallness of ϵ also admits every mean used in this argument. Thus eq. 3.cdxcvi is a uniform-depth property of the actual iterated transports, not a hypothesis of such a property.

3.13.10. *A real weighted site gap.* We first prove the flat block inequality with its scale. Let $\bar\lambda$ be the arithmetic mean on the n^4 sites of a block. The exact variance identity is

$$\sum_x |\lambda(x) - \bar\lambda|^2 = \frac{1}{2n^4} \sum_{x,z} |\lambda(x) - \lambda(z)|^2. \tag{3.cdxcvii}$$

Connect each pair by the coordinate-order path. Its length is at most $4n$. A fixed oriented edge lies in at most n^5 of these paths: its two longitudinal endpoint coordinates give at most n^2 choices, and the three other coordinates give at most n^3. Cauchy on the path and then eq. 3.cdxcvii give a constant times n^2 times the sum of squared edge differences. Multiplying by $\eta^4\xi^{-2}$ proves

$$\xi^{-2}\|\lambda\|_{2,B}^2 \le C\{\|\partial_{\mathrm{int}}\lambda\|_{2,B}^2 + \xi^2|\bar\lambda|^2\}. \tag{3.cdxcviii}$$

Here the fine norm uses η^4, and ∂ divides a bond difference by η. The mean part is $\eta^4 n^4 \xi^{-2}|\bar\lambda|^2 = \xi^2|\bar\lambda|^2$. For $n = 1$ the variance vanishes and the same inequality holds.

Apply the real comb gauge of eq. 3.cdxcii in each pillar. Only internal bonds are used in the block inequality, so the gauges of neighboring pillars may be different. They define a unitary site gauge globally, and all covariant norms are unchanged. In this frame

$$\|(\partial_{\mathrm{int}} - D_{U,\mathrm{int}})\lambda\|_{2,B} \le C_L \epsilon\, \xi^{-1}\|\lambda\|_{2,B}. \tag{3.cdxcix}$$

The estimate follows from $|\operatorname{Ad}(U_b) - 1| \le C_L\epsilon\eta/\xi$ and the at-most-eight incidences at a site.

Let Q_0' be arithmetic block average. eq. 3.cdxcvi, Cauchy for the finite average and $\xi^4 = n^4\eta^4$ give

$$\xi^4|(Q'_{\mathrm{pill}} - Q_0')\lambda|^2 \le C_L\epsilon^2\|\lambda\|_{2,B}^2. \tag{3.d}$$

Use eq. 3.cdxcix–eq. 3.d on the right of eq. 3.cdxcviii. The result is the same two terms with D_U and Q'_{pill}, plus $C_L\epsilon^2\xi^{-2}\|\lambda\|_{2,B}^2$. Choose the fixed curvature ceiling so that this coefficient is at most one half of the left coefficient. Absorption proves

$$\xi^{-2}\|\lambda\|_{2,B}^2 \le C_L\{\|D_{U,\mathrm{int}}\lambda\|_{2,B}^2 + \xi^2|Q'_{\mathrm{pill}}\lambda|^2\}. \tag{3.di}$$

Sum over the disjoint pillars. Every internal fine bond is counted at most once; all other gradient terms in the full energy are nonnegative. Suppose $a(y) = c_y \xi_y^{-2}$ with $c_y \geq a_* > 0$. Then

$$\begin{aligned} \sum_x \eta^4 \xi(x)^{-2} |\lambda(x)|^2 &\leq C_{L,a_*} \{ \|D_U \lambda\|_2^2 + \langle Q'_{\mathrm{pill}} \lambda, a Q'_{\mathrm{pill}} \lambda \rangle_{\mathrm{tops}} \} \\ &= C_{L,a_*} \langle \lambda, L_{\mathrm{site}} \lambda \rangle. \end{aligned} \tag{3.dii}$$

This is the actual site weighted gap, uniform in depth, volume, region shape and real holonomy. It uses the small real curvature and actual transport construction; no physical current or criticality is used. Crossing-edge energy is kept, not replaced by a clipped block mean.

For a complex site vector split into Hermitian real and imaginary parts. Since the real unitary connection is a real matrix in an orthonormal Lie-algebra basis, the same inequality holds for its Hermitian energy. If the top scale is at most one, it in particular gives an ordinary finite L^2 gap independent of the bare mesh. In other physical units its smallest unweighted gap is scaled by the inverse square of the largest local scale.

3.13.11. *The complex site domain uses the actual iterated means.* The preceding transport argument has a complex version with a fixed physical radius, independent of the number of fine sites. We give it to avoid assuming a uniform radius for the iterated site average.

Consider one step on a fixed two-block neighborhood. Suppose all its edge matrices satisfy $|W_b - 1| \leq a$, and let $\varpi = \sup |\partial W - 1|$. There are constants r_L, C_L for which the actual means and logarithms are admitted if $a, \varpi < r_L$, and

$$\begin{aligned} a_{\mathrm{next}} &\leq La + C_L a^2 + C_L \varpi, \\ \varpi_{\mathrm{next}} &\leq L^2 (1 + C_L a) \varpi + C_L \varpi^2. \end{aligned} \tag{3.diii}$$

For the first line, a central straight product differs from one by at most $La + C_L a^2$. Plaquette sliding bounds each closed comparison logarithm by $C_L \varpi$: all prefix transports have condition number at most $1 + C_L a$ on this finite neighborhood. The defining exponential average therefore changes the central product by at most that amount.

For the second line, take the local complex comb gauge. Its values and inverses are $1 + O(C_L a)$. It sets the tree bonds to one; each remaining bond is then $1 + O(C_L \varpi)$ by the finite plaquette sliding identity. In that gauge the Taylor/flux argument for the actual one-step map gives the coefficient L^2 and a quadratic error $C_L \varpi^2$. Conjugating the fine and coarse plaquettes through the small complex gauge changes their norms by $1 + C_L a$. This proves eq. 3.diii. Complex covariance here follows directly from the conjugation identity for the small logarithm, or from uniqueness of the admitted finite mean. No absolute-value formula is continued holomorphically.

These constants can be bounded before an iteration is run. The finite mean construction has a joint raw-edge holomorphic ball of radius c/L, with universal supremum bounds; two scalar Cauchy circles bound its second derivative by CL^2. A comb on the one-step patch sweeps at most CL^2 plaquettes, so its non-tree logarithms have size $CL^2 \varpi$. The quadratic Taylor error in the coarse plaquette is therefore at most $CL^2 (L^2 \varpi)^2 = CL^6 \varpi^2$. The fine logarithmic curl error times its L^2 flux factor has the same upper order. Prefix conjugations cost $1 + CLa$. For example $r_L = cL^{-3}$ and $C_L = CL^8$, with fixed universal shrinkages and enlargements, suffice in eq. 3.diii. This count uses directional Cauchy on the proved full supremum ball, not one coordinate estimate summed over all field coordinates.

On a pillar let $t_r = \xi_r / \xi$, and normalize $A_r = a_r / t_r$, $V_r = \varpi_r / t_r^2$. eq. 3.diii implies, with an increased fixed constant,

$$Z_{r+1} \leq Z_r + C_L t_r (Z_r + Z_r^2), \qquad Z_r = A_r + V_r, \qquad \sum_{r<j} t_r \leq \frac{1}{L-1}. \tag{3.div}$$

For $Z_r \le 1$, the factor is at most $1 + 2C_L t_r$. Its product is at most $\exp(2C_L/(L-1))$. Choose Z_0 below one half the minimum one-step chart radius times the inverse of this number. Induction then gives $Z_r \le C_L Z_0$ and keeps every step in its chart. The constants depend on L, not j. With the preceding finite choices a sufficient common small input radius has the explicit form $cL^{-3}\exp(-CL^8)$. The precise numerical constants are not needed below, but this gives a positive lower radius rather than an asserted upper cap. The product of the internal means and its inverse have norm at most $\exp(C_L \sum_r a_r)$. Hence

$$|\mathsf{T}_j(W;y,x) - 1| \le C_L Z_0, \qquad |\mathsf{T}_j(W;y,x)| + |\mathsf{T}_j(W;y,x)^{-1}| \le C_L. \tag{3.dv}$$

This proves the existence and boundedness of the whole finite hierarchical formula on that domain.

Now start with a real field satisfying eq. 3.cdxci, put it in the real comb gauge eq. 3.cdxcii, and let $W = e^{i\eta E}U$. Assume the actual physical first-order input satisfies

$$h = \max\{\|\xi E\|_\infty, \|\xi^2 \nabla_U E\|_\infty\} \le h_L. \tag{3.dvi}$$

In the comb frame the ordinary first difference of E differs from its covariant one by $O(\epsilon\xi^{-1}|E|)$. The elementary plaquette product then gives $a_0 \le C(\epsilon + h)\eta/\xi$ and $\varpi_0 \le C(\epsilon + h + h^2)(\eta/\xi)^2$. Thus the starting Z_0 in eq. 3.div is at most $C(\epsilon + h)$.

Choose a fixed $h_L > 0$ so that the same argument holds with E replaced by sE for $|s| < h_L/h$, and assume $h \le h_L/4$. Reduce the real curvature ceiling at the same time so that $\epsilon \le h_L$ and the resulting starting Z_0 satisfies eq. 3.div. The transport is holomorphic in s on this disc, with a uniform bound. Cauchy's formula on a smaller concentric disc, or the geometric sum of its Taylor coefficients, yields

$$|\mathsf{T}_j(e^{i\eta E}U;y,x) - \mathsf{T}_j(U;y,x)| \le C_L h. \tag{3.dvii}$$

The bound in eq. 3.dv is uniform in j and in the number of coordinates. This is a single directional Cauchy argument on an actual admitted physical disc. It does not assert an entrywise absolute Hessian sum for an arbitrary many-variable functional.

For the complex site average write Q'_E and for the real reference write Q'_U. The transported finite-average calculation used in eq. 3.d gives

$$\|a^{1/2}(Q'_E - Q'_U)\lambda\|_{2,\mathrm{tops}} \le C_L h\, \|\xi^{-1}\lambda\|_2. \tag{3.dviii}$$

Here the real row weights satisfy $a(y) \le a^* \xi_y^{-2}$. The proof squares the average difference in each disjoint pillar, uses eq. 3.dvii, and sums its fine volume. There is no factor equal to the number of fine sites. The same argument applies to the outer endpoint extension eq. 3.cdlxxxiii: its neighborhood uses one adjacent scale, so the input constants change by fixed powers of L.

3.13.12. *Relative forms give the complex site inverse.* It remains to compare the actual site operators, not their unscaled matrix coefficients. Let L_U be the real site operator and let $L_E = D^\sharp_{e^{i\eta E}U} D_{e^{i\eta E}U} + Q'^\sharp_E a Q'_E$. The transposes in L_E are bilinear analytic transposes. At a real reference they are the usual Hermitian adjoints.

For a fine bond the difference of the two site derivatives is bounded by $C|E_b||\lambda(b_+)|$. Adjacent pillar scales differ by at most the fixed factor L; the region gaps exclude a bare bond jumping over another layer. The finite incidence count therefore gives

$$\|(D_{e^{i\eta E}U} - D_U)\lambda\|_2 \le C_L h \|\xi^{-1}\lambda\|_2. \tag{3.dix}$$

Keeping derivatives on the two arguments, expand the kinetic difference. Use eq. 3.dix, then eq. 3.dviii for the mass difference, and finally the real weighted site gap in eq. 3.dii. For arbitrary complex vectors v, w, this gives

$$|\langle v, (L_E - L_U)w\rangle_{\mathrm{H}}| \le C_L h\, \langle v, L_U v\rangle_{\mathrm{H}}^{1/2} \langle w, L_U w\rangle_{\mathrm{H}}^{1/2}. \tag{3.dx}$$

For example the quadratic mass term is $(Q'_E - Q'_U)^\sharp a (Q'_E - Q'_U)$; the two cross terms contain only one difference. On replacing the left argument by its complex conjugate, the same absolute bounds

apply to the analytic bilinear transpose. No Hermitian conjugation of the complex coefficients is inserted into their definition.

Let $B_E = L_U^{-1/2}(L_E - L_U)L_U^{-1/2}$. eq. 3.dx proves $\|B_E\|_{2\to 2} \le C_L h$. For $C_L h \le 1/2$ one has

$$G'_E = L_U^{-1/2}(1 + B_E)^{-1} L_U^{-1/2}, \qquad \mathrm{Re}\langle \lambda, L_E \lambda\rangle_{\mathrm{H}} \ge \tfrac{1}{2}\langle \lambda, L_U \lambda\rangle_{\mathrm{H}}. \tag{3.dxi}$$

The inverse is holomorphic on the whole admitted physical ball. It has the same weighted coercivity, up to a fixed factor, uniformly in depth and volume. This is a relative-form argument. The unscaled operator norm of a coefficient perturbation need not be bounded as $\eta \downarrow 0$.

The proof establishes the site inverse part of the primitive package. It has not yet established the site Gram inverse, the fine vector Green function, or the layered current precision. Those require their separate row, readout and gap arguments.

3.13.13. *Exponential decay from the weighted site form.* Let V denote multiplication by $\xi(x)^{-2}$ on sites. The real gap in eq. 3.dii is $L_U \ge cV$. We prove a weighted inverse bound before converting it to pointwise regularity. This avoids estimating a bare kinetic operator by its unscaled norm.

Let ψ be bounded and one-Lipschitz for eq. 3.cdl, and let $M_s = e^{s\psi}$ on sites. Use the value $\psi(b_-)$ on an edge and $\psi(y)$ on a top. Put

$$D_s = M_s^{\mathrm{edge}} D_U M_s^{-1}, \qquad Q'_s = M_s^{\mathrm{top}} Q'_U M_s^{-1}. \tag{3.dxii}$$

On an edge the two endpoint values of ψ differ by at most $C_L\eta/\xi_b$. Inside a pillar their difference from the top value is at most a fixed constant. The difference from the unweighted row therefore satisfies

$$\|(D_s - D_U)\lambda\|_2 + \|a^{1/2}(Q'_s - Q'_U)\lambda\|_{2,\mathrm{tops}} \le C_L|s|\,\|V^{1/2}\lambda\|_2 \tag{3.dxiii}$$

for $|s| \le s_L$. The edge estimate follows from $|e^{st} - 1| \le C|s||t|$ on the stated bounded interval. For the site row use the same estimate in its finite transported average, then Cauchy with the actual pillar volume. Its constant is independent of $\|\psi\|_\infty$.

The conjugated form has the exact factorization

$$M_s L_U M_s^{-1} = D_{-s}^{\sharp} D_s + (Q'_{-s})^{\sharp} a Q'_s. \tag{3.dxiv}$$

Expanding it and using eq. 3.dxiii, eq. 3.dii proves a relative form error at most $C_L|s|$. With a complex field perturbation in the ball of eq. 3.dxi, the same calculation gives error $C_L(h + |s|)$ relative to the real L_U. Choose both small enough for that number to be at most one half. All these forms are invertible.

For any such inverse $\mathcal{G}_s$, testing the equation $L_s\lambda = V^{1/2}f$ against λ gives

$$\|V^{1/2}\mathcal{G}_s V^{1/2}\|_{2\to 2} \le 2/c. \tag{3.dxv}$$

Indeed its real part is at least $(c/2)\|V^{1/2}\lambda\|_2^2$, whereas the right pairing is at most $\|V^{1/2}\lambda\|_2\|f\|_2$. This proof uses neither a normal matrix nor a pointwise positive complex kernel.

Choose $\psi(x) = \min\{d(x, \Delta(z)), N\}$. It is one-Lipschitz. The diameter of a pillar in eq. 3.cdl is bounded, so on $\Delta(y)$ its value is at least $d(y, z) - C$ after N is large enough. eq. 3.dxv then yields

$$\|P_y G'_E P_z\|_{2\to 2} \le C_L \xi_y \xi_z e^{-m d(y,z)} \tag{3.dxvi}$$

for a fixed $m = m(L) > 0$. On a finite torus take the periodic distance. On the cover first use bounded N and then increase it. The constants are independent of this truncation.

In particular the normalized operator $V^{1/2}G'_E V^{1/2}$ has exponentially decaying cell L^2 entries. Its two-sided cell Schur norm follows from eq. 3.cdlvi–eq. 3.cdlix when the separation is chosen with

$$\frac{8\log L}{\rho} < m/2. \tag{3.dxvii}$$

The rate m above depends only on the fixed one-step constants and the site gap; it does not depend on ρ. Thus this is a genuine order of choice: increase the separation after those constants, or verify

that the already chosen separation satisfies this finite inequality. It is not an appeal to unspecified polynomial volume growth.

3.13.14. *A scalar subsolution estimate at the fine mesh.* We use a local estimate whose proof also explains why a fine Coulomb singularity causes no loss in eq. 3.dxvi. On the infinite scalar fine lattice in four dimensions, let $\mathcal{L} = -\Delta_\eta$. The positive heat kernel gives a positive Green kernel

$$G_0(x) = \int_0^\infty p_t^\eta(x)\,dt, \qquad |G_0(x)| \le C(|x|+\eta)^{-2}, \quad |\nabla G_0(x)| \le C(|x|+\eta)^{-3}. \tag{3.dxviii}$$

These inequalities follow by integrating the mesh-uniform heat kernel derivative bounds. For example split at $t = |x|^2$, use a polynomial off-diagonal tail before the split, and Ct^{-2}, respectively $Ct^{-5/2}$, afterwards. At $|x| \le \eta$ the bounds are the corresponding lattice scaling bounds. Also $\mathcal{L}G_0$ is the normalized lattice delta, by integrating $-\partial_t p_t^\eta$.

Suppose $w \ge 0$ and $\mathcal{L}w \le F_0$ on a ball of radius $2r$, $r \ge 8\eta$. Choose a nonnegative cutoff χ, equal to one on the r-ball, supported in the $2r$-ball, with its first two differences bounded by Cr^{-1}, Cr^{-2}. At the center x, summation by parts gives

$$w(x) = \langle \chi G_0(x-\cdot), \mathcal{L}w\rangle - \langle [\mathcal{L},\chi]G_0(x-\cdot), w\rangle. \tag{3.dxix}$$

All sums use η^4. This identity follows by moving $\mathcal{L}$ off w and using $\mathcal{L}G_0 = \delta_x$. There is no derivative of w in its last term. Since the first test is nonnegative, its contribution is at most CF_0r^2. Indeed the lattice sum of G_0 on that ball is at most Cr^2, by dyadic shells.

The commutator is supported on the cutoff annulus. Writing it as $(\mathcal{L}\chi)G_0$ plus products of first differences shows that its absolute value is at most Cr^{-4} there, by eq. 3.dxviii. Cauchy and the annulus volume therefore prove

$$w(x) \le C\{r^{-2}\|w\|_{2,B_{2r}} + r^2F_0\}. \tag{3.dxx}$$

If r/η is bounded, the point-value estimate $|w(x)| \le \eta^{-2}\|w\|_2$ gives the same inequality with a changed constant. Thus the local estimate is uniform at coarse meshes as well.

For a real unitary connection, let λ be Lie-algebra valued and put $w = |\lambda|$. For $\lambda(x) \ne 0$, pair each term $\lambda(x) - \mathrm{Ad}(U_{x,x'})\lambda(x')$ with $\lambda(x)/|\lambda(x)|$. Unitarity gives

$$-\Delta_\eta|\lambda|(x) \le |D_U^\sharp D_U\lambda(x)|. \tag{3.dxxi}$$

At a zero value of λ the left side is nonpositive, so the same inequality holds. This proves the covariant scalar subsolution inequality without differentiating a gauge. It is used only on a patch with the full covariant Laplacian stencil. Bare boundary cells will use the point-value fallback instead.

3.13.15. *Pointwise site Green bounds.* First take a real U and $\lambda = G_U'f$. At a site in pillar $\Delta(y)$, the mass part of its equation obeys

$$|(Q_U'^\sharp a Q_U'\lambda)(x)| \le C_L\xi_y^{-4}\|\lambda\|_{2,\Delta(y)}. \tag{3.dxxii}$$

In fact it is the transported vector $a(y)Q_U'\lambda(y)$, whose norm is at most $a^*\xi_y^{-2}|Q_U'\lambda(y)|$. Cauchy in the average gives the additional ξ_y^{-2}.

Take a local ball of radius comparable to ξ_y. It meets a bounded L-dependent number of pillars, all with scales in $[\xi_y/L, L\xi_y]$. The gaps exclude a second intervening layer in that ball once $\rho > C_LL$. Call the corresponding whole-pillar neighborhood $\mathcal{N}(y)$. Its cells are at bounded d-distance from y. Apply eq. 3.dxx–eq. 3.dxxii on a lift of this ball. This proves

$$\|\lambda\|_{\infty,\Delta(y)} \le C_L\xi_y^{-2}\sum_{w\in\mathcal{N}(y)}\|\lambda\|_{2,\Delta(w)} + C_L\xi_y^2\|f\|_{\infty,\mathcal{N}(y)}. \tag{3.dxxiii}$$

Near a boundary of the action region, every pillar lacking this full patch is bare: the nonbare regions have the prescribed gap from that boundary. The single-cell fallback in eq. 3.dxx proves

eq. 3.dxxiii there directly. On a torus the local ball is lifted to the periodic cover. Its fixed radius can meet only a fixed number of copies of a cell, since every period contains at least two top blocks. This changes only the constant.

If f is supported in $\Delta(z)$, use eq. 3.dxvi and $\|f\|_{2,\Delta(z)} \le \xi_z^2 \|f\|_\infty$ on the right side. The far contribution is $C\xi_z^3 \xi_y^{-1} e^{-md(y,z)} \|f\|_\infty$. The local forcing term has $d(y,z) \le C_L$. eq. 3.cdliii absorbs the scale ratio:

$$\|G'_U f\|_{\infty,\Delta(y)} \le C_L \xi_y^2 e^{-m_1 d(y,z)} \|f\|_\infty, \qquad 0 < m_1 < m - \frac{3\log L}{\rho}. \tag{3.dxxiv}$$

Choosing the separation large enough leaves a positive fixed m_1. This is a pointwise estimate for a bounded cell source. It is not a uniform bound on the Green kernel evaluated at two individual fine sites.

The actual equation also gives

$$\|D_U^\sharp D_U G'_U f\|_{\infty,\Delta(y)} \le C_L e^{-m_1 d(y,z)} \|f\|_\infty. \tag{3.dxxv}$$

Use $D_U^\sharp D_U \lambda = f - Q_U'^\sharp a Q'_U \lambda$, and bound its mass term by the supremum on its same pillar. The cell diameter in the layer metric is bounded.

3.13.16. *Site gradients and their complex continuation.* For differentiated pointwise bounds use the actual local gauge clause of the regular-pair class. On the required patch around a cell it supplies a unitary gauge with

$$U = e^{i\eta A}, \qquad \xi|A| + \xi^2 |\nabla A| \le a_{\mathrm{loc}}, \qquad a_{\mathrm{loc}} \le a_L. \tag{3.dxxvi}$$

The constant a_L is fixed small. Near one interface the patch may be described in the finer adjacent scale; converting to ξ changes these bounds by fixed powers of L. The region gaps and the fixed patch collar are chosen to include no third layer. This gauge clause is an input defining the regular-pair class. Deriving it for an actual background from weaker tests is the separate background estimate.

In this local gauge the site equation is a scalar componentwise Laplace equation with first- and zeroth-order errors. Expanding the transported differences gives

$$|\Delta_\eta \lambda| \le |f - Q'^\sharp a Q' \lambda| + C_L a_{\mathrm{loc}} \{\xi^{-1} |\nabla \lambda| + \xi^{-2} |\lambda|\}. \tag{3.dxxvii}$$

Each difference of a link exponential costs $\eta|\nabla A|$; each undifferentiated link error costs $\eta|A|$. After division by the two powers of η in the Laplacian the terms have exactly the displayed dimensions.

Here is the interior absorption that supplies the gradient. On a slightly larger ball of radius $C\xi$, put $M = \|\lambda\|_\infty$ and $F = \|f - Q'^\sharp a Q' \lambda\|_\infty$. Let d_b be distance of a fine edge to the ball boundary and take the finite maximum of $d_b |\nabla \lambda(b)|$. If d_b is only a fixed multiple of η, the point-value bound on a difference controls it by CM. Otherwise apply the scalar interior gradient estimate to a ball of radius $d_b/4$ around an edge where this maximum is approached. Distances in that smaller ball are comparable to d_b. Its gradient supremum is therefore at most the weighted maximum divided by cd_b. Using eq. 3.dxxvii in the scalar estimate gives

$$\sup_b d_b |\nabla \lambda(b)| \le C_L (M + \xi^2 F) + C_L a_{\mathrm{loc}} \sup_b d_b |\nabla \lambda(b)|. \tag{3.dxxviii}$$

Choose $C_L a_{\mathrm{loc}} \le 1/2$. Absorption, eq. 3.dxxiv–eq. 3.dxxv and the scalar interior Hölder estimate then give, for a bounded source in $\Delta(z)$,

$$\begin{aligned} \|\nabla_U G'_U f\|_{\infty,\Delta(y)} &\le C_L \xi_y e^{-\delta d(y,z)} \|f\|_\infty, \\ [\nabla_U G'_U f]_{\alpha,\Delta(y)} &\le C_{L,\alpha} \xi_y^{1-\alpha} e^{-\delta d(y,z)} \|f\|_\infty, \qquad 0 < \alpha < 1. \end{aligned} \tag{3.dxxix}$$

The Hölder comparison is made in the assigned local frame, or with its declared transport to a common base. The bounded potential and pointwise gradient give the transported version. The

constant is not asserted bounded as $\alpha \uparrow 1$. Cells with a bounded number of fine sites use the direct difference bound; near the action boundary they are bare, as already noted.

These pointwise estimates continue to the actual complex site operator by a stronger norm argument than a pointwise matrix coefficient estimate. For a fixed source cell z, let

$$\begin{aligned} \|\lambda\|_{\mathcal{Y}_z} &= \sup_y e^{\delta d(y,z)} \max\{\xi_y^{-2}\|\lambda\|_{\infty,\Delta(y)}, \xi_y^{-1}\|\nabla_U\lambda\|_{\infty,\Delta(y)}\}, \\ \|f\|_{\mathcal{F}_z} &= \sup_y e^{\delta d(y,z)}\|f\|_{\infty,\Delta(y)}. \end{aligned} \tag{3.dxxx}$$

Use a rate δ strictly below the cell Green rate, with its spare rate larger than the ball-growth rate in eq. 3.cdlvi. Summing the bounded-source cell estimates then proves $\|G'_U\|_{\mathcal{F}_z\to\mathcal{Y}_z} \le C_L$, uniformly in z.

For the actual left perturbation $U_E = e^{i\eta E}U$, expand the two covariant site differences and the two site averages. The kinetic difference has a coefficient bounded by $|E|$ on a first difference of λ, and a coefficient bounded by $|\nabla_U E| + |E|^2$ on λ. The mass difference uses eq. 3.dvii, has size $C_L h\xi^{-2}$, and reads only the same pillar. Hence

$$\|(L_E - L_U)\lambda\|_{\mathcal{F}_z} \le C_L h\|\lambda\|_{\mathcal{Y}_z}. \tag{3.dxxxi}$$

No second difference of λ occurs: the difference of two connections in a site Laplacian is lower order. The first-order input on E is used here; its supremum alone would not bound the zeroth-order coefficient. The metric diameter of a pillar is bounded, so the profile weight passes through the mass average with a fixed factor.

For h below the resulting fixed threshold, the series

$$G'_E = \sum_{n\ge 0}[-G'_U(L_E - L_U)]^n G'_U \tag{3.dxxxii}$$

converges from $\mathcal{F}_z$ to $\mathcal{Y}_z$. At finite volume it coincides with the inverse already constructed in eq. 3.dxi, by uniqueness. It therefore proves the complex versions of the pointwise potential and gradient estimates. The equation supplies the complex covariant Laplacian bound. In the same real local frame, $e^{i\eta E}e^{i\eta A}$ has a physical logarithm with the first-order bounds $C(a_{\mathrm{loc}} + h)$. The scalar interior estimate then gives the complex Hölder member as well.

The argument establishes the site estimates for bounded cell sources. A mixed gradient with a divergence source has a Calderón–Zygmund singularity and requires its specified cancellation or Hölder input. No uniform bound for that mixed operator on all bounded raw sources has been inferred.

3.13.17. *The site Gram inverse has its own lower-bound proof.* Invertibility of G' does not by itself give a uniform inverse for $Q'G'^2Q'^\sharp$. We prove that estimate using site bump functions. Let Ξ multiply a top value by ξ_y.

Choose a fixed smooth scalar bump χ_y, supported in the middle portion of its pillar and equal to one on a smaller middle portion. Its first two differences are bounded by $C\xi_y^{-1}$ and $C\xi_y^{-2}$. The arithmetic average $\beta_y = Q'_0\chi_y$ has a positive lower bound independent of the fine mesh: count the grid points in that smaller cube. The finitely coarse cases use the center point.

Use the real local gauge eq. 3.dxxvi on a neighborhood of the pillar and its one-fine-cell collar. In this gauge the initial open bond bound is $Ca_{\mathrm{loc}}\eta/\xi_y$. The recurrence eq. 3.cdxciv, with the same real curvature bound, therefore puts the hierarchical transports within $C_L(a_{\mathrm{loc}} + \epsilon)$ of one. Consequently the three by three matrix $m_y\psi = Q'_U(\chi_y\psi)$ equals $\beta_y I + O(C_L(a_{\mathrm{loc}} + \epsilon))$. For the fixed small class ceiling it is invertible with uniform bound.

Define a site lift on that pillar by $\chi_y m_y^{-1}\psi(y)$ in the local gauge and undo the gauge. At the node use its transformed frame as well. The resulting operator E_{sm} satisfies

$$Q'_U E_{\mathrm{sm}} = 1, \qquad \|E_{\mathrm{sm}}\psi\|_2 \le C_L\|\psi\|_{2,\mathrm{tops}}, \qquad \|L_U E_{\mathrm{sm}}\psi\|_2 \le C_L\|\Xi^{-2}\psi\|_{2,\mathrm{tops}}. \tag{3.dxxxiii}$$

The first equality holds pillar by pillar, since the site averages have disjoint supports. For the last inequality, the covariant Laplacian of one bump is bounded by $C_L\xi_y^{-2}|\psi(y)|$. Expand it in the local gauge: the second cutoff differences, the connection times first differences, and the differentiated connection all have that bound by eq. 3.dxxvi. Its mass term is the transported vector $a(y)\psi(y)$ on the same pillar. The volume is ξ_y^4, giving the last L^2 scale in eq. 3.dxxxiii. One fine collar of different bumps has bounded overlap, since each fine site has a fixed number of neighbors. For a bare pillar, take the single site bump; its Laplacian is bounded by $C\eta^{-2}|\psi|$, which is exactly the same scale. Thus no missing local gauge at the outer bare boundary is used.

For a real top vector ψ, use eq. 3.dxxxiii with $\Xi^4\psi$ and the equation $L_U G'_U = 1$:

$$\begin{aligned}\|\Xi^2\psi\|_{2,\mathrm{tops}}^2 &= \langle (Q'_U)^\sharp\psi, E_{\mathrm{sm}}\Xi^4\psi\rangle \\ &= \langle G'_U(Q'_U)^\sharp\psi, L_U E_{\mathrm{sm}}\Xi^4\psi\rangle \\ &\le C_L\|G'_U(Q'_U)^\sharp\psi\|_2\|\Xi^2\psi\|_{2,\mathrm{tops}}.\end{aligned} \tag{3.dxxxiv}$$

Divide by the last node norm, with the zero case immediate. This proves the operator lower bound

$$Q'_U G'^2_U (Q'_U)^\sharp \ge c_L\Xi^4. \tag{3.dxxxv}$$

The Ξ^4 test in eq. 3.dxxxiv is essential. Testing only with $E_{\mathrm{sm}}\psi$ would give a weaker ratio of two norms and would not prove the stated weighted lower bound at different local scales.

For the upper bound and locality, set

$$\mathcal{F}_U = G'_U(Q'_U)^\sharp\Xi^{-2}, \qquad M_U = \Xi^{-2}Q'_U G'^2_U(Q'_U)^\sharp\Xi^{-2} = \mathcal{F}_U^\sharp\mathcal{F}_U. \tag{3.dxxxvi}$$

The site injection $(Q'_U)^\sharp$ is an isometry between node L^2 and its transported constant pillar fields. eq. 3.dxvi therefore bounds the normalized cell entry of $\mathcal{F}_U$ by

$$C_L(\xi_y/\xi_z)e^{-md(y,z)}. \tag{3.dxxxvii}$$

The same estimate holds for the complex $\mathcal{F}_E$, with the bounded transport condition numbers already proved. The cell summability calculation with $p = 1$ gives a uniform exponential two-sided Schur norm of these operators, after increasing the fixed separation if needed. Their products therefore have the same type of norm. In particular $c_L I \le M_U \le C_L I$ at a real pair.

The complex perturbation is uniform as well. The finite matrix $\mathcal{F}_E$ is holomorphic on the actual physical first-order ball constructed above. Its operator norm is uniformly bounded there by eq. 3.dxxxvii. Apply one scalar Cauchy circle to the line through E. This gives $\|\mathcal{F}_E - \mathcal{F}_U\| \le C_L h$, independent of the number of coordinates. Hence

$$\|M_E - M_U\|_{2\to2} \le C_L h, \qquad \|M_E^{-1}\|_{2\to2} \le 2/c_L \tag{3.dxxxviii}$$

on a fixed smaller ball. Here $M_E = \mathcal{F}_E^\sharp\mathcal{F}_E$ uses the analytic bilinear transpose. Its norm difference is bounded by $(\|\mathcal{F}_E\| + \|\mathcal{F}_U\|)\|\mathcal{F}_E - \mathcal{F}_U\|$. The transpose has the same Hilbert operator norm in the real weighted orthonormal bases. No Hermitian positivity of the complex Gram matrix is assumed.

An exponentially weighted Schur norm also controls its conjugation. For a bounded node function ψ that is one-Lipschitz in d, its cell entries change by the factor $e^{s(\psi(y)-\psi(z))} - 1$. The inequality

$$|e^{st} - 1| \le |s|\,|t|e^{|s||t|} \tag{3.dxxxix}$$

and a spare fraction of the exponential rate bound this perturbation by $C_L|s|$ in operator norm. Indeed $\sup_{r\ge0} re^{-\delta r/2} < \infty$. Choose s small and use eq. 3.dxxxviii. The inverse of the conjugated M_E is uniformly bounded. The distance-weight argument used for eq. 3.dxvi gives exponential entries of M_E^{-1}.

In the physical top pairing the weighted orthonormal basis at y is ξ_y^{-2} times the color basis. If B_{yz} are the entries of M_E^{-1} in those orthonormal coordinates, then $\|B_{yz}\| \le C_L e^{-m_2 d(y,z)}$. Undoing

both Ξ^{-2} factors and the orthonormal bases gives the counting kernel

$$\left|(Q'_E G'^2_E (Q'_E)^\sharp)^{-1}(y,z)\right| \le C_L \xi_y^{-4} e^{-m_2 d(y,z)}. \tag{3.dxl}$$

Explicitly the unnormalized entries of M_E^{-1} are $(\xi_z^2/\xi_y^2)B_{yz}$. Multiplying on the left and right by ξ_y^{-2}, ξ_z^{-2} leaves $\xi_y^{-4}B_{yz}$. This explains the asymmetric fourth power in a counting-kernel formula, despite symmetry in the physical weighted pairing.

Finally the actual site projector has the representation

$$R_E = 1 - \mathcal{F}_E M_E^{-1} \mathcal{F}_E^\sharp. \tag{3.dxli}$$

It agrees with its original Gram formula by eq. 3.dxxxvi. The smoothing part has an exponential cell L^2 Schur norm, and the matrix is holomorphic on the whole smaller physical ball. At a real field it is the orthogonal projector already identified. This completes the site Gram and projector part of the package. Fine vector coercivity, mixed derivative source norms and the current constraint terms are not consequences of eq. 3.dxli.

3.13.18. *The physical fine-to-coarse readout is a Hessian identity.* We next identify the three quadratic forms in the physical calculation. This is a finite-dimensional identity on any admitted chart; it precedes a uniform inverse estimate. Let U be the reference critical field, j_U its action current, Q the derivative of the actual straightened constraint, and ω its multiplier. Take a fixed reference slice, so that its linear condition is $RD_U^\sharp a = 0$.

Criticality on that slice already gives the full stationarity equation

$$j_U = Q^\sharp \omega. \tag{3.dxlii}$$

To see this, first note that $Q\mathsf{S} = Q$, $\mathsf{S}a$ is in the slice, and $a - \mathsf{S}a = D_U G' R D_U^\sharp a$. For $a \in \ker Q$, criticality annihilates $\mathsf{S}a$; the Ward identity annihilates its remaining gauge part. Thus j_U annihilates $\ker Q$. The finite-dimensional annihilator identity gives eq. 3.dxlii. When the row space is the actual independent datum space, Q is onto and ω is unique. Equivalently it is unique whenever the row Gram inverse used in eq. 3.cdlxxiii exists.

Because $Q\widehat{H} = 1$, eq. 3.dxlii implies $\widehat{H}^\sharp j_U = \omega$. Define the actual Lagrangian Hessian

$$K_{\mathrm{L}} = \mathscr{D}_U - \Delta^{(2)}[\omega]. \tag{3.dxliii}$$

The quadratic constraint term here is the second derivative of the same straightened constraint as Q, with the same per-length pairing. It cannot be replaced by the quadratic part of a different row map.

For the explicitly chosen Ward correction eq. 3.cdlxvii, the physical second variant is therefore

$$\widehat{G}_1[j_U]^{-1} = \mathsf{S}^\sharp K_{\mathrm{L}} \mathsf{S} + D_U R D_U^\sharp + Q^\sharp a Q. \tag{3.dxliv}$$

Let $W_1 = Q\widehat{G}_1[j_U]Q^\sharp$ and $H_1 = \widehat{G}_1[j_U]Q^\sharp W_1^{-1}$. The physical version of eq. 3.cdlxxiv gives $RD_U^\sharp H_1 = 0$. Consequently $\mathsf{S}H_1 = H_1$, and direct multiplication of eq. 3.dxliv gives

$$H_1^\sharp K_{\mathrm{L}} H_1 = W_1^{-1} - a. \tag{3.dxlv}$$

For example, $H_1^\sharp \widehat{G}_1^{-1} H_1 = W_1^{-1}$, the gauge contribution is zero, and the row mass contributes a, since $QH_1 = 1$. This proves all signs in eq. 3.dxlv. It does not prove the existence of either inverse.

Let the actual local critical branch be parametrized by a coarse variation B, with reduced datum $b(B)$. Its derivative h_B at zero is taken in the fixed reference slice. Differentiated stationarity gives the constrained linear equations for K_{L}, with row value $Db(0)\dot{B}$. They imply

$$h_B = H_1 Db(0), \qquad D^2\mathcal{A}_{\mathrm{eff}}(0) = Db(0)^\sharp (W_1^{-1} - a) Db(0) + \langle \omega, D^2 b(0) \rangle. \tag{3.dxlvi}$$

Here $\mathcal{A}_{\mathrm{eff}}$ is the action evaluated on that branch. For the first assertion, the differentiated equation tested against slice vectors in $\ker Q$ says $\mathsf{S}^\sharp K_{\mathrm{L}} h_B$ lies in the range of $Q^\sharp$. Adding $Q^\sharp a Q h_B$ and using eq. 3.dxliv then solves the row problem by its defining inverse. For the second, differentiate the

value function twice. The second derivative of the branch contracts with $j_U = Q^\sharp\omega$; differentiating its constraint replaces that contraction by $\omega D^2 b - \omega D^2 q[h_B, h_B]$. The latter term is exactly the subtraction in K_{L}.

3.13.19. *Which coarse coordinates remove the datum curvature.* The statement $b(B) = B$ has a specific coordinate meaning. In the present chart the actual coarse group field is

$$V(B)(c) = e^{i\xi_c B(c)} V_0(c). \tag{3.dxlvii}$$

The fine straightened row logarithm is relative to the same reference V_0. On an interior row the exact node identity then gives $b(B)(c) = B(c)$. It holds for nontrivial $V_0(c)$ as well. No assertion about the absolute logarithm of $V(B)(c)$ is involved.

An outward row instead has its prescribed factor at the finer outer endpoint. In raw notation its equation is

$$e^{i\xi_c b(B)(c)} = e^{i\xi_c B(c)}\,\mathrm{Ad}_{V_0(c)}\, v_z(B_{\mathrm{int}}). \tag{3.dxlviii}$$

It can have both linear and quadratic datum corrections. If only the highest active level is varied, the lower-level data B_{int} in this factor are fixed to zero. Then $v_z(0) = 1$ and the factor is constant. More generally the next-step support mask must be checked against every outward carrier. Deep interior rows give an immediate instance; a mask by itself does not change a logarithmic coordinate.

For contrast, if an absolute coordinate $W_c = \log(V_0(c))/i$ is used and the variable is still a relative increment D, its new absolute logarithm is $\log(e^{iD}e^{iW_c})/i$. Its second derivative in D generally does not vanish. eq. 3.dxlvi then retains its datum-curvature term. This distinction is independent of the support mask.

Let ι inject the actual active next-step coarse bond variables into the row space. When the literal map in eq. 3.dxlvii–eq. 3.dxlviii satisfies

$$Db(0)\iota = \iota, \qquad D^2 b(0)[\iota\,\cdot, \iota\,\cdot] = 0, \tag{3.dxlix}$$

its coarse action precision on those variables is $\iota^\sharp(W_1^{-1} - a)\iota$. Its coarse current is $\iota^\sharp H_1^\sharp j_U$. The restriction $\iota^\sharp$ and the physical dual weights are part of the readout, even when notation suppresses them.

3.13.20. *The next curved fibre inserts a different multiplier.* At the next lattice, write raw bond increments as D, so that the group field is $e^{iD}V$. The actual plain constraint logarithm is

$$\mathfrak{q}_V(D) = \log\Big(M(e^{iD}V)M(V)^{-1}\Big)/i. \tag{3.dl}$$

Its local pivot graph has derivative C_V, and the pivot injection h_V satisfies $D\mathfrak{q}_V(0)h_V = 1$. Twice differentiating the graph equation gives

$$D^2\Phi_V(0)[u,v] = -h_V D^2\mathfrak{q}_V(0)[C_V u, C_V v]. \tag{3.dli}$$

This is the actual pivot graph, not a free extension chosen after the Hessian.

Let $\widehat{K}$ and $\widehat{J}$ be the coarse effective action Hessian and gradient in these raw counting coordinates. The chain rule on that graph is

$$\begin{aligned} D^2(\mathcal{A}_{\mathrm{eff}} \circ \Phi_V)(0)[u,v] = {} & \langle C_V u, \widehat{K} C_V v\rangle \\ & - \langle h_V^\sharp \widehat{J}, D^2\mathfrak{q}_V(0)[C_V u, C_V v]\rangle. \end{aligned} \tag{3.dlii}$$

Thus the next constraint multiplier is $h_V^\sharp\widehat{J}$. It is not $\widehat{J}$ on the new row space unless the notation already includes this $h_V^\sharp$. Define $E_V^{(2)}[\widehat{J}]$ by this last contraction. With the actual soft gauge Hessian $\widehat{K}_{\mathrm{GF}}$, the next free precision is

$$C_V^\sharp(\widehat{K} - E_V^{(2)}[\widehat{J}] + \widehat{K}_{\mathrm{GF}})C_V. \tag{3.dliii}$$

A gauge term relative to V and the absolute contour gauge have equal values on an axial physical reference. Off that locus their Hessians can differ, as shown in the domain section. eq. 3.dliii uses the actual gauge definition of the model being considered.

For a uniform next-lattice spacing ξ, the raw and physical conversions are

$$\widehat{K} = \xi^2 K_{\mathrm{phys,count}}, \qquad \widehat{J} = \xi^3 J_{\mathrm{phys}}. \tag{3.dliv}$$

Indeed $\xi^4 \sum B(KB) = \xi^2 \sum D(KD)$ when $D = \xi B$, and $\xi^4 \sum J_{\mathrm{phys}} B = \sum \xi^3 J_{\mathrm{phys}} D$. At nonuniform row lengths the corresponding diagonal length matrices must be kept on both sides; their commutation is not assumed. The coupling coefficients in the original action remain inside K and J.

Combining eq. 3.dxlv, eq. 3.dxlix and eq. 3.dlii gives the physical diagram: fine Lagrangian Hessian, coarse value Hessian, then next-fibre Hessian. Each arrow has its own row map, its own dual current, and its own gauge term. The physical identity proves none of those three objects interchangeable.

For completeness the chosen off-current extension has an exact additional readout. Put $h = H_1[J]$, $r = RD_U^\sharp h$, $\delta J = J - j_U$, and $K[J] = \mathscr{D}_U - \Delta^{(2)}[\widehat{H}[J]^\sharp J]$. Using eq. 3.cdlxviii in eq. 3.cdlxxvi gives

$$(Q\widehat{G}_1[J]Q^\sharp)^{-1} - a = h^\sharp \mathsf{S}^\sharp K[J] \mathsf{S} h - h^\sharp \mathcal{B}_U[\delta J] h + r^\sharp r. \tag{3.dlv}$$

All pairings are bilinear on the complex domain. On a real pair the last term is nonnegative; it vanishes on the physical graph. The middle term is a current defect and does not disappear from a Ward property alone. For a separately named normal form, the complete projected difference between eq. 3.dliii and that form must be identified, including its horizontal multiplier and gauge terms.

3.13.21. *A flat Feynman comparison on all the layers.* There is a useful vector estimate which does not involve the Landau projection or an independent current. It uses the actual flat straightened averages. We prove it to specify exactly what is available before those two additional operations.

First take the full periodic fine lattice as the ambient graph. Let $a_\mu(x)$ be a fine vector one-form, with physical L^2 measure η^4. For a positive level-j row of length $\xi_j = n\eta$, $n = L^j$, its flat per-length average is

$$(Q_j^0 a)_\mu(y) = n^{-5} \sum_{u \in \mathcal{B}_n} \sum_{t=0}^{n-1} a_\mu(y + \eta u + \eta t e_\mu). \tag{3.dlvi}$$

Here $\mathcal{B}_n$ is the centered set of n^4 fine block sites. The formula is the flat straightened map, not the plain path map. At $j = 0$ it is the identity. The coefficient of each fine bond is nonnegative, the coefficients sum to one, and each is at most n^{-4}. The last fact follows because at most n pairs (u_μ, t) give a fixed longitudinal position, while the three other coordinates are fixed.

Its support lies in the union of the two endpoint blocks. Consequently

$$|Q_j^0 a(c)| \le C \xi_j^{-2} \|a_\mu\|_{2,\mathcal{D}_c}. \tag{3.dlvii}$$

For example Cauchy gives $\sum_b w_b^2 \le n^{-4}$ from $\sum_b w_b = 1$ and $w_b \le n^{-4}$; converting counting L^2 to physical L^2 contributes η^{-2}. Thus the resulting coefficient is $\eta^{-2} n^{-2} = \xi_j^{-2}$. This bound is specific to this flat row formula.

For a fine bond b, put ξ_b equal to the larger of its endpoint pillar scales and define

$$\|a\|_{\mathrm{mass}}^2 = \sum_b \eta^4 \xi_b^{-2} |a(b)|^2, \qquad \mathcal{E}_{\mathrm{F}}^0(a) = \|\partial a\|_2^2 + \sum_{c \in \Gamma} c_c \xi_c^2 |Q^0 a(c)|^2, \quad 0 < c_* \le c_c \le c^*. \tag{3.dlviii}$$

The component gradient contains all fine coordinate differences on the ambient torus. The second term is exactly the physical row pairing with $a(c) = c_c \xi_c^{-2}$. In particular it has neither an extra fine volume factor nor an unweighted counting transpose.

For each nonbare top y and each direction μ, one of the adjacent level-j rows has y as an endpoint and is a determining row. Indeed the excluded higher region is a union of aligned blocks of side at least $L\xi_j$. Along that coordinate line, the excluded block containing an exterior point has at least $L \geq 3$ level-j sites. Both neighboring sites cannot belong to the higher region. Choose one that does not. If the other endpoint is outside Ω_j, this is precisely an outward row, which is retained. At the highest level there is no higher region to exclude.

Let $m_{y,\mu}$ be the arithmetic mean of a_μ on the pillar enlarged by one fine cell. A rectangular carrier containing that enlarged pillar and the chosen row's two endpoint blocks has side length at most $C\xi_j$. For $j \geq 1$ it lies inside the ambient fine graph by the nesting gap. The ordinary box Poincare inequality, proved by the coordinate-path count used for eq. 3.cdxcvi, gives

$$|Q_j^0 a(c(y,\mu)) - m_{y,\mu}| \leq C\xi_j^{-1} \|\partial a_\mu\|_{2,\mathcal{D}_{y,\mu}}. \tag{3.dlix}$$

To verify this without a pointwise trace estimate, subtract the carrier's arithmetic mean. Both functionals annihilate that constant in their difference and have L^2 norm at most $C\xi_j^{-2}$. Poincare then supplies one factor ξ_j.

A second use of Poincare on the enlarged pillar gives

$$\xi_j^{-2} \|a\|_{2,\mathcal{B}_y^+}^2 \leq C \sum_\mu \|\partial a_\mu\|_{2,\mathcal{D}_{y,\mu}}^2 + C\xi_j^2 \sum_\mu |Q_j^0 a(c(y,\mu))|^2. \tag{3.dlx}$$

Every fine bond with a nonbare endpoint can be assigned to a pillar of its larger endpoint scale and is included in that pillar's enlargement. If both endpoints are bare, its level-zero row is the identity and controls it directly.

The overlap in the gradient sum is uniform. For a fixed level, all carrier centers are on its grid and their diameters are $C\xi_j$, so a fine point belongs to a fixed number of them. A carrier of an outward level-j row is inside Ω_{j-1}, and its endpoint blocks are outside Ω_{j+1}. Its one-fine-cell collar can enter only an adjacent level. Thus a fixed fine point is counted at only a fixed number of levels, not at every level of the sequence. Each chosen row has at most its two endpoints as selecting tops. Summing eq. 3.dlx therefore proves

$$\|a\|_{\mathrm{mass}}^2 \leq C_L \mathcal{E}_{\mathrm{F}}^0(a). \tag{3.dlxi}$$

The constants are independent of depth, fine mesh, volume and the shapes of the separated regions. Periodic carriers which wrap are lifted to their rectangles; the compatible torus has at least two top blocks, so the multiplicity of that lift is bounded.

There is also the upper row estimate

$$\sum_{c \in \Gamma} \xi_c^2 |Q^0 a(c)|^2 \leq C_L \|a\|_{\mathrm{mass}}^2. \tag{3.dlxii}$$

Use eq. 3.dlvii on each row carrier. All fine endpoint scales there are comparable to ξ_c, within the fixed adjacent scale factor. The preceding overlap count then applies. eq. 3.dlxi and eq. 3.dlxii are estimates for the flat component Feynman form.

For a proper active region, extend the sequence by bare cells on the ambient torus and compress this full positive form by zero extension of its active bond coordinates. Its lower bound survives exactly: apply eq. 3.dlxi to the extended vector. This is the Dirichlet compression of the component Laplacian. An inner-plaquette Maxwell Hessian has a different boundary form. Nor has the nonlocal subtraction $D_U(1-R)D_U^\sharp$ been included. Those comparisons are separate in the vector precision problem.

3.13.22. *What small curvature does to the actual Wilson Hessian.* The Wilson part admits a relative form estimate without assuming a matrix norm bound. We derive it directly from the plaquette product. Use $\langle X, Y \rangle_{\mathrm{col}} = \frac{1}{2}\,\mathrm{Tr}(XY)$ on Hermitian traceless matrices. For a plaquette with oriented bonds $b_1, \ldots, b_4$, put $P = U(b_1)\cdots U(b_4)$ and $T_{r-1} = U(b_1)\cdots U(b_{r-1})$. A left variation $e^{i\eta v(b)}U(b)$

inserts $X_r = \eta \operatorname{Ad}(T_{r-1})v(b_r)$. On reversed bonds the variation is $v(\bar{b}) = -\operatorname{Ad}(U(b)^{-1})v(b)$, as follows by inverting the group field.

The varied plaquette is $\prod_{r=1}^{4} e^{iX_r} P$. At $P = 1$, the trace of the mixed second derivative is the trace of the product of the two sums of insertions. Cyclicity of the trace cancels their commutators. For general real P, subtract that calculation and use the factor $P - 1$ in every remaining term. Thus the plaquette action $1 - \frac{1}{2}\operatorname{Tr} P$ satisfies

$$\begin{aligned} D^2\mathcal{A}_p(U)[v,w] &= \left\langle \sum_r X_r, \sum_r Y_r \right\rangle_{\mathrm{col}} + \mathcal{R}_p(v,w), \\ |\mathcal{R}_p(v,w)| &\le C\|P-1\| \left(\sum_r |X_r|^2\right)^{1/2} \left(\sum_r |Y_r|^2\right)^{1/2}. \end{aligned} \tag{3.dlxiii}$$

There are only sixteen mixed insertion terms. Unitarity of the prefixes makes $\sum |X_r|^2 = \eta^2 \sum |v(b_r)|^2$. The same polynomial trace expression, with no real-part operation, is its holomorphic continuation.

Define the plaquette linearized curl by

$$(\mathfrak{d}_U v)(p) = \eta^{-1} \sum_{r=1}^{4} \operatorname{Ad}(T_{r-1})v(b_r). \tag{3.dlxiv}$$

Then $\sum_r X_r = \eta^2 \mathfrak{d}_U v(p)$. If $\|P-1\| \le \epsilon\eta^2\xi_p^{-2}$, with ξ_p the largest corner scale, summing eq. 3.dlxiii over the actual plaquettes gives

$$|\langle v, \mathscr{D}_U w\rangle - \langle \mathfrak{d}_U v, \mathfrak{d}_U w\rangle_2| \le C_L\epsilon \|v\|_{\mathrm{mass}} \|w\|_{\mathrm{mass}}. \tag{3.dlxv}$$

Every bond is in at most six unoriented plaquettes. Each error has the factor $\eta^2\epsilon\xi_p^{-2}$ from $P-1$ and another η^2 from the two insertions. Their product is the physical η^4 measure times the natural inverse scale squared. There is no loss $\epsilon\eta^{-2}$ in this form estimate.

This curl is close to the ordinary forward covariant curl $\mathrm{d}_U v = \nabla_{U,\mu} v_\nu - \nabla_{U,\nu} v_\mu$. For example on a $\mu\nu$ plaquette the difference of their numerator sums is

$$(1 - \operatorname{Ad} P)\big(\operatorname{Ad} U_\nu(x) v_\mu(x + \eta e_\nu) + v_\nu(x)\big). \tag{3.dlxvi}$$

Direct multiplication of the four prefixes proves this identity. It gives $\|\mathfrak{d}_U v - \mathrm{d}_U v\|_2 \le C_L\epsilon\|v\|_{\mathrm{mass}}$, since $\eta \le \xi_p$. In particular

$$\langle v, \mathscr{D}_U v\rangle \ge (1 - C_L\epsilon)\|\mathrm{d}_U v\|_2^2 - C_L\epsilon\|v\|_{\mathrm{mass}}^2 \tag{3.dlxvii}$$

for a real field, after decreasing the fixed curvature ceiling. Positive bounded plaquette weights give the same statement with their lower and upper bounds. Signed layer profiles or additional current subtractions must be estimated separately.

On the full periodic graph, the covariant Hodge calculation is also explicit:

$$\left| \|\mathrm{d}_U v\|_2^2 + \|D_U^\sharp v\|_2^2 - \sum_\mu \|\nabla_{U,\mu} v\|_2^2 \right| \le C_L\epsilon\|v\|_{\mathrm{mass}}^2. \tag{3.dlxviii}$$

Expand both squares. The diagonal terms agree because each covariant shift is unitary. For different directions the uncancelled terms are commutators of the two shifts, or of a shift and an inverse shift. Their coefficients are conjugates of $\operatorname{Ad} P - 1$. The two difference denominators contribute η^{-2}; the plaquette bound leaves $C\epsilon\xi^{-2}$. There are a fixed number of neighboring terms at each bond. Adjacent scales are comparable, so Cauchy proves eq. 3.dlxviii. On a proper inner graph the summation by parts has additional boundary terms.

The full Feynman gauge uses $D_U D_U^\sharp$. The actual fine Landau form instead uses $D_U R D_U^\sharp$. Its difference is the nonnegative real smoothing form

$$D_U(1 - R)D_U^\sharp = (D_U\mathcal{F}_U)M_U^{-1}(D_U\mathcal{F}_U)^\sharp. \tag{3.dlxix}$$

A lower bound for the Feynman form does not survive this subtraction by monotonicity. This is one reason the vector coercivity step remains distinct from the site gap and eq. 3.dlxi.

For the admitted complex perturbation E, the actual plaquette Taylor formula gives $\|P(U_E) - P(U)\| \le C_L h\eta^2 \xi_p^{-2}$. Indeed the first order boundary sum of E is its covariant curl; the remaining terms contain either two increments or one increment times a real connection on a local gauge patch. The first-order core bounds control each by that scale. Also $\|\mathrm{d}_{U_E} v - \mathrm{d}_U v\|_2 \le C_L h \|v\|_{\mathrm{mass}}$. Subtracting eq. 3.dlxiii therefore proves

$$|\langle v, (\mathscr{D}_{U_E} - \mathscr{D}_U) w\rangle| \le C_L h (\|\mathrm{d}_U v\|_2 + \|v\|_{\mathrm{mass}})(\|\mathrm{d}_U w\|_2 + \|w\|_{\mathrm{mass}}). \tag{3.dlxx}$$

This uses a physical first-order perturbation radius, not an unscaled matrix norm for the fine precision. It is a genuine part of the complex comparison. The corresponding actual field-row, projected-current and constraint form comparisons remain to be joined to it.

3.13.23. *A mixed derivative needs cancellation.* One cannot replace those comparisons by a universal supremum bound for every order-zero projection. Already at a flat field the operator $\partial_1\partial_2(-\Delta+1)^{-1}$ is not bounded on L^∞. Its kernel near zero is $c\, x_1 x_2 |x|^{-6}$ plus a locally integrable term in four dimensions. Let f_η equal the sign of this leading kernel on the annulus $C\eta < |x| < 1/4$, with a bounded smooth cutoff at its edges. Then

$$\|f_\eta\|_\infty \le 1, \qquad \left|(\partial_1\partial_2(-\Delta+1)^{-1} f_\eta)(0)\right| \ge c \log(\eta^{-1}) - C. \tag{3.dlxxi}$$

The radial integral is $\int_{C\eta}^{1/4} dr/r$; the angular integral of $|x_1 x_2|/|x|^2$ is positive. The integrable remainder is uniformly bounded. Discrete kernels have the same annular estimate away from a fixed number of fine cells, or the continuum example follows as a limit of any proposed uniform lattice supremum estimate.

The required replacement has a precise cancellation form. If a kernel $K(x,z)$ has size $C|x-z|^{-4}$ on a cell of scale ξ, and a uniformly bounded constant-source response, write its action as

$$\int K(x,z)(f(z) - f(x))\, dz + f(x) \int K(x,z)\, dz. \tag{3.dlxxii}$$

For a transported Hölder test, the first term is bounded by

$$C[f]_\alpha \int_0^{C\xi} r^{\alpha-1}\, dr \le (C_\alpha \xi^\alpha)[f]_\alpha. \tag{3.dlxxiii}$$

The same shell calculation applies to fine sums, with the first shell at η; the bound remains uniform as its lower endpoint decreases. The second term is the stated constant-source response. Thus an actual mixed-kernel estimate plus its cancellation clause gives the required Hölder-to-supremum bound. Size alone does not.

For the fine gauge projection $\mathsf{S} = 1 - D_U G' R D_U^\sharp$, this distinction is material. Its differentiated site inverse has order zero at the fine diagonal. Energy estimates use its L^2 form bounds; point estimates must either keep it composed with a smoothing field Green operator or use actual Hölder data and eq. 3.dlxxii. No unqualified supremum Schur norm of S on arbitrary bounded fine fields is being asserted.

3.13.24. *Compact dual bumps for the actual flat field rows.* We can also prove a uniform right inverse for the flat layered field rows. This is a different statement from the site lift eq. 3.dxxxiii. The proof uses two longitudinal moments and a strictly triangular correction between adjacent levels.

Fix a top y of level $j \ge 1$, put $n = L^j = 2m+1$, and work on its fine block $\eta\mathcal{B}_n + y$. Choose a field with just its μ-component nonzero there:

$$a_\mu(y + \eta u) = \psi\, \phi(u_\mu) \prod_{\nu \ne \mu} \chi(u_\nu). \tag{3.dlxxiv}$$

It is zero outside the block and on bonds whose other endpoint is outside. For sufficiently large n, take $\chi(u)$ from a fixed even smooth profile of u/n, supported in $(-1/4, 1/4)$ and positive on a smaller interval. Write

$$\beta = n^{-1}\sum_u \chi(u), \qquad \sigma = n^{-1}\sum_u (u/n)^2\chi(u). \tag{3.dlxxv}$$

Both have positive lower and finite upper bounds independent of n.

For a fine longitudinal position u in this block, the right coarse row in eq. 3.dlvi counts that bond $u+m+1$ times. The left row counts it $m-u$ times. No other coarse row sees it. After the transverse sums, their two response functionals are

$$\ell_+(\phi) = \beta^3 n^{-2}\sum_u (u+m+1)\phi(u), \qquad \ell_-(\phi) = \beta^3 n^{-2}\sum_u (m-u)\phi(u). \tag{3.dlxxvi}$$

Define

$$\begin{aligned} \phi_+(u) &= \beta^{-4}\chi(u) + \frac{m}{n}\frac{\beta^{-3}}{\sigma}\frac{u}{n}\chi(u), \\ \phi_-(u) &= \beta^{-4}\chi(u) - \frac{m+1}{n}\frac{\beta^{-3}}{\sigma}\frac{u}{n}\chi(u). \end{aligned} \tag{3.dlxxvii}$$

Evenness gives $\sum u\chi(u) = 0$. Substitution into eq. 3.dlxxvi now gives

$$(\ell_+(\phi_+), \ell_-(\phi_+)) = (1, 0), \qquad (\ell_+(\phi_-), \ell_-(\phi_-)) = (0, 1). \tag{3.dlxxviii}$$

For example the sum of the two functionals is $\beta^3 n^{-1}\sum\phi$. For either profile this is one; the odd term in ϕ_+ sets the left functional to zero. The right one is then one. The calculation for ϕ_- is the same with the other moment. The signed profiles are uniformly bounded and their first differences are $O(n^{-1})$.

The finitely many odd values below this smooth-profile range need no limiting argument. Put the three transverse profiles at their center point and use longitudinal bonds with positions $-1, 0$. Both endpoints of these bonds are in the block for $n \geq 3$. Their two response columns form

$$n^{-5}\begin{pmatrix} m & m+1 \\ m+1 & m \end{pmatrix}. \tag{3.dlxxix}$$

Its determinant is $-n^{-9}$. Its inverse therefore gives the required two exact dual profiles, with a bound depending only on the fixed cutoff between this finite set and the smooth range. That is a universal constant, not a depth dependence.

Assign a determining row c to one of its level-j top endpoints y. An outward row has its interior endpoint as that top. Use ϕ_+ or ϕ_- according to the chosen endpoint. Its seed $E_c^0\psi$ is supported on fine bonds strictly inside that pillar and satisfies, on the full regular level-j grid,

$$Q_j^0 E_c^0\psi = \delta_c\psi. \tag{3.dlxxx}$$

The transverse support lies in a single coarse transverse block, and eq. 3.dlxxviii removes the only other longitudinal row. For a bare row take its single fine bond value. It has both endpoints in the bare layer.

Let $E^0\psi$ be the sum of these seeds at every level. There are at most eight assigned seeds at a top. Their supports belong to distinct pillars, and the collars in their gradient norm have bounded overlap. The amplitude and first-difference bounds just proved give

$$\|E^0\psi\|_{\text{mass}}^2 + \|\partial E^0\psi\|_2^2 \leq C\sum_{c\in\Gamma}\xi_c^2|\psi(c)|^2. \tag{3.dlxxxi}$$

The factor on the right is forced by the dimensions: the supporting volume is ξ_c^4, and a first difference or mass factor is ξ_c^{-1}. For a bare seed the same calculation is $\eta^4\eta^{-2}|\psi|^2$.

3.13.25. *A contraction estimate between adjacent levels.* A seed of level j has zero value under every lower determining row. Indeed its fine support is in Ω_j, whereas a lower row's entire carrier is outside the next region of that lower level. For $i < j$, that next region contains Ω_j. It also has zero value under every row of level $i \geq j+2$: such a carrier is inside $\Omega_{i-1} \subset \Omega_{j+1}$, whereas the seed pillar is outside Ω_{j+1}. The same argument uses the two bare endpoints for $j = 0$. Thus only the next level can receive an unwanted value.

The full flat averages compose exactly:

$$Q_{j+1}^{0,\mathrm{full}} = Q_L^0 Q_j^{0,\mathrm{full}}. \tag{3.dlxxxii}$$

In the defining sums, the transverse digits are $nr + u$, where r is in the centered L-range and u in the centered n-range. They tile the centered Ln-range. The longitudinal digits are $nt + s$, with $0 \leq t < L$, $0 \leq s < n$. They tile $0, \dots, Ln-1$. The product normalization is $L^{-5}n^{-5}$. This proves eq. 3.dlxxxii, including the per-length normalization.

Let the row Hilbert norm be $\|\psi\|_{\mathrm{row}}^2 = \sum_c \xi_c^2 |\psi(c)|^2$. A regular L-step average has row coefficient sum one and column coefficient sum L^{-4}. The column identity can be checked directly: the two longitudinal counts add to L, while the three transverse coordinates select one block. The ordinary counting ℓ^2 operator norm is therefore at most L^{-2} by Schur. The row norm at the next level has one extra factor L in its square root. Hence the map between these row norms has norm at most L^{-1}.

Writing T for the next-level leakage, eq. 3.dlxxx–eq. 3.dlxxxii give

$$Q^0 E^0 = 1 + T, \qquad T_{ij} = 0 \ (i \neq j+1), \qquad \|T\|_{\mathrm{row}\to\mathrm{row}} \leq L^{-1}. \tag{3.dlxxxiii}$$

Restriction to actual determining rows and injection from their subset of the regular grid cannot increase the norm. Different level blocks of T have different input and output levels, so the whole direct-sum norm is the supremum of those block norms. No sum over the number of levels is introduced.

We have proved the explicit flat row lift

$$E_{\mathrm{row}}^0 = E^0(1+T)^{-1}, \qquad Q^0 E_{\mathrm{row}}^0 = 1, \qquad \|E_{\mathrm{row}}^0 \psi\|_{\mathrm{mass}}^2 + \|\partial E_{\mathrm{row}}^0 \psi\|_2^2 \leq \frac{C}{(1-L^{-1})^2} \|\psi\|_{\mathrm{row}}^2. \tag{3.dlxxxiv}$$

At finite depth the inverse is the finite triangular series; its norm is bounded by the displayed geometric series. The same series converges in the row Hilbert space for an infinite compatible sequence. The assertion is a right inverse with an energy bound, not an estimate of a nonlinear background map.

At a real flat connection the same construction uses a flat unitary frame on each pillar. The response at the other coarse endpoint differs by its fixed unitary transport. The two scalar moments still annihilate the unwanted row; the desired row is normalized in its own color frame. Schur uses the same positive scalar coefficient majorants, so its constants are unchanged. All profile supports lie inside their pillars. This handles periodic flat holonomies without choosing a single globally small logarithm. Under this gauge transfer the gradient in the energy bound is ∇_U, or equivalently the ordinary component gradient in its flat parallel frame. An ordinary gradient in an arbitrary original gauge is not bounded by that statement. No analogous bare L^2 field-row estimate at a general nonflat field has been assumed.

3.13.26. *What a field-row Gram estimate actually needs.* The last proof gives the flat instance of a general useful duality reduction. Let K be a real symmetric positive fine precision and $G = K^{-1}$. Let Ξ multiply each field row by its length. Suppose the actual row map has an extension E_{row} such that

$$Q E_{\mathrm{row}} = 1, \qquad \langle E_{\mathrm{row}}\psi, K E_{\mathrm{row}}\psi \rangle \leq C \|\Xi^{-1}\psi\|_{2,\mathrm{rows}}^2. \tag{3.dlxxxv}$$

The node pairing here has volume ξ_c^4; its last norm is just $\sum_c \xi_c^2|\psi(c)|^2$. Testing with $E_{\mathrm{row}}\Xi^2\psi$ gives

$$\|\Xi\psi\|_{2,\mathrm{rows}}^2 = \langle Q^\sharp\psi, E_{\mathrm{row}}\Xi^2\psi\rangle \le C^{1/2}\langle\psi, QGQ^\sharp\psi\rangle^{1/2}\|\Xi\psi\|_{2,\mathrm{rows}}. \tag{3.dlxxxvi}$$

Thus $QGQ^\sharp \ge C^{-1}\Xi^2$. No pointwise delta-function test in the fine field was used.

An upper bound needs the separate actual trace estimate

$$\|\Xi^{-1}Qa\|_{2,\mathrm{rows}}^2 \le C\langle a, Ka\rangle. \tag{3.dlxxxvii}$$

Indeed apply it to $a = G^{1/2}f$. It proves $\|\Xi^{-1}QG^{1/2}\| \le C^{1/2}$ and therefore $QGQ^\sharp \le C\Xi^2$. For the flat Feynman form, eq. 3.dlxii, eq. 3.dlxi and eq. 3.dlxxxiv prove both premises. For the flat Landau form, eq. 3.dlxxxiv proves the upper energy cost in eq. 3.dlxxxv, since $0 \le R \le 1$; the needed fine coercivity is still a distinct step.

Normalize the row covariance as $N = \Xi^{-1}QGQ^\sharp\Xi^{-1}$. If its exponential cell Schur bound has also been proved, the conjugation argument in eq. 3.dxxxix applies verbatim to N. It gives exponential entries of N^{-1}. In physical weighted orthonormal row coordinates, undoing normalization gives the counting kernel estimate

$$|(QGQ^\sharp)^{-1}(c,d)| \le C\,\xi_c^{-3}\xi_d\, e^{-m_3 d(c,d)}. \tag{3.dlxxxviii}$$

To check the powers, an orthonormal entry of N^{-1} becomes (ξ_d^2/ξ_c^2) times that entry on unnormalized values. The two exterior Ξ^{-1} factors leave $\xi_c^{-3}\xi_d$. This differs from the ξ_y^{-4} in eq. 3.dxl: the site Gram contains G'^2, whereas this row covariance contains G.

Finally a nonflat row extension is reduced to a definite error estimate. Starting from a specified flat or locally flat extension E_0, set $D_Q = QE_0 - 1$. If the actual primitive comparison proves

$$\|D_Q\|_{\mathrm{row}\to\mathrm{row}} \le \vartheta < 1, \tag{3.dlxxxix}$$

then $E_{\mathrm{row}} = E_0(1 + D_Q)^{-1}$ is an actual right inverse, with its energy cost multiplied by $(1-\vartheta)^{-2}$, provided that cost for E_0 has been proved in the actual precision. The remaining task is eq. 3.dlxxxix for the full actual row map on the admitted domain, together with eq. 3.dlxxxvii; it is not an assumed bound for the desired Green kernel.

3.13.27. *The actual straightened row is a finite analytic recursion.* We now obtain the needed row coefficient bounds from the actual formula, rather than from a proposed inverse. Use raw one-step link logarithms on a lattice whose spacing has been set to one. Let $T_{yx}(W)$ be the internal mean transport of the block chart, with its specified coordinate-order path multiset. For a reference W and a raw increment a, put

$$\begin{aligned} u_W(a)(y) &= \exp\left[L^{-4}\sum_{x\in B_L(y)} \log\Big(T_{yx}(e^{ia}W)T_{yx}(W)^{-1}\Big)\right], \\ F_W(a)(c) &= \frac{1}{i}\log\Big[u_W(a)(c_-)^{-1}M(e^{ia}W)(c)u_W(a)(c_+)M(W)(c)^{-1}\Big]. \end{aligned} \tag{3.dxc}$$

All logarithms are the regular branch. The first line is an exponential of averaged relative logarithms; it is not another unspecified mean. The internal transports themselves use the actual Federbush mean defined in the block chart. This distinction fixes both levels of averaging.

For $\|\log W/i\|_\infty$ and $\|a\|_\infty$ below c/L, these are holomorphic finite functions. Every path has at most CL bonds. Products of their exponentials remain in a fixed logarithmic neighborhood; the mean contraction proved in the block chart is uniform in the number of paths. After a fixed decrease of c, the expression inside the second logarithm remains in that same neighborhood. Thus $\|F_W(a)\|_\infty \le C$ on this joint raw ball, with universal C.

Differentiating at $W = 1, a = 0$ cancels the two internal path sums from the plain average against the two factors u. The remaining sum is exactly the straight segment average S_L, with raw row sum L and raw column sum L^{-3}. It is essential to use both factors in eq. 3.dxc; the plain average has a different derivative.

Let $A_W(a) = D_a F_W(a)$. Two scalar Cauchy circles, in arbitrary sup-norm directions of the reference logarithm and of a, give

$$\|A_W(a)\|_{\mathrm{row}} \le L(1 + C_L\delta), \quad \|A_W(a)\|_{\mathrm{col}} \le L^{-3}(1 + C_L\delta),$$
$$\sup_b \sum_{c,b'} \|D_b D_{b'} F_W(a)(c)\| \le C_L, \qquad \delta = \|\log W/i\|_\infty + \|a\|_\infty. \tag{3.dxci}$$

Here and below the norm of a color entry is its finite matrix norm. We explain why the derivative estimate is independent of a field-coordinate count. The two circles bound a second directional derivative by CL^2. For a fixed output color row, its operator norm from bounded input colors controls the sum of its entry norms, up to the fixed color dimension: sum the dual norms of its three scalar rows. A fixed input bond affects only the coarse rows at the endpoints of the one or two blocks containing it. Their number is fixed. Apply the same argument with one input bond fixed to obtain the last line. Dividing the row and column errors by their flat values costs only powers of L. For definiteness, all one-step constants in eq. 3.dxci may be enlarged to CL^{12}. This deliberately loose polynomial bound is before any number of levels is introduced.

The multilevel recursion is literal. Write $W_r = M^r(W_0)$, $a_0 = \eta A$, and

$$a_{r+1} = F_{W_r}(a_r), \qquad v_{r+1} = v_r|_{\mathrm{next}}\, u_{W_r}(a_r). \tag{3.dxcii}$$

Equivariance of the plain mean gives, by induction,

$$M^r(e^{i\eta A} W_0) = (e^{ia_r} W_r)^{v_r}. \tag{3.dxciii}$$

Indeed apply M to the previous factorization, restrict its gauge to the next nodes, and then use eq. 3.dxc. The gauge factors multiply in the order in eq. 3.dxcii. They do not alter the recursion for a_r.

3.13.28. *Summability of the raw radii gives a depth-uniform row bound.* For the row estimates from this point on, ϵ is a common ceiling for the real curvature and the local real-gauge bounds. Thus the earlier a_{loc} and the curvature radius are both at most ϵ; when they are supplied separately, take their maximum here. Existence of those local gauges remains the primitive regular-pair hypothesis. No bound for a_{loc} is inferred from curvature alone.

Fix a row of length $\xi = n\eta$, $n = L^j$. On its determining carrier, the regular-pair gauge clause gives a real local potential and its first difference at scale ξ, with at most the fixed adjacent-layer factor at a seam. The open-bond and curvature recurrences eq. 3.cdxciv, eq. 3.diii therefore give

$$\|\log W_r/i\|_\infty \le C_L(\epsilon + h)t_r, \qquad t_r = L^r/n, \qquad r < j. \tag{3.dxciv}$$

These estimates are used only on the dependence cone of that row. They also follow by extending its local small potential with a cutoff on a fixed larger cube and then using locality. The cutoff keeps its first difference at the same scale. The torus room required for nonflat local classes permits this cube; the flat periodic formulas need no such extension. No gauge bound growing with M_1 is used.

Allow an arbitrary fine increment with $\xi\|A\|_\infty \le r$. It need not have small fine derivatives. On the recursion ball, eq. 3.dxci and $F_W(0) = 0$ give

$$\|a_{r_0}\|_\infty \le 2r\, t_{r_0} \quad (0 \le r_0 \le j) \tag{3.dxcv}$$

when $\epsilon + h + r$ is below a fixed threshold depending on L. To avoid confusing the index with the radius, write $p_s = \|a_s\|_\infty/t_s$. As long as $p_s \le 2r$, Taylor's formula and eq. 3.dxci imply

$$p_{s+1} \le p_s[1 + C_L t_s(\epsilon + h + p_s)]. \tag{3.dxcvi}$$

The sum of t_s is below $(L-1)^{-1}$. Choose the fixed ceiling so that $C_L(\epsilon + h + 2r)/(L-1) < \log 2$. Multiplying the factors proves eq. 3.dxcv by first exit. The raw radii also stay strictly inside the c/L one-step balls. Finally $\|u_{W_s}(a_s) - 1\| \le C_L\|a_s\|_\infty$; their condition numbers have product at

most $\exp(C_L \sum_s \|a_s\|_\infty)$. A further fixed decrease makes this at most two, supplying the room for the complex covariance in eq. 3.dxciii.

Put $A_s = D_a F_{W_s}(a_s)$ and $P_{b,a} = A_{b-1} \cdots A_a$. The same summable radii in eq. 3.dxci give

$$\|P_{b,a}\|_{\mathrm{row}} \le C L^{b-a}, \qquad \|P_{b,a}\|_{\mathrm{col}} \le C L^{-3(b-a)}. \tag{3.dxcvii}$$

The constant is bounded by the product of $1 + C_L(\|\log W_s/i\|_\infty + \|a_s\|_\infty)$. It is independent of a, b, j. Multiplying only uniform bounds larger than one at each level would miss this point.

The per-length row logarithm is $q_j(A) = a_j/\xi$. Its derivative with respect to the physical fine coordinates is $(\eta/\xi)P_{j,0} = n^{-1}P_{j,0}$. Consequently

$$\|Dq_j(A)\|_{\mathrm{row}} \le C, \qquad \|Dq_j(A)\|_{\mathrm{col}} \le Cn^{-4}, \qquad |D_b q_j(A)(c)| \le C(\eta/\xi)^4. \tag{3.dxcviii}$$

These are counting-coordinate derivatives. A functional derivative uses the additional η^{-4}. Telescoping the products against their flat factors also gives row error $C_L(\epsilon + h + r)$ and column error $C_L(\epsilon + h + r)n^{-4}$, in the common local unitary frames.

An actual row carrier has only its two endpoint blocks. A fixed fine bond in a layer can occur in carriers of only adjacent levels: the outer block is inside the previous region and both endpoint blocks are outside the next. At each of those levels the number of rows is fixed. Thus eq. 3.dxcviii implies for the full layered field map

$$\|\Xi^{-1}Qa\|_{2,\mathrm{rows}} \le C_L \|a\|_{\mathrm{mass}}. \tag{3.dxcix}$$

For a single row, its coefficient sum is bounded and each entry is at most $C(\eta/\xi_c)^4$. Cauchy therefore gives the analogue of eq. 3.dlvii; the carrier overlap argument of eq. 3.dlxii then proves eq. 3.dxcix. This estimate has been obtained from the actual finite recursion, not by treating an infinity norm bound alone as an L^2 bound.

3.13.29. *The two-legged constraint coefficient has a uniform moment.* The same computation gives the coefficient estimate needed for the quadratic current term. Let $n_s = L^s$ and $m_s = L^{j-s-1}$. Twice differentiating the recursion gives

$$D^2_{a_0} a_j = \sum_{s<j} P_{j,s+1} D^2 F_{W_s}(a_s)[P_{s,0}\,\cdot, P_{s,0}\,\cdot]. \tag{3.dc}$$

Fix the first fine bond b and sum absolutely over the second. For the term indexed by s, the largest entry of the outer product is at most Cm_s^{-3}, by its column sum. The sum over the first inner leg is at most Cn_s^{-3}. The second inner row sum is at most Cn_s. The remaining sum over the one-step Hessian, with its first input fixed, is bounded by eq. 3.dxci. Thus

$$\sum_{b'} \|D_{a_0(b)} D_{a_0(b')} a_j(c)\| \le C_L \sum_{s<j} m_s^{-3} n_s^{-2}. \tag{3.dci}$$

This step uses a column sum on the fixed leg and a row sum on the summed leg. Using two row sums would lose the fine density.

Physical input derivatives contribute η^2; the output per-length normalization contributes ξ^{-1}. Since $m_s^{-3}n_s^{-2} = L^3 n_s/n^3$ and $\sum_{s<j} n_s \le n/(L-1)$, we obtain

$$\sup_b \sum_{b'} \|D_b D_{b'} q_j(A)(c)\| \le C_L\, \xi\, (\eta/\xi)^4. \tag{3.dcii}$$

There is no number-of-levels factor. The geometric sum is dominated by its final scales. Symmetry of the second derivative gives the corresponding other-leg sum.

Let $\omega(c)$ be an arbitrary row current with $|\omega(c)| \le \gamma_\omega \xi_c^{-3}$. Pair the Hessian at zero with the physical row volume. eq. 3.dcii, Schur and the same bounded carrier overlap give

$$\left| \sum_c \xi_c^4 \langle \omega(c), D^2 q_c(0)[u, v] \rangle_{\mathrm{col}} \right| \le C_L \gamma_\omega \|u\|_{\mathrm{mass}} \|v\|_{\mathrm{mass}}. \tag{3.dciii}$$

For clarity, the row prefactor $\xi_c^4|\omega(c)|$ is bounded by $\gamma_\omega\xi_c$. Multiplying it by the leg moment $C_L\xi_c(\eta/\xi_c)^4$ leaves $C_L\gamma_\omega\eta^4\xi_c^{-2}$ on each fine leg. Adjacent scales replace ξ_c by the fine bond scale at only a fixed cost.

The holomorphic ball was used to extract these coefficients. The quadratic form in eq. 3.dciii then extends to every finite fine vector by its coefficient formula. It does not require a Gaussian sample to lie in that holomorphic ball. For the second variant one must still bound the actual induced current $\widehat{H}[J]^\sharp J$ in this row norm, and bound S in the weighted fine energy spaces. Those are separate operator readouts.

3.13.30. *The nonflat field-row lift follows from the row comparison.* The coefficient estimates allow one to complete eq. 3.dlxxxix at a regular pair. Keep the real local gauges of its center. Construct the profiles eq. 3.dlxxiv in each pillar in such a gauge, and undo the gauge. For a seed assigned to the far endpoint of a row, normalize its color by the fixed unitary transport of that row. Denote this operator again by E^0. It is fixed at the real center while the complex increment varies.

Two local real gauges used on the same pillar differ there by a nearly constant unitary matrix. To prove this, write their connection equation on each fine bond and telescope along a coordinate path of length $C\xi_j$. Both gauge potentials have size at most $C_L\epsilon/\xi_j$. The transition therefore differs from its root value by at most $C_L\epsilon$. The first-order class on a fixed larger cube supplies both gauges. Only a path of size $C_L\xi_j$ is used, not the full $M_1\xi_j$ cube.

It follows from eq. 3.dxcviii and this transition bound that the same-level seed response is the identity with an error of row and column norm $C_L(\epsilon+h)$ in the row energy norm. Only a fixed number of same-level rows meet a seed pillar. The next-level response has a leading part with the positive scalar majorant of Q_L^0, multiplied by fixed unitary color matrices, and an error. There are at most CL^4 lower-level seeds in one such carrier; a seed affects at most a fixed number of next-level rows. An error entry of size $C_L(\epsilon+h)$ therefore has row sum $C_LL^5(\epsilon+h)$ and column sum $C_LL(\epsilon+h)$ after the row-energy normalization. Schur bounds this error by $C_LL^3(\epsilon+h)$. Absorb this fixed power into C_L.

All other level blocks are zero by the carrier argument preceding eq. 3.dlxxxii. The leading next-level part still has norm at most L^{-1}; Schur uses only the scalar majorants, not a compatible global choice of flat color frames. We have proved

$$\|Q_{\mathbf{U}}E^0-1\|_{\mathrm{row}\to\mathrm{row}}\le L^{-1}+C_L(\epsilon+h)=:\vartheta<1. \tag{3.dciv}$$

The ceiling needed here depends on L and not on depth, volume or M_1. The actual right inverse is

$$E_{\mathrm{row}}=E^0(Q_{\mathbf{U}}E^0)^{-1}. \tag{3.dcv}$$

Both its squared mass norm and its covariant gradient energy are bounded by $C_L(1-\vartheta)^{-2}\|\psi\|_{\mathrm{row}}^2$. For the gradient of a seed, expand in its local gauge: the profile derivative is of size $C\xi_j^{-1}|\psi|$ and the connection term has the same bound. Supports and their fine collars have bounded overlap. The small complex perturbation adds at most C_Lh times the mass norm. This proves the stated energy bound, including bare seeds.

There is a corresponding actual Feynman Poincare inequality. Repeat eq. 3.dlix in a common local real gauge for a pillar and its chosen row carriers. The row comparison after eq. 3.dxcviii has both row and column error bounds. Schur therefore bounds its local L^2 functional norm by $C_L\epsilon\xi_j^{-2}$. Ordinary gradients and covariant gradients differ there by $C_L\epsilon\xi_j^{-1}$ times the field. Consequently eq. 3.dlx, summed over the carriers, gives

$$\|a\|_{\mathrm{mass}}^2\le C_L(\|\nabla_U a\|_2^2+\|a^{1/2}Q_Ua\|_{2,\mathrm{rows}}^2)+C_L\epsilon^2\|a\|_{\mathrm{mass}}^2. \tag{3.dcvi}$$

The repeated letter a in $a^{1/2}$ is the fixed positive row weight, whereas the arguments are fine fields. Equivalently that term is $\sum_c c_c\xi_c^2|Q_Ua(c)|^2$. Absorb the last term by the fixed weak-field ceiling. Only carrier differences in the interior are used; the bare boundary fields are controlled by their

identity rows. Thus the same argument applies to an active component-gradient form containing all those interior differences.

The full complex Feynman form is stable on a fixed physical ball. The actual row comparison gives

$$\|a^{1/2}(Q_{\mathbf{U}} - Q_U)v\|_2 + \|(\nabla_{\mathbf{U}} - \nabla_U)v\|_2 \le C_L h\|v\|_{\mathrm{mass}}. \tag{3.dcvii}$$

For the first term use the row and column differences, the physical row volumes and the bounded carrier overlap. For the second use $\mathrm{Ad}(e^{i\eta E}) - 1 = O(\eta E)$. Expanding the two bilinear squares and using eq. 3.dcvi gives a relative form perturbation $C_L h$. Its inverse exists by the normalized Neumann series. This proves a component Feynman inverse statement. The actual Landau subtraction eq. 3.dlxix is still absent.

3.14. **Response equations and weighted inverse estimates.** The response of a constrained background is a solution of a coupled field–multiplier system. Bounds on the inverse of one positive quadratic form give only part of that response. Constraints, gauges, the current readout, the local length factors, and admissibility of the substituted data must all be included. This section derives the exact reductions needed for these tasks. Its linear algebra and analytic estimates are proved. On an admitted strong reference domain, Props. 3.112, 3.163 and 3.169 construct the primitive coefficients and the selected nonlinear current germ. The construction of a reference from homogeneous curvature-small data is Prop. 3.194. Applications to complementary histories retain their specified geometry, source and admission hypotheses.

All calculations are first made in a finite compatible geometry. The constants in an infinite-volume or arbitrary-depth application must be uniform in that geometry before a limit is taken. In particular, a finite-dimensional implicit-function theorem by itself supplies no uniform radius.

The actual equations and their differentiated right-hand sides. Use the real reference field U_0 and write the varied fine field as $e^{i\eta A}U_0$. For the multilevel determining set $\mathbf{B}$, the straightened average is denoted by $\mathcal{Q}^{\mathrm{st}}(A)$ and its derivative by K_A. This is the nonlinear straightening of the group average, rather than the straight linear average. With the reduced datum $\mathsf{b}(B)$, the physical critical pair satisfies

$$\begin{aligned} F'(A) &= K_A^{\mathsf{T}}\omega, & \mathcal{Q}^{\mathrm{st}}(A) &= \mathsf{b}(B), \\ RD^{\mathsf{T}}A &= 0, & F(A) &= A_{\Omega_0}(e^{i\eta A}U_0). \end{aligned} \tag{3.dcviii}$$

Here R and D are formed at the reference field. The first equation is the full physical stationarity identity when that identity has been proved; its restriction to the slice is sufficient for the algebra below. When the reference is changed with the datum, differentiating the slice also contributes $(\dot{R}D^{\mathsf{T}} + R\dot{D}^{\mathsf{T}})A$. We keep the reference fixed in eq. 3.dcviii. A calculation that moves the reference and then omits this contribution does not differentiate eq. 3.dcviii.

The reduced datum has a local triangular correction at an outward bond. For an outer endpoint $z = c_+$ it is defined by

$$e^{i\mathsf{b}(B)(c)} = e^{iB(c)}\,\mathrm{Ad}(\mathbf{V}_0(c))\mathsf{v}_z(B). \tag{3.dcix}$$

At an interior bond it equals $B(c)$. The block factor v_z depends on the interior bonds of its block. Consequently the derivative of b is triangular in the same ordering. On a smaller regular logarithm chart, differentiation of the exponential and logarithm gives

$$\dot{b} = D\mathsf{b}(B)\dot{B}, \qquad \dot{b}(c) = L_c(B)\dot{B}(c) + \sum_{c'\ \mathrm{interior}} T_{cc'}(B)\dot{B}(c') \tag{3.dcx}$$

on the outward rows. Define the right logarithmic differential $\mathcal{E}_X(V) = (1/i)[\frac{d}{dt}\exp(i(X + tV))]_{t=0}\exp(-iX)$. Differentiating eq. 3.dcix after right multiplication by $\exp(-i\mathsf{b})$ gives $L_c = \mathcal{E}^{-1}_{\mathsf{b}(B)(c)}\mathcal{E}_{B(c)}$. The same differential and the derivative of the block factor give T. Thus the outward diagonal is invertible near the regular chart; it need not be the identity. The

bounds require a fixed distance to the logarithm cut and the actual local block-factor estimate. Triangularity establishes invertibility once those diagonal logarithmic derivatives are invertible; it does not bound an unrestricted product of triangular operators over an arbitrary number of levels.

Let $\mathcal{V}$ be the fixed linear slice, after the residual node gauge has been fixed. Its fine pairing and the datum pairing are the actual cell-weighted pairings. Write $q = K_A|_{\mathcal{V}}$ and let $q^\sharp$ be its transpose for these pairings. The constrained second variation is

$$\mathcal{K} = F''(A) - \sum_a \mu_a \omega_a (\mathcal{Q}_a^{\mathrm{st}})''(A) \quad \text{on } \mathcal{V}. \tag{3.dcxi}$$

The weights μ_a in this coordinate expression are the datum cell weights. Equivalently the second term is the Hessian of the scalar pairing $\langle \omega, \mathcal{Q}^{\mathrm{st}}(A)\rangle$. This latter description fixes the convention if a different coordinate basis is used. The curvature term in eq. 3.dcxi cannot be replaced by the Hessian of F alone. It is the usual second fundamental form of the constraint fibre.

Differentiating eq. 3.dcviii at a fixed reference gives the exact system

$$\mathcal{K}\dot{A} - q^\sharp \dot{\omega} = 0, \qquad q\dot{A} = D\mathsf{b}(B)\dot{B}. \tag{3.dcxii}$$

More generally, for explicit parameters p in the action, gauge or constraints, put $\mathcal{C}(A,p) = 0$ and $\mathcal{E}(A,\omega,p) = F_p'(A) - \mathcal{C}_A^\sharp \omega$. The right-hand sides are then

$$f = -D_p\mathcal{E}\,\dot{p}, \qquad b = -D_p\mathcal{C}\,\dot{p}, \qquad \mathcal{K}\dot{A} - q^\sharp\dot{\omega} = f, \quad q\dot{A} = b. \tag{3.dcxiii}$$

Every differentiation in D_p is made before substituting the solution $A(p), \omega(p)$. This distinction prevents an implicit extra response term on the right-hand side.

An independent-current extension is an additional specified operator. The formula in eq. 3.dcxi identifies the physical constrained Hessian. It does not identify every separately defined $\Delta_\pi'[J]$ with that Hessian. Likewise, an absolute contour gauge functional and its relative version have the same quadratic gauge block at an axial field, but generally have different blocks away from that field. The complete gauge and current normal form must be matched before an independently named propagator can be inserted into eq. 3.dcxii.

A complete block inverse, including the multiplier. The following result is finite-dimensional and exact. It also applies to bounded operators when the displayed inverses and compositions exist on the stated spaces. Every transpose in the complex calculation is bilinear, with no conjugation.

Proposition 3.37 (Response from a primitive constrained inverse)**.** Suppose $q : \mathcal{V} \to \mathcal{D}$ is onto, $E : \mathcal{D} \to \mathcal{V}$ satisfies $qE = I$, and $P : \mathcal{X} \to \mathcal{V}$ is an isomorphism onto $\ker q$. Assume

$$H = P^\sharp \mathcal{K} P \quad \text{is invertible}, \qquad L = PH^{-1}P^\sharp, \qquad T = E - L\mathcal{K}E. \tag{3.dcxiv}$$

Then the unique solution of eq. 3.dcxiii is

$$\begin{aligned} \dot{A} &= Lf + Tb, \\ \dot{\omega} &= E^\sharp(\mathcal{K}L - I)f + E^\sharp \mathcal{K} T b. \end{aligned} \tag{3.dcxv}$$

If $\mathcal{K}^\sharp = \mathcal{K}$, this simplifies to

$$\dot{\omega} = -T^\sharp f + Mb, \qquad M = E^\sharp \mathcal{K} E - E^\sharp \mathcal{K} L \mathcal{K} E, \qquad M^\sharp = M. \tag{3.dcxvi}$$

■

Proof. Write $\dot{A} = Eb + Pv$. Applying $P^\sharp$ to the first equation of eq. 3.dcxiii, and using $qP = 0$, gives $Hv = P^\sharp(f - \mathcal{K}Eb)$. This determines v and gives the first formula of eq. 3.dcxv. The residual $\mathcal{K}\dot{A} - f$ annihilates $\ker q$. It therefore belongs to the range of $q^\sharp$. Since $E^\sharp q^\sharp = I$, its unique multiplier is the second formula of eq. 3.dcxv. Conversely these formulas satisfy both equations, so there is no lost multiplier equation. For a homogeneous solution, the same argument gives $v = 0$, then $\dot{A} = 0$ and $\dot{\omega} = 0$.

For the symmetric assertion, $H^\sharp = H$ and $L^\sharp = L$. Thus $T^\sharp = E^\sharp - E^\sharp \mathcal{K} L$, which gives eq. 3.dcxvi. Finally $E^\sharp \mathcal{K} T$ equals the displayed expression for M; both its terms are symmetric. Positivity of the full $\mathcal{K}$ was not used. Invertibility was needed on the actual constrained slice. □

The inverse L acts on fine forces; T lifts the constraint datum after the energetic correction; M is the multiplier response. Bounding L alone leaves the products $L\mathcal{K}E$ and $E^\sharp \mathcal{K} T$ to be controlled. The size and locality of E also matter. A right inverse with a norm growing in the number of layers would not prove a uniform response theorem.

At one step the actual raw pivot derivative has size L^{-3}, whereas the derivative after division of the coarse logarithm by L has size L^{-4}. Accordingly a change of the constraint normalization changes both E and the dual multiplier. For example, replacing q by $\widetilde{q} = q/L$ while keeping the same pairings replaces ω by $\widetilde{\omega} = L\omega$ in the scalar Lagrangian. Using the new right inverse with the old multiplier would change eq. 3.dcxi, not merely its notation.

Cell weights and a kernel algebra. We describe the norm in which the preceding formulas can be estimated without a bare-mesh counting loss. Let each component i have a positive cell weight μ_i and an amplitude $s_i > 0$. A vector is measured by $\|v\|_s = \sup_i |v_i|/s_i$. A kernel is written as

$$(Av)_i = \sum_j \mu_j A_{ij} v_j, \qquad \widehat{A}_{ij} = s_i^{-1} A_{ij} s_j. \tag{3.dcxvii}$$

For different input and output species their respective amplitudes and cell weights are used. The identity kernel is δ_{ij}/μ_j. Thus even the identity is not represented by δ_{ij} when it is used with a weighted summation convention.

For a metric d common to the component locations define

$$\|A\|_m = \max\Big\{ \sup_i \sum_j \mu_j |\widehat{A}_{ij}| e^{md(i,j)}, \\ \sup_j \sum_i \mu_i |\widehat{A}_{ij}| e^{md(i,j)} \Big\}. \tag{3.dcxviii}$$

Matrix norms in a colour or local finite-dimensional fibre are operator norms. The two sums use the correct weights for their two species. The triangle inequality for d and absolute convergence give

$$\|AB\|_m \le \|A\|_m \|B\|_m. \tag{3.dcxix}$$

Indeed, insert the intermediate sum with weight μ_k, use $d(i,j) \le d(i,k) + d(k,j)$ and cancel the intermediate amplitudes. For the row bound take the supremum of the inner B row sum; for the column bound use the corresponding A column sum. These are distinct calculations and neither counts the number of fine bonds.

The first row sum bounds A on the normalized supremum norm. The two sums together bound it on the normalized, cell-weighted ℓ^2 space by the Schur estimate. To see the latter directly, apply weighted Cauchy–Schwarz to each row with weights $\mu_j |\widehat{A}_{ij}|$, then sum in i and use the column bound. The result is $\|Av\|_{2,s} \le \|A\|_0 \|v\|_{2,s}$.

For the natural response components above a top of scale ξ_y, the amplitudes are

$$s_H(y) = \xi_y^{-1}, \qquad s_{\nabla H}(y) = \xi_y^{-2}, \qquad s_J(y) = \xi_y^{-3}. \tag{3.dcxx}$$

Equivalently the output is $(\xi_y H, \xi_y^2 \nabla H, \xi_y^3 J)$. The cell weights are determined by the fine, coarse and pillar pairings. Each constraint length factor belongs in the matrix before eq. 3.dcxvii is formed. The domain section gives the resulting transposes. These transpose conventions are needed when applying eq. 3.dcxix to a product that changes species at a seam.

For a raw logarithm $a = gy$, a physical radius α becomes α/g in the canonical Gaussian variable y. A derivative with respect to y contributes g times the derivative with respect to a. Thus the second

derivative of a scalar activity in Gaussian coordinates is g^2 times its raw-logarithm Hessian. This conversion occurs in addition to the length and cell-weight conversions in eq. 3.dcxvii–eq. 3.dcxx.

Corollary 3.38 (Uniform response after the primitive bounds)**.** Suppose the actual normalized kernels in eq. 3.dcxiv satisfy

$$\|L\|_m \le a, \quad \|E\|_m \le e, \quad \|\mathcal{K}E\|_m \le k, \quad \|E^\sharp\mathcal{K}\|_m \le k'. \tag{3.dcxxi}$$

Then

$$\|T\|_m \le e + ak, \qquad \|M\|_m \le k'(e + ak). \tag{3.dcxxii}$$

In the nonsymmetric case the force-to-multiplier block has norm at most $k'a + \|E^\sharp\|_m$. In the symmetric case it is $-T^\sharp$. Its norm equals the norm of T with reversed species if the dual amplitudes are chosen reciprocally for the same cell-weighted pairings. For other force and current amplitudes its weighted transpose bound must be checked separately. ■□

The last qualification is necessary. A raw transpose and a transpose after conjugation by amplitude weights are different matrices. If $\widehat{T}_{ij} = s_i^{-1}T_{ij}s_j$, its transposed normalized kernel is obtained by giving the dual components amplitudes s_i^{-1} and s_j^{-1}. A natural force weight of a different physical dimension does not satisfy this rule automatically. Its conversion belongs in the kernel before a Schur norm is claimed.

The bounds in eq. 3.dcxxi are the primitive targets. They must hold for the actual enlarged saddle system on the retained complex domain and at every allowed seam. The corollary does not assert them. In particular, an unweighted flat inverse does not supply k, k' on a current-dependent layered domain. It does establish an exact-model anchor from which a perturbative comparison can start.

Invertibility on the whole complex ball. Let $\mathcal{S}$ denote the full field–constraint operator in eq. 3.dcxiii, with all gauge rows included. Fix a reference operator $\mathcal{S}_0$ on the same spaces. If the primitive estimates give

$$\|\mathcal{S}_0^{-1}\|_m \le C_0, \qquad \|\mathcal{S}(B) - \mathcal{S}_0\|_m \le \varepsilon, \qquad C_0\varepsilon < 1, \tag{3.dcxxiii}$$

then the Neumann series converges in the kernel algebra and proves

$$\|\mathcal{S}(B)^{-1}\|_m \le \frac{C_0}{1 - C_0\varepsilon}. \tag{3.dcxxiv}$$

It is essential that the second bound in eq. 3.dcxxiii holds on the whole retained complex ball. A bound only along the real solutions does not give the analytic disc needed later for Cauchy estimates.

If $\mathcal{S}_0$ is unbounded in the chosen norm, the correct statement uses the relative perturbation $\mathcal{S}_0^{-1}(\mathcal{S} - \mathcal{S}_0)$ between its actual graph spaces. The same series applies there. In particular an elliptic second-order operator cannot be treated as a bounded supremum-norm matrix with a mesh-independent norm merely because its inverse is bounded.

If the coefficients of $\mathcal{S}(B)$ are holomorphic in the indicated operator norm, holomorphy follows term by term on a strictly smaller disc, or by the resolvent identity

$$\mathcal{S}(B')^{-1} - \mathcal{S}(B)^{-1} = -\mathcal{S}(B')^{-1}[\mathcal{S}(B') - \mathcal{S}(B)]\mathcal{S}(B)^{-1}. \tag{3.dcxxv}$$

The identity also proves continuity and the derivative formula wherever the coefficient derivative exists in the indicated operator norm. No complex positivity assertion is used. Real coercivity may construct $\mathcal{S}_0^{-1}$; the complex inverse then requires a genuine norm comparison or another explicitly convergent construction.

For a complete identification of the proposed response, eq. 3.dcxxiii has to be checked with the nonlinear K_A, the full constraint-curvature block, the prescribed relative or absolute gauge block, and the seam rows. Changing any of these while keeping the same notation for $\mathcal{S}$ invalidates the comparison.

From local forcing to first response. Suppose a change in one datum coordinate $B(c)$ gives a forcing column F_c in the enlarged system. The column consists of both the field force and the constraint force in eq. 3.dcxiii. If it is supported within distance r_0 of the top y_c and has normalized supremum norm at most b_0, then eq. 3.dcxxiv gives

$$|D_{B(c)}Z_y[e]|/s_y \le \frac{C_0 b_0 e^{mr_0}}{1-C_0\varepsilon} e^{-md(y,y_c)}|e|. \tag{3.dcxxvi}$$

Here Z contains the output species actually controlled by the inverse, with amplitude s_y from eq. 3.dcxvii. Equivalently apply the bound to the normalized readout Z_y/s_y; subsequent Cauchy estimates use normalized readouts. The proof is the row estimate: for each contributing component j, $d(y,y_c) \le d(y,j)+r_0$, so multiply by $e^{md(y,y_c)}$ and sum the kernel against F_c. A triangular datum correction from eq. 3.dcx changes b_0, r_0 by its actual block bounds. It must be included in F_c.

For an exponentially local forcing column, a bound $|F_c(j)|/s_j \le b_0 e^{-ad(j,y_c)}$ gives eq. 3.dcxxvi with any $0 < m' < \min(m,a)$ and m' in place of m. Indeed the triangle inequality leaves a factor $e^{-(a-m')d(j,y_c)} \le 1$, and the remaining sum is a weighted row sum at rate m'. No uncontrolled number of sites appears.

This proves response decay from three smaller tasks: construct the actual primitive inverse, verify its weighted row norm, and compute the actual datum forcing. It does not assume response decay as a premise. If the output inverse controls only H and the multiplier, the estimate has not yet been proved for ∇H or the current. Those outputs require their own readout maps.

For example the physical current is a specified nonlinear function $J(U)$. In a fixed logarithmic chart its derivative is

$$\dot J = D_A[J(e^{i\eta A}U_0)]\dot A. \tag{3.dcxxvii}$$

An implementation may replace this expression by the multiplier and lower-order terms through the differentiated field equation. Such a replacement must be derived from eq. 3.dcviii and the definition of J. The equality is not implied by the fact that both quantities have dimension three. On an independent-current core the variable $\mathbf{J}$ and the computed current $J(\mathbf{U})$ are distinct until the physical pair is imposed.

Why a kernel bound does not prove a difference bound. Uniform locality and a gap do not control variation at the bare scale. On a one-dimensional mesh, the positive diagonal inverse $R_{ii} = 1 + \frac{1}{2}(-1)^i$ has norm at most $3/2$ and zero range. Applied to a constant force it produces a difference of size η^{-1}. Its inverse is positive and uniformly bounded as well. This example shows exactly why a separate regularity estimate is needed.

There is a useful exact identity for that estimate. On a translation patch let T shift by one mesh step, $\nabla = (T-I)/\eta$ and $\mathcal{K}_T = T\mathcal{K}T^{-1}$. If $\mathcal{K}v = f$, then

$$\mathcal{K}_T\nabla v = \nabla f - \frac{\mathcal{K}_T - \mathcal{K}}{\eta} v. \tag{3.dcxxviii}$$

To prove it, write $T(\mathcal{K}v) = \mathcal{K}_T T v$, subtract $\mathcal{K}v$ and divide by η. At a boundary this calculation must be made on the common interior patch; it does not shift an inadmissible boundary row into the equation.

For a scalar divergence-form example $\mathcal{K} = D^\sharp a D + V$, with constant mesh difference D, the coefficient commutator in eq. 3.dcxxviii is

$$\frac{\mathcal{K}_T - \mathcal{K}}{\eta} = D^\sharp(\nabla a)D + \nabla V. \tag{3.dcxxix}$$

If the energy norm is $\|v\|_{\mathcal{E}}^2 = \|Dv\|_2^2 + \|v\|_2^2$, the bilinear pairing and Cauchy–Schwarz imply

$$\big\|[(\mathcal{K}_T - \mathcal{K})/\eta]v\big\|_{\mathcal{E}^*} \le (\|\nabla a\|_\infty + \|\nabla V\|_\infty)\|v\|_{\mathcal{E}}. \tag{3.dcxxx}$$

Thus a bounded inverse from $\mathcal{E}^*$ to $\mathcal{E}$, together with coefficient regularity, bounds ∇v in energy norm. This does not assert a supremum bound; passing to a supremum or Hölder bound requires the corresponding local elliptic estimate.

In the gauge system, shifting the covariant differences adds transport commutators, the average rows add contour terms, and a seam adds its own boundary comparison. The required finite list is: the translated interior equation, the gauge-row commutator, the constraint-row commutator, and each seam or exterior boundary row. Each term must be bounded between its actual force and output norms. The uniform primitive regularity estimate is precisely this list of bounds and the associated local elliptic estimate. It is not supplied by exponential decay of H^{-1} alone.

Joint Cauchy estimates with joining distances. Once eq. 3.dcxxvi has been established uniformly on a complex product ball, several useful higher response bounds require no further model estimate. We give the argument with all radius losses visible.

Let $\mathcal{B}_r$ be a ball in the supremum of the dimensionless bond logarithms, with a fixed norm on the three colour coordinates. Suppose a holomorphic map Z_y on $\mathcal{B}_r$ satisfies

$$|\partial_c Z_y(B)[e]| \le C e^{-m d(y,y_c)} |e|, \qquad B \in \mathcal{B}_r. \tag{3.dcxxxi}$$

Fix $0 < \theta < 1$. There is a colour constant c_* such that the coordinate polydisc of radius $c_*(1-\theta)r$ about every $B \in \mathcal{B}_{\theta r}$ lies in $\mathcal{B}_r$. The number of bonds does not enter this assertion, since the norm is a supremum over bonds; simultaneous variation of three colour components changes only c_*. Cauchy's formula applied to the first derivative gives

$$|\partial_{c_1} \cdots \partial_{c_q} Z_y(B)| \le C(q-1)! [c_*(1-\theta)r]^{-(q-1)} e^{-m \max_j d(y,y_{c_j})}. \tag{3.dcxxxii}$$

Repeated coordinates are allowed. The relevant multi-index factorial is at most $(q-1)!$. Holomorphic derivatives commute, so each one of the q coordinates can be selected as the first derivative in eq. 3.dcxxxi; taking the minimum of the resulting exponential bounds proves the maximum in eq. 3.dcxxxii.

Let $\mathcal{T}(y, c_1, \dots, c_q)$ be the minimum spanning-tree length in the underlying metric. The star through y is a competing tree, and therefore

$$\mathcal{T} \le \sum_{j=1}^{q} d(y, y_{c_j}) \le q \max_j d(y, y_{c_j}). \tag{3.dcxxxiii}$$

Consequently eq. 3.dcxxxii gives a joining-tree exponential with rate m/q. For the second derivative it also gives the more explicit bound

$$|\partial_c \partial_{c'} Z_y(B)| \le \frac{C}{(1-\theta)r} e^{-\frac{m}{2}[d(y,y_c)+d(y,y_{c'})]}. \tag{3.dcxxxiv}$$

This is the estimate used in the pointed Taylor remainder. It costs one datum radius. The formula in eq. 3.dcxxxii is not a uniform-in-q tree bound at a fixed rate: its rate deteriorates with q. If an arbitrary-order polymer estimate needs a fixed rate, one must use the local nonlinear equations and their tree expansion, with the resulting factorial and entropy costs. A fixed-order application may use eq. 3.dcxxxii directly.

The same Cauchy argument applies to an output Hölder seminorm if the first response is already bounded in that seminorm on the larger ball. Cauchy's formula can be applied to every normalized difference $[Z_y - Z_{y'}]/|y-y'|^\gamma$ and then a supremum taken. It cannot create spatial Hölder regularity from a pointwise bound.

Finite boxes and compatible boundary forcing. Let $\mathcal{S}$ be the actual linearized saddle operator and $\mathcal{S}_\Lambda$ its prescribed finite-box version. To compare solutions, their equations must be put on common variables and rows in an interior collar. Write the resulting exact difference equation as

$$\mathcal{S}_\Lambda \, \delta X = f_\Lambda. \tag{3.dcxxxv}$$

The force includes the difference of boundary rows, the datum restriction, the gauge-restoration term and any cutoff commutator. The identity in eq. 3.dcxxxv is checked before its right-hand side is bounded. Replacing an actual box boundary by a convenient Dirichlet boundary changes this force and requires a new comparison.

Suppose the inverse has weighted row bound C at rate m and the force is supported in a collar $\mathcal{C}$. If $\|f_\Lambda\|_s \le AR^p$, then for a component at y

$$|\delta X_y|/s_y \le CAR^p e^{-m\,\mathrm{dist}(y,\mathcal{C})}. \tag{3.dcxxxvi}$$

This follows by extracting the exponential distance from the weighted row sum. In particular no factor equal to the number of bare sites in the collar is necessary. Such a factor would generally destroy uniformity as the mesh tends to zero.

The same conclusion, at any rate $m' < \min(m, a)$, holds if

$$|f_\Lambda(j)|/s_j \le AR^p e^{-a\,\mathrm{dist}(j,\mathcal{C})}. \tag{3.dcxxxvii}$$

For each j, the distance from y to the collar is at most $d(y, j)+\mathrm{dist}(j, \mathcal{C})$. Multiplying the summand by $e^{m'\,\mathrm{dist}(y,\mathcal{C})}$ leaves a weighted row sum and a remaining exponential at most one. This proves the claim.

A cutoff must be made in physical coordinates. For a smooth function $\chi(x/R)$ on a mesh η, its first difference divided by η is $O(R^{-1})$ and its second difference divided by η^2 is $O(R^{-2})$, by the integral form of the mean-value formula. The unnormalized difference itself has an extra factor η. These are different quantities. A cutoff of an affine potential of size $O(R)$ can therefore have bounded first derivatives and polynomially bounded forcing, rather than a bare-mesh singularity.

For a nonlinear equation a cutoff of a solution is not a solution even where the cutoff is a constant strictly between zero and one. All such points belong to the transition collar. On that collar the force is computed from the actual nonlinear formula or its integral Taylor formula. The admissibility of the cutoff field, its averages, and its tower backgrounds is a separate domain check. A bounded formal commutator cannot replace it.

For two nonlinear backgrounds, subtracting their equations gives an averaged Jacobian along a common admissible coordinate segment. The inverse estimate for that averaged operator must be justified, for example by a uniform comparison of every Jacobian with the same reference as in eq. 3.dcxxiii. An arbitrary average of invertible complex matrices need not be invertible. The first-step background section uses just such a common comparison; a multilevel application needs it on the actual multilevel ball.

The full substitution and the test for staying inside a core. An old-origin source is evaluated on data of the form

$$V_j(\nu) = \mathcal{M}^j\big(e^{i\eta(t+\nu\zeta)H}U\big)|_{\Gamma_j}. \tag{3.dcxxxviii}$$

The parameters on the fine bonds in ζ may vary independently. The inner analytic argument uses $|\nu| < c/s$, not merely the physical segment between zero and one. There are also outer and removed substitutions. Each must satisfy the same list of field, independent current, node, gauge and tower conditions that defines its assigned core. A proof only of the curvature clause is incomplete.

Here is a precise useful criterion. Express the core as inequalities $\|\mathcal{R}_a(X)\| < r_a$ for its actual clauses, including all hereditary tower clauses. Let X_0 be the complete reference pair and assume margins $\|\mathcal{R}_a(X_0)\| \le (1-\epsilon_a)r_a$. If a common analytic curve satisfies

$$\sup_{\nu \text{ on the retained disc}} \|\mathcal{R}_a(X_\nu) - \mathcal{R}_a(X_0)\| < \epsilon_a r_a \quad \text{for every } a, \tag{3.dcxxxix}$$

then it stays in the core. The proof is the triangle inequality for every defining clause. Its substantive content in an application is the uniform bound for the infinite hereditary list, not that triangle inequality.

If the actual response and average derivatives imply

$$\frac{\|\mathcal{R}_a(X_\nu)-\mathcal{R}_a(X_0)\|}{r_a}\le C_a|\nu|\,\delta_k\sigma_j/\alpha_j, \tag{3.dcxl}$$

then the inner disc is admitted whenever $c\sup_a C_a\delta_k\sigma_j/(s\alpha_j)<\inf_a\epsilon_a$. This calculation shows the exact estimate required; it does not establish eq. 3.dcxl for the actual maps. The ratio σ_j is the old-to-current physical length ratio and must be inserted with the units of the relevant average. It cannot be guessed by identifying raw logarithms with potentials.

One part of this check is explicit on the fixed real-base tower class. At a positive bare bond b let $l(b)$ be its layer spacing in the ambient sequence. Let n_b be the maximum of the potential and fixed real-base covariant first-difference seminorms scaled by $l(b)$ and $l(b)^2$, respectively. For a shift $\mathbf{A}$ of $\mathbf{U}=e^{i\eta A'}U$, set

$$u(b)=\max\{l(b)|\mathbf{A}(b)|,\,l(b)^2|\nabla_{\mathbf{U}}\mathbf{A}|(b)\},\qquad A'_{\mathrm{new}}(b)=\frac{1}{i\eta}\log\bigl(e^{i\eta\mathbf{A}(b)}e^{i\eta A'(b)}\bigr).$$

Here the first differences are those inside the domain of the tower. Write $u^+(b)$ for the maximum of u at b and its available translates by one positive bare step. The chart estimate gives $n_b(A'_{\mathrm{new}}-A')\le 2u^+(b)$ when $u(b)\le(256L^2)^{-1}$ throughout the chart and the base potential belongs to the admitted tower class. The neighboring entries occur because a first difference of the product of the two exponentials uses both endpoints. Thus if $n_b(A')+2u^+(b)<a_{\mathrm{T}}$, the new potential lies in the same fixed-base class with radius a_{T}. The tower response estimate then gives the increment at an element whose tower index agrees with the ambient index capped at the tower height, in the form $2e^{\delta}C\sup_b e^{-\delta d^{\flat}(x,x_b)}u(b)$ at its base point x, using the weighted distance $d^{\flat}$ of the ambient sequence. The factor e^{δ} absorbs the one bare step in u^+. For the inner contour put $\mathbf{A}=\nu\zeta H$ and check these bounds on the full retained disc, using the actual fine-bond differences of ζH. This verifies the fixed real-base potential clause when there is the stated margin. The induced tower current is part of that response. The clauses for independently varied currents and outer and removed substitutions still require their own bounds.

There are two logically different uses of a displacement estimate. A bound for $X_\nu-X_0$ on a disc already known to be admitted proves a Taylor estimate. To prove admission, one needs the bound while continuing up to a possible first exit. On a finite geometry this is done on the connected part of the analytic solution branch before exit. If eq. 3.dcxxxix is strict up to its closure and the primitive inverse has a uniform continuation radius there, no first exit occurs. The uniform continuation radius and the strict margin are both needed. Without them the first-exit argument is circular.

At young ages the factor σ_j may be too large to make eq. 3.dcxl small. The permitted fallback is a direct estimate at the finitely many such ages, using their actual local disc and radius. It must bound the whole reference value as well as the increment. An increment that vanishes at $\nu=0$ does not prove that X_0 itself satisfies its core inequalities.

For removed substitutions the current and the background may change together. The path used in the comparison must then remain in the joint core. Separate coordinate Cauchy estimates at the two endpoints do not imply that the segment connecting them is admitted, especially when a hereditary condition is not convex. One can instead use the actual common analytic chart and the strict clause margins in eq. 3.dcxxxix.

The remaining quantitative tasks. The preceding arguments reduce the multilevel response problem to the following specific estimates on the primitive domain. First, the actual constraint rows and gauge slice must admit E,P with uniform weighted bounds, including every outward seam row. Second, the constrained inverse and its energetic compositions must satisfy eq. 3.dcxxi–eq. 3.dcxxiv on the whole retained complex ball. Third, the datum forcing and current readout must satisfy their local weighted bounds. Fourth, the translated equations and boundary rows must give the required

first-difference and Hölder estimates. Fifth, all inner, outer and removed substitutions must satisfy eq. 3.dcxxxix, with a supremum over the actual tower list and independent fine parameters.

These tasks have different mechanisms and should be checked separately. Proving the first-step versions does not prove their constants uniform in depth. Once these estimates hold, the field and multiplier response follows from the block inverse, joining distance estimates follow from Cauchy on the admitted ball, and window-background comparison follows from the exact boundary-force equation. These last implications are the proved part of the section and may be used without adding a new response assumption.

3.15. **A mesh-uniform interior Hölder estimate.** The response system needs spatial regularity as well as decay. We prove the particular scalar estimate that converts a bounded potential and a bounded componentwise Laplacian into a Hölder bound for its first differences. The estimate is uniform in the mesh. It also applies in a parallel frame for an unweighted flat unitary connection, including arbitrary flat holonomies on a compatible torus. The nonlinear gauge application is then reduced to explicit coefficient estimates. The construction of those local gauges and the layered equations supplying the Laplacian bound remain model-dependent tasks.

Fix $0 < \alpha < 1$. On $\eta\mathbb{Z}^4$ define

$$D_i^+ u(x) = \frac{u(x+\eta e_i) - u(x)}{\eta}, \quad D_i^- u(x) = \frac{u(x) - u(x-\eta e_i)}{\eta}, \quad \Delta_\eta = \sum_{i=1}^4 D_i^- D_i^+. \tag{3.dcxli}$$

The Laplacian has nonpositive Fourier symbol. The counting measure in all convolution kernels is η^4 times counting measure. We use the Euclidean distance, allowing dimension-dependent constants when a coordinate path is used. A derivative of order r means an arbitrary product of r of the forward or backward differences in eq. 3.dcxli.

Heat kernels with enough derivative and tail control. Start on the unit lattice. For $T \geq 0$ set

$$q_T(n) = \frac{1}{(2\pi)^4} \int_{[-\pi,\pi]^4} e^{-T\omega(\theta)} e^{in\cdot\theta}\, d\theta, \qquad \omega(\theta) = 4\sum_i \sin^2(\theta_i/2). \tag{3.dcxlii}$$

This is a nonnegative probability kernel. Indeed, if A is the sum of the eight nearest-neighbour translations, then $\Delta_1 = \mathsf{A} - 8I$ and

$$e^{T\Delta_1} = e^{-8T} \sum_{k=0}^\infty \frac{T^k \mathsf{A}^k}{k!}. \tag{3.dcxliii}$$

Every coefficient is nonnegative, and applying the operator to the constant function gives one. Fourier transformation gives eq. 3.dcxlii, so the two constructions agree. The physical heat-kernel density is

$$p_t^\eta(\eta n) = \eta^{-4} q_{t/\eta^2}(n). \tag{3.dcxliv}$$

It follows directly that convolution with p_t^η is a contraction on bounded functions.

The following polynomial tail estimates suffice.

Lemma 3.39 (Uniform differentiated heat-kernel tails)**.** For integers $r, N \geq 0$ there is $C_{r,N}$ independent of η, t, a such that

$$\begin{aligned} \sum_{|x|\geq a} \eta^4 |D^r p_t^\eta(x)| &\leq C_{r,N} t^{-r/2} (1 + a/\sqrt{t})^{-N}, && t \geq \eta^2, \\ \sum_{|x|\geq a} \eta^4 |D^r p_t^\eta(x)| &\leq C_{r,N} \eta^{-r} (1 + a/\eta)^{-N}, && 0 \leq t \leq \eta^2. \end{aligned} \tag{3.dcxlv}$$

■

Proof. A product of r unit differences has Fourier multiplier $m_r(\theta)$, a product of factors $e^{\pm i\theta_i}-1$. For every multi-index b,

$$|\partial^b m_r(\theta)| \le C_{r,b}|\theta|^{(r-|b|)_+}. \tag{3.dcxlvi}$$

The bound follows by assigning the derivatives to factors. A factor that has not been differentiated vanishes to first order at zero; all its positive-order derivatives are bounded. If more than r derivatives occur the asserted power is zero.

For $\theta \in [-\pi,\pi]^4$, $\omega(\theta) \ge c|\theta|^2$. Its first derivatives are $O(|\theta|)$ and its higher derivatives are bounded. Differentiating $e^{-T\omega}$ for $T \ge 1$ gives

$$|\partial^b e^{-T\omega(\theta)}| \le C_b T^{|b|/2}(1+|\sqrt{T}\theta|)^{M_b} e^{-c_b T|\theta|^2}. \tag{3.dcxlvii}$$

For completeness, each term of the repeated product rule consists of $e^{-T\omega}$ times factors $T\partial^{b_j}\omega$, with $b_j \ne 0$ and $\sum b_j = b$. A first derivative contributes $\sqrt{T}\,O(|\sqrt{T}\theta|)$. A factor of order at least two is at most a constant times $T^{|b_j|/2}$ because $T \ge 1$. Multiplying proves eq. 3.dcxlvii; the finite polynomial can be absorbed by a smaller Gaussian exponent when integrating.

Leibniz' rule, eq. 3.dcxlvi, and eq. 3.dcxlvii now imply

$$\int_{[-\pi,\pi]^4} |\partial^b(m_r e^{-T\omega})|^2\,d\theta \le C_{r,b}T^{|b|-r-2}, \qquad T \ge 1. \tag{3.dcxlviii}$$

When at most r derivatives hit the multiplier, scale $\theta = T^{-1/2}v$ in that term. When more than r hit it, its bound is smaller than the displayed power since $T \ge 1$. The four-dimensional volume factor is T^{-2}. This explains every power in eq. 3.dcxlviii.

Let δ^r denote the corresponding unit differences. Parseval's identity and differentiation of the periodic Fourier multiplier give, for every integer $M \ge 0$,

$$\sum_n (1+|n|^2/T)^M |\delta^r q_T(n)|^2 \le C_{r,M}T^{-r-2}, \qquad T \ge 1. \tag{3.dcxlix}$$

Expand the weight into coordinate monomials. The term $|n^b|^2 T^{-|b|}$ is bounded by eq. 3.dcxlviii times $T^{-|b|}$. All multiplier functions are smooth and periodic, so there are no boundary terms at $\pm\pi$.

Choose $M > N+2$, increasing it by one if necessary. Comparing the lattice sum with the radial integral in four dimensions gives

$$\sum_{|n|\ge A} (1+|n|^2/T)^{-M} \le C_{M,N}T^2(1+A/\sqrt{T})^{-2N}, \qquad T \ge 1. \tag{3.dcl}$$

One way to check the comparison is to cover the lattice by unit cubes. For $T \ge 1$ the values of $1+|x|/\sqrt{T}$ at any two points of a cube are comparable by a fixed dimensional factor. The integral of $(1+|x|^2/T)^{-M}$ outside a ball of radius comparable with A is T^2 times the corresponding integral in scaled coordinates. That integral decays at least as $(1+A/\sqrt{T})^{-2N}$ for this choice of M. Small values of A are absorbed by the full integral bound.

Cauchy–Schwarz with eq. 3.dcxlix and eq. 3.dcl proves $\sum_{|n|\ge A}|\delta^r q_T(n)| \le CT^{-r/2}(1+A/\sqrt{T})^{-N}$. For $0 \le T \le 1$, all derivatives of $m_r e^{-T\omega}$ of any fixed order are uniformly bounded. The same Parseval argument, with weight $(1+|n|^2)^M$, gives instead $C(1+A)^{-N}$. Finally eq. 3.dcxliv contributes η^{-r} to the weighted ℓ^1 norm. Substitution of $T = t/\eta^2$ proves eq. 3.dcxlv. □

These constants depend on the fixed derivative order and the desired tail power. They do not depend on the number of lattice sites. The small-time part of eq. 3.dcxlv is important: replacing it by a continuum heat-kernel formula all the way to $t = 0$ would not justify the uniform estimates for the discrete second and third differences.

A massive resolvent and its first-difference modulus. For $\mu > 0$ define

$$G_\mu^\eta(x) = \int_0^\infty e^{-\mu^2 t} p_t^\eta(x)\, dt, \qquad R_\mu f = G_\mu^\eta * f. \tag{3.dcli}$$

Its kernel is nonnegative and has total mass μ^{-2}. For fixed η, Δ_η is a bounded operator on bounded functions. Integrating the derivative of $e^{-\mu^2 t} e^{t\Delta_\eta}$ in operator norm shows

$$(-\Delta_\eta + \mu^2) R_\mu f = f, \qquad \|R_\mu f\|_\infty \le \mu^{-2} \|f\|_\infty. \tag{3.dclii}$$

Conversely, any bounded solution of this equation equals $R_\mu f$. Indeed integrate the same identity applied to the bounded solution; the terminal term tends to zero because of $e^{-\mu^2 t}$ and the heat contraction. This also proves uniqueness without a maximum attainment argument on an infinite lattice.

Assume $\mu\eta \le 1$. Integrating eq. 3.dcxlv for $r = 1$, first on $[0, \eta^2]$ and then on $[\eta^2, \infty)$, gives

$$\sum_x \eta^4 |DG_\mu^\eta(x)| \le C\mu^{-1}. \tag{3.dcliii}$$

The first interval contributes $C\eta$ and the second is bounded by $C \int_0^\infty e^{-\mu^2 t} t^{-1/2}\, dt = C'\mu^{-1}$.

For a lattice displacement h, telescoping along a coordinate path and using eq. 3.dcxlv with $r = 1, 2$ gives, for $t \ge \eta^2$,

$$\|\tau_h D p_t^\eta - D p_t^\eta\|_1 \le C \min(t^{-1/2}, |h| t^{-1}). \tag{3.dcliv}$$

The second bound follows by summing the second difference over the path of physical length at most $2|h|$ in four dimensions; the first is twice the first-difference norm. For $t \le \eta^2$ use $C\eta^{-1}$ instead. Every nonzero lattice displacement has $|h| \ge \eta$.

Suppose first that $\eta \le |h| \le \mu^{-1}$. Integrate eq. 3.dcliv on $[\eta^2, |h|^2]$, on $[|h|^2, \mu^{-2}]$ and on the remaining tail. Together with the small-time interval, this gives

$$\|\tau_h DG_\mu^\eta - DG_\mu^\eta\|_1 \le C|h|(1 + \log(1/(\mu|h|))). \tag{3.dclv}$$

On the middle interval the integral is $|h| \int_{|h|^2}^{\mu^{-2}} t^{-1} dt$. The first interval contributes $O(|h|)$, and the exponentially damped last interval does as well. If $|h| > \mu^{-1}$ use twice eq. 3.dcliii. Since for $0 < x \le 1$

$$x^{1-\alpha}(1 + \log(1/x)) \le 1 + \frac{1}{e(1-\alpha)}, \tag{3.dclvi}$$

both ranges imply

$$\|\tau_h DG_\mu^\eta - DG_\mu^\eta\|_1 \le C_\alpha \mu^{\alpha-1} |h|^\alpha. \tag{3.dclvii}$$

The value at $h = 0$ is zero. It follows for bounded f that

$$\|DR_\mu f\|_\infty \le C\mu^{-1} \|f\|_\infty, \qquad [DR_\mu f]_\alpha \le C_\alpha \mu^{\alpha-1} \|f\|_\infty. \tag{3.dclviii}$$

The seminorm compares lattice points, using their physical distance. The logarithmic modulus eq. 3.dclv explains why these estimates do not give a mesh-uniform Lipschitz bound for $DR_\mu f$ from bounded f alone. The constants are permitted to diverge as α tends to one.

Off-diagonal resolvent derivatives. Let $R \ge \eta$ and $\mu = R^{-1}$. For every fixed $c > 0$ and $r = 0, 1, 2, 3$,

$$\sum_{|x| \ge cR} \eta^4 |D^r G_{1/R}^\eta(x)| \le C_{r,c} R^{2-r}. \tag{3.dclix}$$

Choose $N > \max(0, r-2)$. On the time interval $[\eta^2, R^2]$, the large-time part of eq. 3.dcxlv is bounded by $Ct^{-r/2}(\sqrt{t}/R)^N$. Its integral is $O(R^{2-r})$. On $[R^2, \infty)$ the exponential e^{-t/R^2} gives the same bound by scaling. The interval $[0, \eta^2]$ contributes at most $C\eta^{2-r}(\eta/R)^N$, which is also $O(R^{2-r})$. This proves eq. 3.dclix, including the second and third derivatives for which the uncut global norms would have a worse small-scale behaviour.

There is no assertion here that the second resolvent derivative has a uniformly bounded global absolute sum. Its off-diagonal bound is what makes the interior cutoff argument work.

An interior estimate with no unknown cutoff gradient. Let Q_R be the cube of side $2R$ centred at a lattice point. The following formulation uses a fixed ratio of cubes; changing that ratio changes only the constants.

Proposition 3.40 (Interior first-difference Hölder bound)**.** Let $R \geq 64\eta$. Suppose u is defined on Q_{2R} and $\Delta_\eta u = f$ at every point needed by the equation there. Put $M = \|u\|_{\infty,Q_{2R}}$ and $F = \|f\|_{\infty,Q_{2R}}$. On $Q_{R/2}$, with all first differences and comparisons taken inside its one-mesh enlargement,

$$\begin{aligned} \|Du\|_\infty &\leq C(R^{-1}M + RF), \\ [Du]_\alpha &\leq C_\alpha(R^{-1-\alpha}M + R^{1-\alpha}F). \end{aligned} \tag{3.dclx}$$

The constants are independent of R, η, u. ■

Proof. Choose the restriction of a smooth cutoff $\chi(x/R)$, equal to one on Q_R and supported in $Q_{3R/2}$. It satisfies $|D\chi| \leq C/R$ and $|\Delta_\eta\chi| \leq C/R^2$. Its difference supports lie in a collar at distance at least cR from the evaluation cube and its one-mesh enlargement. The condition $R \geq 64\eta$ makes this separation uniform after every difference used below. Extend u arbitrarily outside Q_{2R}; the value of $v = \chi u$ and all forces below are independent of that extension.

With $\mu = 1/R$ the exact product identity is

$$(-\Delta_\eta + \mu^2)v = a - [\Delta_\eta, \chi]u, \qquad a = \chi(-f + \mu^2 u). \tag{3.dclxi}$$

Both sides are extended by their actual compactly supported formulas. The equation for u is used only where χ or its differences are nonzero, inside the given domain. By eq. 3.dclii, $v = R_\mu a - R_\mu[\Delta_\eta, \chi]u$. The first term has force norm at most $F + R^{-2}M$, so eq. 3.dclviii gives exactly its contributions to eq. 3.dclx.

To treat the commutator one must avoid estimating the unknown Du in the cutoff collar. Move the commutator onto the kernel. For scalar multiplication by χ and the constant cell-weighted pairing,

$$[\Delta_\eta, \chi]^{\mathsf{T}} = [\chi, \Delta_\eta] = -[\Delta_\eta, \chi]. \tag{3.dclxii}$$

For $j = 1, 2$, apply this identity to $K_j(y) = D_x^j G_\mu^\eta(x - y)$ in the convolution. The discrete product rule shows that its absolute value is bounded by

$$CM\left(R^{-2}\|1_{|\cdot|\geq cR}D^j G_\mu^\eta\|_1 + R^{-1}\|1_{|\cdot|\geq cR}D^{j+1}G_\mu^\eta\|_1\right). \tag{3.dclxiii}$$

To check the rule explicitly, $\Delta(\chi K) - \chi\Delta K - K\Delta\chi$ is the sum over i of $(D_i^+\chi)(D_i^+K) + (D_i^-\chi)(D_i^-K)$. All factors containing a difference of χ are supported in the separated collar. Changes of the evaluation point by at most the fixed number of mesh steps in a derivative merely change c. The kernel is absolutely summable on that collar by eq. 3.dclix, which also justifies the summation by parts.

For $j = 1$, eq. 3.dclix bounds in eq. 3.dclxiii by CM/R. For $j = 2$ it bounds it by CM/R^2. Let $w = R_\mu[\Delta_\eta, \chi]u$. A coordinate path between two points of $Q_{R/2}$ stays in that cube; telescoping the first differences of w gives $|Dw(x) - Dw(x')| \leq CMR^{-2}|x - x'|$. Its supremum bound is CM/R. Since $|x - x'| \leq CR$ in the cube, this gives $[Dw]_\alpha \leq C_\alpha MR^{-1-\alpha}$. Adding the contribution of $R_\mu a$ proves both estimates. On the evaluation cube $v = u$, including all the differences used, so the estimates apply to u itself. □

The proof has not used a previously known bound on Du in the outer collar. Estimating the original cutoff commutator directly by $R^{-1}\|Du\|$ would have introduced that extra premise. Moving the commutator onto the separated resolvent kernel is the step that removes it.

The result holds componentwise for vectors in any fixed finite-dimensional normed space. Equivalent coordinate norms contribute a constant depending on that fixed dimension. No number of lattice sites appears.

Tori and flat unitary holonomies. On a torus with periods ℓ_i, the scalar heat kernel and massive resolvent are periodizations of their infinite-lattice kernels. Their absolute derivative sums are bounded by the corresponding infinite sums. For a set at periodic distance at least cR from the origin, every lift has Euclidean distance at least cR. Thus eq. 3.dclix holds for periodic distance as well. If the cubes and their collars in the interior theorem embed without wrapping, the same cutoff proof gives eq. 3.dclx with the same constants. For example $\min_i \ell_i \geq 8R$ suffices for the stated cubes.

A flat unitary connection can be made trivial on the lifted lattice. The deck transformations act by its commuting unitary holonomies. The kernel on the torus is the image sum with the corresponding unitary factors. On a common parallel frame in the embedded cube, differences act on the lifted kernel. Taking the norm and using unitarity bounds the image sum by the scalar sum already estimated. Hence all the preceding local bounds remain uniform in the holonomies. Their distance from the identity is irrelevant.

The argument requires flatness. Curved parallel transports have additional commutators. Nor does it give the same estimate for an arbitrary nonlocal or layered positive operator: the proof used the componentwise constant-coefficient Laplacian in eq. 3.dcxli.

The local gauge application. Here is how eq. 3.dclx enters the background and response estimates. Suppose a local real gauge has supplied a potential on a cube enlarged by a fixed multiple of its local scale ξ, with

$$\|A\|_\infty \leq C_0 m\varepsilon\xi^{-1}, \qquad \|\Delta_\eta A\|_\infty \leq C_1 m\varepsilon\xi^{-3}. \tag{3.dclxiv}$$

Apply the theorem on cubes of radius a fixed fraction of ξ, covering the interior. It proves

$$[DA]_\alpha \leq C_\alpha m\varepsilon\xi^{-2-\alpha}, \qquad \|DA\|_\infty \leq Cm\varepsilon\xi^{-2}. \tag{3.dclxv}$$

For pairs farther apart than a fixed fraction of ξ, the supremum bound gives the same Hölder estimate. Thus local cubes give the full indicated interior seminorm. On the enlarged real cubes of the layered profile, the single-gauge construction supplies both premises of eq. 3.dclxiv from curvature and full-current bounds.

There is a finite coarse-mesh case in this application. If the chosen fraction of ξ is less than 64η, the ratio ξ/η is bounded by a fixed constant. Directly, $|DA| \leq 2\|A\|_\infty/\eta$ and $[DA]_\alpha \leq 4\|A\|_\infty\eta^{-1-\alpha}$. They give eq. 3.dclxv with the same powers of ξ and a larger fixed constant. The same fallback applies to the response application below. Thus no unmentioned lower bound on ξ/η is needed.

For a response, the available equation often controls the positive covariant componentwise Laplacian $\mathcal{L}_{U_0} = \sum_i \nabla_{U_0,i}^{\mathsf{T}}\nabla_{U_0,i}$. Thus $\mathcal{L}_{\mathbf{1}} = -\Delta_\eta$ with the heat-generator sign in eq. 3.dcxli. Its conversion can also be made quantitative. In a local gauge write $U_0(b) = e^{i\eta A_0(b)}$ and let $T_b = \mathrm{Ad}(U_0(b))$ in the chosen unitary colour representation. If $\eta|A_0|$ stays in a fixed small exponential chart, then

$$\|(T_b - I)/\eta\| \leq C|A_0(b)|. \tag{3.dclxvi}$$

Differencing T_b in a transverse direction uses the integral derivative of the exponential. It gives $|DT_b| \leq C\eta|DA_0|$, with the adjacent bond values interpreted in the same local frame. The inverse transport satisfies the same bound. Expanding the forward and backward covariant differences therefore gives

$$|(\mathcal{L}_{U_0} + \Delta_\eta)h| \leq C\big(|A_0|\,|Dh| + (|DA_0| + |A_0|^2)|h|\big). \tag{3.dclxvii}$$

One can verify this by first writing each covariant first difference as the ordinary difference plus $(T_b - I)/\eta$ times a neighbouring value. In the second difference the apparent η^{-1} terms combine into a first difference of h, a difference of the coefficient $(T_b - I)/\eta$, and a product of two such

coefficients. These are exactly the three terms on the right of eq. 3.dclxvii. There is no estimate of an individual uncombined $\eta^{-1}A_0h$ term.

Assume on a local-scale cube that

$$\xi|A_0| + \xi^2|DA_0| \le a_0,$$
$$\xi|h| + \xi^2|\nabla_{U_0}h| + \xi^3|\mathcal{L}_{U_0}h| \le B. \tag{3.dclxviii}$$

The formula in eq. 3.dclxvi first gives $\xi^2|Dh| \le C(1+a_0)B$. Then eq. 3.dclxvii implies

$$\xi^3|\Delta_\eta h| \le C(1+a_0+a_0^2)B. \tag{3.dclxix}$$

Applying eq. 3.dclx at scale ξ yields $[Dh]_\alpha \le C_{\alpha,a_0}B\xi^{-2-\alpha}$. The difference between Dh and $\nabla_{U_0}h$ is a bounded coefficient times a neighbouring h. Its Hölder seminorm is controlled by the same local bounds, using the Lipschitz coefficient bound from DA_0 and the first-difference bound for h. Thus

$$[\nabla_{U_0}h]_\alpha \le C_{\alpha,a_0}B\xi^{-2-\alpha}. \tag{3.dclxx}$$

This initially compares gradient components in the chosen local gauge. If the assigned Hölder seminorm transports one component to the other along paths of length at most $C|x-x'|$, unitary product telescoping and eq. 3.dclxviii give $\|\operatorname{Ad}U_0(\Gamma)-I\| \le Ca_0|x-x'|/\xi$. Multiplying by $|\nabla_{U_0}h| \le B/\xi^2$ adds at most $Ca_0B\xi^{-2-\alpha}|x-x'|^\alpha$ on the scale-ξ cube. Hence eq. 3.dclxx also holds in that transported seminorm. Its premise still includes the pointwise covariant-gradient bound in eq. 3.dclxviii; the argument removes an additional Hölder premise, rather than that gradient bound.

If the right-hand side of eq. 3.dclxviii has the response factor $B = Ce^{-md(y,y_c)}|e|$, that factor persists on a fixed-size local-scale cube up to the fixed exponential comparison of distances within the cube. This gives the corresponding Hölder member of the response estimate. The primitive model input is now explicit: the actual local gauge and the three bounds in eq. 3.dclxviii, with the proper current and boundary readouts. No separate Hölder estimate is needed once those inputs have been proved. At a seam the cube, frame and difference equation must be compatible on both sides; the scalar theorem cannot supply that compatibility.

3.16. **Local gauges from curvature and the Wilson current.** The background estimates require a local potential and its first differences in physical units. A bound on plaquettes gives a small potential in a comb gauge, but does not directly bound its first differences. We construct a Coulomb gauge in a finite L^p space and then use the actual Wilson current to obtain the additional derivative. The distinction between these two steps is essential: no boundedness of an order-zero singular integral on L^∞ is used.

The problem of choosing regular local representatives is part of Bałaban's gauge-fixing construction [B85b]. The proof here specifies a different local gauge and normalizes the current directly by differentiating the Wilson action. The representative need not preserve block averages or a previously imposed contour gauge. Those additional requirements are discussed at the end.

3.16.1. *The statement and its physical normalization.* Let $\eta > 0$ be a lattice spacing. For $R > 0$ with R/η an integer, write

$$Q_R = \{x \in \eta\mathbb{Z}^4 : |x|_\infty \le R\}.$$

An assertion on bonds or plaquettes of a cube concerns those having all their vertices in the cube. A connection assigns $U_\mu(x) \in \mathrm{SU}(2)$ to the positive bond from x to $x+\eta e_\mu$; the reverse bond has the inverse value. Gauge transformations act by

$$U_\mu^g(x) = g(x)U_\mu(x)g(x+\eta e_\mu)^{-1}. \tag{3.dclxxi}$$

Lie-algebra elements are traceless Hermitian matrices. We use $\langle X, Y\rangle = \frac{1}{2}\mathrm{tr}(XY)$ and its Euclidean norm. All estimates below remain valid for the equivalent operator norm, with a changed absolute constant.

For distinct μ,ν, put

$$\begin{aligned} P_{\mu\nu}(x) &= U_\mu(x)U_\nu(x+\eta e_\mu) \\ &\qquad \times U_\mu(x+\eta e_\nu)^{-1}U_\nu(x)^{-1}, \\ F_{\mu\nu}(x) &= \frac{1}{i\eta^2}\log P_{\mu\nu}(x), \\ W_{\mu\nu}(x) &= \frac{P_{\mu\nu}(x)-P_{\mu\nu}(x)^*}{2i\eta^2}. \end{aligned} \tag{3.dclxxii}$$

The logarithm is the branch near the identity. On this branch $F_{\nu\mu}=-F_{\mu\nu}$, and $W_{\mu\nu}$ is the matrix sine $\eta^{-2}\sin(\eta^2 F_{\mu\nu})$.

The Wilson current is the physical gradient of $\sum_p(1-\frac12\operatorname{tr}U_p)$. At every bond whose full plaquette stencil is present, it is normalized by

$$\frac{d}{dt}A(e^{i\eta t a}U)\Big|_{t=0} = \eta^4\sum_{x,\mu}\langle J_\mu(x),a_\mu(x)\rangle. \tag{3.dclxxiii}$$

This is a local definition: compactly supported variations change only finitely many plaquettes. No finite total action on an infinite lattice is assumed.

For a matrix-valued function let

$$D^+_\mu f(x)=\frac{f(x+\eta e_\mu)-f(x)}{\eta},\quad D^-_\mu f(x)=\frac{f(x)-f(x-\eta e_\mu)}{\eta},\quad L_\eta=-\sum_\mu D^-_\mu D^+_\mu. \tag{3.dclxxiv}$$

The Coulomb condition on a potential is $\operatorname{div}_\eta A:=\sum_\mu D^-_\mu A_\mu=0$. The notation DA includes every forward first difference of every component. For a function on a cube, $[f]_{\alpha,Q}$ is the ordinary discrete Hölder seminorm, with physical Euclidean distance.

Proposition 3.41 (A local gauge controlled by the physical current)**.** There are absolute constants $\varepsilon_*>0$ and $C<\infty$ with the following property. Let $0<\eta\le r$, $r/\eta\in\mathbb{N}$, and let a real connection be given on Q_{8r}. Assume that all its plaquettes lie in the logarithm branch of eq. 3.dclxxii, and that

$$\|F\|_{\infty,Q_{8r}}\le\kappa,\qquad r^2\kappa\le\varepsilon_*. \tag{3.dclxxv}$$

Suppose the actual current in eq. 3.dclxxiii satisfies $\|J\|_{\infty,Q_{7r}}\le j$. Then there is a real site gauge g such that $U^g=e^{i\eta A}$ on Q_{6r}, in the logarithm branch near the identity, and $\operatorname{div}_\eta A=0$ wherever its stencil lies in Q_{6r}. On Q_r,

$$\begin{aligned} \|A\|_\infty &\le Cr\kappa, \\ \|DA\|_\infty &\le C(\kappa+rj), \\ \|L_\eta A\|_\infty &\le C(j+r\kappa^2). \end{aligned} \tag{3.dclxxvi}$$

For each fixed $0<\alpha<1$,

$$[DA]_{\alpha,Q_r}\le C_\alpha r^{-\alpha}(\kappa+rj). \tag{3.dclxxvii}$$

The constants are independent of η, r, the connection and its holonomies outside the cube. No smallness condition on j is needed. The gauge and the bound on A use only the curvature assumption; the current enters the derivative estimates. ∎

The condition can equivalently be imposed using $\eta^{-2}\|P-1\|_\infty$: on a fixed small logarithm branch it is comparable with $\|F\|_\infty$. In particular the hypothesis has the physical curvature scaling of the background domains, rather than a bound on an unscaled bond potential.

We prove the proposition after the analytic estimates below. Under $x=r\widetilde{x}$, the scaled quantities are

$$\widetilde{\eta}=\eta/r,\quad \widetilde{A}=rA,\quad \widetilde{F}=r^2F,\quad \widetilde{J}=r^3J. \tag{3.dclxxviii}$$

Thus it suffices to prove the statement at $r=1$.

3.16.2. *Uniform finite-L^p estimates on a lattice torus.* The auxiliary torus in this proof has physical side 32. Its spacing is $h = 1/N$, $N \in \mathbb{N}$, and integration means h^4 times counting measure. All constants in this subsection may depend on p and on that fixed side, but not on N. Let Π be the arithmetic mean and let $G_h = L_h^{-1}(1 - \Pi)$.

Lemma 3.42 (Uniform Green and Riesz estimates)**.** For $1 < p < \infty$ and any choices of forward or backward differences,

$$\|D_i D_j G_h f\|_p \le C_p \|f\|_p. \tag{3.dclxxix}$$

For $p > 4$,

$$\|DG_h f\|_\infty \le C_p \|f\|_p, \qquad \|u - \Pi u\|_\infty \le C_p \|Du\|_p. \tag{3.dclxxx}$$

For a one-form a,

$$\|Da\|_p \le C_p(\|\mathrm{d}a\|_p + \|\operatorname{div}_h a\|_p), \quad (\mathrm{d}a)_{\mu\nu} = D^+_\mu a_\nu - D^+_\nu a_\mu. \tag{3.dclxxxi}$$

These estimates hold componentwise for the fixed colour space. ∎

Proof. We give the kernel argument, including the mesh uniformity at the diagonal. The Fourier symbol of L_h is

$$\lambda_h(k) = 4h^{-2} \sum_{\mu=1}^{4} \sin^2(hk_\mu/2), \qquad k \in (2\pi/32)\mathbb{Z}^4 \cap [-\pi/h, \pi/h)^4. \tag{3.dclxxxii}$$

It is comparable with $|k|^2$ on the Brillouin cube. Fourier orthogonality proves the L^2 estimate in eq. 3.dclxxix; each first-difference symbol has modulus at most $\lambda_h^{1/2}$.

Let p_t^h be the physical heat kernel. Direct Fourier integration gives, for a product of s differences,

$$\|D^s p_t^h\|_\infty \le C_s(t + h^2)^{-(4+s)/2}, \qquad 0 < t \le 1. \tag{3.dclxxxiii}$$

For $t \le h^2$, use the volume of the Brillouin cube and $|D| \le 2/h$. For $t \ge h^2$, put $q = k\sqrt{t}$ and use $\lambda_h \ge c|k|^2$. The corresponding physical L^1 tails are

$$\sum_{|x| \ge a} h^4 |D^s p_t^h(x)| \le C_{s,M}(t + h^2)^{-s/2}(1 + a/\sqrt{t + h^2})^{-M}. \tag{3.dclxxxiv}$$

Here and below the distance is periodic. One may obtain this estimate from the differentiated heat-kernel tail calculation in § 3.15. For clarity, its Fourier argument uses integration by parts in a coordinate with $|x_\mu| \ge |x|/2$ when $t \ge h^2$. Each differentiation of the Gaussian multiplier is bounded by a polynomial in $k\sqrt{t}$ times $e^{-ct|k|^2}$, and supplies one factor $\sqrt{t}$. At $t \le h^2$, the random-walk series $e^{t\Delta_h} = e^{-8t/h^2} \sum_{n \ge 0} (t/h^2)^n \mathcal{A}^n/n!$ has uniformly bounded moments of every order; a product of s differences costs $C_s h^{-s}$. Periodizing the infinite-lattice estimate proves the displayed torus version.

The semigroup law turns these two bounds into a pointwise bound. In $D^s p_t = (D^s p_{t/2}) * p_{t/2}$, either the first or the second variable has distance at least $|x|/2$. Use the L^1 tail for that factor and the L^∞ bound for the other. Consequently

$$|D^s p_t^h(x)| \le C_{s,M}(t + h^2)^{-(4+s)/2}(1 + |x|/\sqrt{t + h^2})^{-M}. \tag{3.dclxxxv}$$

For $t \ge 1$, subtract the constant mode. The nonzero frequencies have a fixed positive lower spectral bound, and the same Fourier estimate gives $C_s e^{-ct}$ for every fixed derivative order.

Integrate the heat kernel in time. With $\rho(x)$ the periodic distance from zero, the kernels with physical summation convention satisfy

$$\begin{aligned} |DG_h(x)| &\le C(\rho(x) + h)^{-3} + C, \\ |D_i D_j G_h(x)| &\le C(\rho(x) + h)^{-4} + C, \\ |D_\ell D_i D_j G_h(x)| &\le C(\rho(x) + h)^{-5} + C. \end{aligned} \tag{3.dclxxxvi}$$

For example split the integral for a second derivative at $t = (\rho + h)^2$, use $M > 6$ below that point and the power t^{-3} above it. The interval $0 < t < h^2$ contributes at most Ch^{-4} at the diagonal. The first and third derivative estimates follow with powers $t^{-5/2}$ and $t^{-7/2}$. Thus a diagonal matrix entry is large, but its physical mass h^4 is retained.

We now prove the L^p consequence for $T = D_i D_j G_h$. Its physical kernel has sum zero, its L^2 norm is at most one, and eq. 3.dclxxxvi implies

$$\sum_{\rho(x-y)>4|y-z|} h^4 |K_h(x-y) - K_h(x-z)| \le C \quad (y \neq z). \tag{3.dclxxxvii}$$

Indeed join y to z by a shortest coordinate path. The third difference estimate, summed along that path, bounds the difference by $C|y-z|\rho(x-y)^{-5}$ away from the displayed ball. Summing annuli in four dimensions gives a uniform constant. The bounded large-distance term is harmless on the fixed torus.

Use the Calderón–Zygmund decomposition [CZ52], which we spell out for these finite lattices. Split the coordinate intervals of the torus repeatedly into two integer intervals of lengths differing by at most one. The resulting rectangles have uniformly bounded aspect ratio, and each parent has volume at most 3^4 times that of any child. At the final generation they are single lattice sites. For a level λ above the mean of $|f|$, take the maximal rectangles Q with average greater than λ. They are disjoint, and

$$\sum_Q |Q| \le \lambda^{-1} \|f\|_1, \qquad f = g + \sum_Q b_Q, \quad |g| \le 3^4 \lambda, \quad \|g\|_2^2 \le C\lambda \|f\|_1. \tag{3.dclxxxviii}$$

Here $b_Q = (f - f_Q)1_Q$, so it has mean zero and $\sum_Q \|b_Q\|_1 \le 2\|f\|_1$. The enlarged rectangles have total measure at most $C\lambda^{-1}\|f\|_1$. Outside them, eq. 3.dclxxxvii, with the cancellation of each b_Q, gives $\|\sum_Q T b_Q\|_{L^1(\text{outside})} \le C\|f\|_1$. The L^2 estimate controls Tg. Chebyshev's inequality proves

$$|\{|Tf| > \lambda\}| \le C\lambda^{-1}\|f\|_1. \tag{3.dclxxxix}$$

If λ is below the mean, the same bound is immediate from the total volume of the torus. This includes the last atomic scale; no continuum limit has been used.

For completeness the interpolation is uniform as well. Split f at height proportional to t when estimating $|Tf| > t$, use the weak L^1 bound on the large part and the L^2 bound on the small part, and integrate pt^{p-1} in t. For $1 < p < 2$, the two integrals are bounded by constants times

$$\int |f(x)| \int_0^{|f(x)|} t^{p-2}\, dt\, dx, \qquad \int |f(x)|^2 \int_{|f(x)|}^{\infty} t^{p-3}\, dt\, dx.$$

They equal $\|f\|_p^p/(p-1)$ and $\|f\|_p^p/(2-p)$. Duality proves $2 < p < \infty$, since the adjoint has the same kernel estimates. This proves eq. 3.dclxxix for all forward/backward choices.

For $p > 4$, $p' = p/(p-1) < 4/3$. The first kernel in eq. 3.dclxxxvi has uniformly bounded physical $L^{p'}$ norm, because $\sum_x h^4(\rho(x)+h)^{-3p'} \le C_p$. Hölder's inequality therefore proves the first assertion in eq. 3.dclxxx. The identity $u - \Pi u = -\sum_i D_i^- G_h D_i^+ u$ proves the second.

Finally ordinary differences commute and

$$L_h a_\mu = \sum_\nu D_\nu^- (\mathrm{d}a)_{\mu\nu} - D_\mu^+ \operatorname{div}_h a. \tag{3.dcxc}$$

Apply $D_i^+ G_h$ and eq. 3.dclxxix. Constant one-forms have zero derivative, so their mean causes no additional term. This proves eq. 3.dclxxxi. □

The use of $p > 4$ in eq. 3.dclxxx is strict. The order-zero operator in eq. 3.dclxxix is never applied with $p = \infty$. Its kernel has the borderline singularity $|x|^{-4}$, whereas the kernel used to bound a first derivative from a Laplacian has the integrable power $|x|^{-3}$ in the required dual space.

3.16.3. *A small-potential Coulomb gauge in a finite L^p space.*

Lemma 3.43 (A uniform nonlinear gauge calculation)**.** There are absolute $a_* > 0$ and $C < \infty$ such that the following holds for Hermitian traceless matrices λ, A, w whenever $|\lambda| + h|A| + h|w| < a_*$. Set

$$\mathcal{B}_h(\lambda, A, w) = \frac{1}{ih} \log\left(e^{i\lambda} e^{ihA} e^{-i(\lambda + hw)}\right) = A - w + N_h(\lambda, A, w). \tag{3.dcxci}$$

Then

$$|N_h| \le C\big(|\lambda| + h(|A| + |w|)\big)(|A| + |w|). \tag{3.dcxcii}$$

On a fixed smaller domain its first two derivatives satisfy the corresponding product bounds obtained by differentiating the right side. All constants are uniform in $0 < h \le 1$. ■

Proof. Write $X = hA$, $Y = hw$ and consider $\mathcal{L}(\lambda, X, Y) = i^{-1} \log(e^{i\lambda} e^{iX} e^{-i(\lambda + Y)})$. This is analytic on a fixed matrix polydisc. It vanishes for $X = Y = 0$, for every admitted λ, and its differential in (X, Y) at $(0, 0, 0)$ is $X - Y$. Taylor's integral formula in (X, Y) therefore gives

$$|\mathcal{L} - (X - Y)| \le C|\lambda|(|X| + |Y|) + C(|X| + |Y|)^2.$$

Divide by h. The same integral formula and the Cauchy estimate on a fixed larger polydisc prove the derivative bounds. The argument uses finite matrix analyticity, so its constants do not depend on the number of lattice sites. □

Proposition 3.44 (Coulomb gauge from a small global potential)**.** Fix $p > 4$. On the physical side-32 torus there are constants $b_p > 0$ and $C_p < \infty$, uniform in $h = 1/N$, with this property. If $V_\mu = e^{iha_\mu}$ is real and $\|a\|_\infty \le b_p$, there is a mean-zero real site function λ such that $g = e^{i\lambda}$ and

$$V^g = e^{ihB}, \quad \operatorname{div}_h B = 0, \quad \|D\lambda\|_p + \|\lambda\|_\infty + \|B\|_p \le C_p \|a\|_\infty. \tag{3.dcxciii}$$

The solution is unique in the ball specified in the proof. This is a uniqueness assertion for this small gauge parameter, not for all gauge representatives of the connection. ■

Proof. At the bond (x, μ) use eq. 3.dcxci with $w = D^+_\mu \lambda(x)$ and $A = a_\mu(x)$. Thus

$$B = a - D\lambda + N(\lambda), \qquad \lambda = -G_h \operatorname{div}_h(a + N(\lambda)) \tag{3.dcxciv}$$

is exactly the Coulomb equation. The second map has mean zero. Use the Banach norm $\|D\lambda\|_p$ on mean-zero site functions. The Sobolev estimate in eq. 3.dclxxx controls $\|\lambda\|_\infty$ by this norm. The elementary atomic bound is

$$h\|D\lambda\|_\infty \le h^{1-4/p} \|D\lambda\|_p \le \|D\lambda\|_p. \tag{3.dcxcv}$$

It controls the group increment without asserting a uniform bound on the unscaled L^∞ derivative of λ.

On the ball $\|D\lambda\|_p \le R$ with $\|a\|_\infty \le b$ and $b + R$ small, Lem. 3.43 gives

$$\begin{aligned} \|N(\lambda)\|_p &\le C_p(b + R)(b + R), \\ \|N(\lambda) - N(\widetilde{\lambda})\|_p &\le C_p(b + R)\|D\lambda - D\widetilde{\lambda}\|_p. \end{aligned} \tag{3.dcxcvi}$$

To check the quadratic increment term, use $h\|w^2\|_p \le h\|w\|_\infty \|w\|_p$ and eq. 3.dcxcv. For a difference of two such terms use $w^2 - \widetilde{w}^2$ as two ordered matrix products. The terms containing λ use its uniform Sobolev bound. These arguments also prove the displayed Lipschitz estimate when the matrices do not commute.

By eq. 3.dclxxix, the map on the right of eq. 3.dcxciv is bounded in this norm by $C_p\|a + N\|_p$. Let K_p dominate this constant, the fixed torus volume factor and the constants in eq. 3.dcxcvi. Take $R = 2K_p b$, and then take b_p so small that the domain of Lem. 3.43 contains the whole ball and

$$K_p C_p(b_p + 2K_p b_p) \le \tfrac{1}{4}, \qquad K_p C_p(b_p + 2K_p b_p)^2 \le K_p b_p/2. \tag{3.dcxcvii}$$

The map is a contraction and maps the closed radius-R ball into itself. Its real iterates converge to a real solution. The logarithms remain on the common branch by the same inequalities. Taking the divergence of the first identity in eq. 3.dcxciv proves the Coulomb equation exactly. The estimates for λ and B now follow from the ball bound, Sobolev and eq. 3.dcxcvi. □

The parameter ball is uniform in the mesh. Its proof used a fixed finite p throughout. The smallness of $hD\lambda$ in eq. 3.dcxcv is enough to keep the link logarithm on its branch; an L^∞ estimate for the order-zero gauge projection was not needed.

3.16.4. *Comb gauges and an auxiliary periodic extension.*

Lemma 3.45 (A comb potential and its curvature-preserving extension)**.** Suppose U is real on Q_8, $h = 1/N \le 1$, and $\|F\|_{\infty,Q_8} \le \kappa$ with κ sufficiently small. There is a real gauge g_0 on Q_8 for which $U^{g_0} = e^{iha}$ on Q_7 and $\|a\|_\infty \le C\kappa$. There is also a side-32 periodic potential a^{ext} agreeing with a on Q_6, satisfying

$$\|a^{\mathrm{ext}}\|_\infty \le C\kappa, \qquad \|F(e^{iha^{\mathrm{ext}}})\|_\infty \le C\kappa. \tag{3.dcxcviii}$$

The extension does not assert a current bound outside Q_6. ■

Proof. Use the fixed coordinate-order comb from one corner of Q_8 to each site. Choose g_0 so its tree transports become one. The transformed value of a bond is the closed transport made from the two combs and that bond. Moving the bond past the later coordinate segments expresses this loop as a product of at most C/h conjugated plaquettes. The estimate $\|AB-1\| \le \|A-1\| + \|B-1\|$ for unitary matrices therefore gives

$$\|U^{g_0}(b) - 1\| \le Ch\kappa. \tag{3.dcxcix}$$

Take the logarithm and divide by h. No bound on $g_0 - 1$ is used.

We record a local analytic identity that is also used later. If $V_\mu = e^{ihB_\mu}$ and all $h|B_\mu|$ are in a fixed small ball, then

$$F_{\mu\nu}(V) = (\mathrm{d}B)_{\mu\nu} + E_{\mu\nu}(B), \qquad |E_{\mu\nu}(B)(x)| \le C \max_{b\in\partial p} |B(b)|^2. \tag{3.dcc}$$

Indeed apply the matrix logarithm to the four exponential factors of the plaquette. Its first-order term is $h[B_\mu(x) + B_\nu(x+he_\mu) - B_\mu(x+he_\nu) - B_\nu(x)] = h^2(\mathrm{d}B)_{\mu\nu}$. All remaining terms have degree at least two in these four variables, and division by h^2 gives the stated uniform bound. Its first derivatives with respect to the four B variables are bounded by $C\max|B|$ on a smaller chart.

It follows that $\|\mathrm{d}a\|_\infty \le C\kappa$ on Q_7. Choose a fixed smooth scalar cutoff χ, equal to one on Q_6 and zero outside the interior of Q_7, and put $a^{\mathrm{ext}}(b) = \chi(b_-)a(b)$ on the available bonds and zero elsewhere. Embed its support in the side-32 torus. The discrete product rule gives $\|da^{\mathrm{ext}}\|_\infty \le C\kappa$. Apply eq. 3.dcc once more to the extended potential. This proves eq. 3.dcxcviii. At the finest exceptional collar positions the same formula uses only bonds in Q_8, since $h \le 1$. Thus the construction has the claimed domain even when $N = 1$. □

The extension is an analytic tool on a fixed auxiliary torus. On the inner cube it agrees with a gauge transform of the given field. It imposes no condition on holonomies of any larger ambient torus. The current of the extension is deliberately not used near its cutoff.

3.16.5. *The exact current identity and its elliptic consequence.*

Lemma 3.46 (The Wilson current as a covariant difference)**.** With the normalization in eq. 3.dclxxiii,

$$J_\mu(x) = \frac{1}{h}\sum_{\nu\neq\mu}\left[W_{\mu\nu}(x) - \mathrm{Ad}(U_\nu(x-he_\nu)^{-1})W_{\mu\nu}(x-he_\nu)\right]. \tag{3.dcci}$$

This identity is exact for real SU(2) fields on the logarithm branch. It is not a small-field replacement of the action. If $U = e^{ihB}$, $\operatorname{div}_h B = 0$ and $M = \|F\|_\infty$, then, wherever the full local stencil is present,

$$\begin{aligned} L_h B_\mu &= J_\mu - \sum_{\nu\neq\mu} D_\nu^- E_{\mu\nu}(B) - \sum_{\nu\neq\mu} D_\nu^- S_h(F_{\mu\nu}) - \mathcal{R}_\mu, \\ S_h(X) &= h^{-2}\sin(h^2 X) - X, \\ |\mathcal{R}(x)| &\le C\|B\|_{\infty,\mathrm{stencil}} M, \qquad |\operatorname{div} S_h(F)(x)| \le C h^3 M^3. \end{aligned} \tag{3.dccii}$$

In the same local norms,

$$|DE(B)| \le C\|B\|_\infty \max|DB|. \tag{3.dcciii}$$

■

Proof. Differentiate a plaquette containing the positive bond (x,μ). For the plaquette based at x whose first edge is that bond, the derivative is $h\langle a_\mu(x), h^2 W_{\mu\nu}(x)\rangle$. For the plaquette based at $x - he_\nu$, the bond occurs reversed. Move the insertion to the initial point by cyclicity of the trace. Its contribution is

$$-h^3\left\langle a_\mu(x), \operatorname{Ad}(U_\nu(x-he_\nu)^{-1}) W_{\mu\nu}(x-he_\nu)\right\rangle.$$

The apparent additional conjugation by the plaquette itself drops out: $W(P) = (P - P^*)/(2ih^2)$ commutes with P. The same calculation with the inverse orientation handles $\nu < \mu$, using $W_{\nu\mu} = -W_{\mu\nu}$. Divide the total derivative by the physical factor h^4. This proves eq. 3.dcci, with its sign and all spacing powers fixed.

Replace its covariant difference by the ordinary backward difference. The error is bounded by $C\|B\|_\infty M$, since $\|1 - \operatorname{Ad}(e^{-ihB})\| \le Ch|B|$ and $|W(F)| \le C|F|$ on the branch. Next insert $F = \mathrm{d}B + E(B)$ and $W(F) = F + S_h(F)$, and use eq. 3.dcxc with zero divergence.

The sine series gives $|S_h(X)| \le Ch^4|X|^3$. An ordinary first difference of any bounded lattice function is at most twice its supremum divided by h. Therefore

$$|D^- S_h(F)| \le Ch^3 M^3. \tag{3.dcciv}$$

No derivative bound for F is hidden in this estimate. Finally $E(B)(x)$ is the same analytic function of the four neighbouring B values at every x. Subtract its values at two neighbouring plaquettes and use the integral derivative of that function, bounded as in eq. 3.dcc. This proves eq. 3.dcciii. □

The factor h^3 in eq. 3.dcciv is useful. A bound on the physical curvature is much stronger than a bound on an unscaled plaquette logarithm when the mesh is small. This factor permits the Wilson current to replace the divergence of logarithmic curvature without requiring a modulus of continuity for that curvature.

3.16.6. *Proof of the local gauge bounds.*

Proof of Prop. 3.41. Scale to $r = 1$ as in eq. 3.dclxxviii; write $h = \eta/r$. Apply Lem. 3.45, then Prop. 3.44 with $p = 16$ to the auxiliary connection. Write its transformed potential as B. Choose ε_* small enough that $C\kappa$ in the extension is below b_{16} and all logarithms stay in the fixed branches. On the torus,

$$\operatorname{div}_h B = 0, \qquad \|B\|_{16} \le C\kappa, \qquad \|F(B)\|_\infty \le C\kappa. \tag{3.dccv}$$

The last bound follows from gauge covariance of the actual plaquettes, not from a separate estimate of differentiated gauge parameters.

The group chart also gives $h\|B\|_\infty \le C\kappa$, using eq. 3.dcxcv. Hence eq. 3.dcc is valid at every torus plaquette. By eq. 3.dclxxxi with $p = 8$,

$$\|DB\|_8 \le C(\|F\|_8 + \|B\|_{16}^2) \le C(\kappa + \kappa^2). \tag{3.dccvi}$$

Apply the Sobolev estimate in eq. 3.dclxxx to each component of B, retaining its mean, which is bounded by $C\|B\|_{16}$. We obtain

$$\|B\|_\infty \le C\kappa. \tag{3.dccvii}$$

This is a finite-p estimate. It does not estimate a Riesz transform of F in L^∞. Return to eq. 3.dclxxxi, now with $p = 16$ and the bound $\|E(B)\|_{16} \le C\|B\|_\infty\|B\|_{16}$. Thus

$$\|DB\|_{16} \le C\kappa. \tag{3.dccviii}$$

On Q_6 the auxiliary connection before the last gauge agrees with U^{g_0}. Its current on Q_5 is therefore the gauge transform of the given actual current. Norms of real currents are unchanged by that unitary conjugation. Use Lem. 3.46, eq. 3.dccvii and eq. 3.dccviii; the full current stencil lies in the region of agreement. On a fixed cube between Q_4 and Q_5,

$$\|L_h B\|_{16} \le C(j + \kappa + \kappa^2). \tag{3.dccix}$$

The terms are respectively the actual current, BDB, the transport term BF, and the bounded sine correction h^3F^3. Since $h \le 1$ and $\kappa \le \varepsilon_*$, the last two are bounded in the indicated fixed volume. The extension's current near its cutoff does not enter this estimate.

Let ψ be a fixed scalar cutoff supported in Q_4 and equal to one on Q_3. Its sampled first and second differences are uniformly bounded, including when $h = 1$. The discrete product rule, eq. 3.dccviii, and eq. 3.dccix give

$$\|L_h(\psi B)\|_{16} \le C(j + \kappa).$$

All neighbours read by the product rule are inside Q_5. The constant mode is killed by D, so $D(\psi B) = DG_hL_h(\psi B)$. The order-minus-one bound in eq. 3.dclxxx proves

$$\|DB\|_{\infty,Q_2} \le C(\kappa + j). \tag{3.dccx}$$

The margin between Q_2 and Q_3 contains every difference stencil even at $h = 1$. This is the step that obtains a bounded first derivative. It uses the current to control a Laplacian in L^{16}, then an order-minus-one kernel. It is not an endpoint consequence of $F \in L^\infty$ alone.

Use the exact equation eq. 3.dccii again, now pointwise on Q_1. If $h \le 1/1024$, the same estimate holds on $Q_{3/2}$: every first-difference base point read by eq. 3.dcciii then lies in Q_2. Equations eq. 3.dccvii, eq. 3.dccx, and eq. 3.dcciv give

$$\|L_h B\|_\infty \le C(j + \kappa(\kappa + j) + h^3\kappa^3) \le C(j + \kappa^2). \tag{3.dccxi}$$

Decrease ε_* once to absorb the harmless factor $1 + C\kappa$ into the constant multiplying j.

When $h \le 1/1024$, apply the mesh-uniform interior Hölder estimate of § 3.15 to the ordinary componentwise Laplacian, using eq. 3.dccvii and eq. 3.dccxi on $Q_{3/2}$. It yields $[DB]_{\alpha,Q_1} \le C_\alpha(\kappa+j)$. If its fixed interior radius is less than $64h$, then h has a fixed positive lower bound. In that finite coarse-mesh range, $|DB(x) - DB(y)| \le 2\|DB\|_\infty$ and $|x - y| \ge h$ prove the same Hölder bound directly from eq. 3.dccx.

The combined gauge is $g = e^{i\lambda}g_0$ on the original cube. It is real and its transformed links agree with e^{ihB} on the inner region. Undo eq. 3.dclxxviii. This gives every power of r in eq. 3.dclxxvi and eq. 3.dclxxvii. □

The smallness constant is chosen in a definite order: first fix the matrix logarithm polydisc and the side-32 torus; then the finite constants in Lem. 3.42 for $p = 8, 16$; then the contraction ball in eq. 3.dcxcvii; finally choose ε_* below the finitely many branch and absorption ceilings in the proof. None of these choices depends on the mesh, the value of j, or the connection outside the original cube.

3.16.7. *Comparison with the background regularity hypotheses.*

Corollary 3.47 (Local-scale regularity)**.** Suppose a cube of radius $8m\xi$ lies inside the action region, including every plaquette used by the current, and

$$\|F\|_\infty \le \alpha\xi^{-2}, \qquad \|J_A(U)\|_\infty \le \alpha\xi^{-3}, \qquad m^2\alpha \le \varepsilon_*. \tag{3.dccxii}$$

Here $m \ge 1$, $m\xi/\eta \in \mathbb{N}$, and $0 < \eta \le \xi$. There is a local gauge on the inner cube for which

$$\begin{aligned} \xi\|A\|_\infty &\le Cm\alpha, \\ \xi^2\|DA\|_\infty &\le C(1+m)\alpha, \\ \xi^3\|L_\eta A\|_\infty &\le C(\alpha + m\alpha^2), \\ \xi^{2+\beta}[DA]_\beta &\le C_\beta m^{-\beta}(1+m)\alpha \quad (0<\beta<1). \end{aligned} \tag{3.dccxiii}$$

■□

Proof. Use Prop. 3.41 with $r = m\xi$, $\kappa = \alpha\xi^{-2}$ and $j = \alpha\xi^{-3}$, then substitute. The first-order bounds are linear in m. The hypothesis $m^2\alpha \le \varepsilon_*$ is a cost of this proof and is retained. □

The corollary supplies the potential, gradient and Laplacian premises needed for the local Hölder deduction. It applies to the physical Wilson current. A separately prescribed auxiliary current satisfying a numerical bound cannot replace $J_A(U)$ in eq. 3.dccxii. At a boundary where some plaquettes of the bond stencil are absent, the exact equation has different terms; the statement above does not remove that boundary problem.

The connection may already have a block-axial or a Landau representative required by its global construction. The local gauge just constructed is an additional frame in which to estimate that connection. Passing a non-covariant gauge functional to this frame requires its own exact transformation law. In particular, the absolute soft contour gauge is only invariant under block-constant gauges. The present g is not claimed to be block constant.

3.16.8. *The coupled inverse and its analytic inputs.* For the actual constrained action, the field operator on its fixed slice is the Lagrangian Hessian

$$K_{\mathrm{L}} = F''(A) - D^2\langle\omega, q(A)\rangle, \qquad \mathcal{S} = \begin{pmatrix} K_{\mathrm{L}} & -q'(A)^\sharp \\ q'(A) & 0 \end{pmatrix}. \tag{3.dccxiv}$$

Here q is the actual nonlinear straightened block constraint, the pairing contains its physical row weights, and ω is the corresponding row multiplier. A uniform bound for $\mathcal{S}^{-1}$ uses the following quantitative ingredients:

(i) a quantitative inverse on the true constrained tangent space, including the boundary and seam conditions;
(ii) a controlled right inverse of the actual nonflat field rows, with their node factors and outward-row correction;
(iii) a relative bound for the constraint-curvature term paired with the actual multiplier, and for every specified independent-current completion;
(iv) the exact comparison of the chosen contour gauge with the gauge block used in the precision;
(v) control of the nonlocal subtraction that replaces the full Feynman term $D_U D_U^\sharp$ by $D_U R D_U^\sharp$.

The local gauge result proves an input to these estimates. Its derivative bounds do not by themselves settle the five requirements. The following single-scale results prove a separate projected-Landau gap and the corresponding real constrained saddle inverse in the homogeneous periodic energy spaces; see Prop. 3.56 and Cor. 3.51. They retain the actual constraint curvature. The proper strong response and its coefficient families on a given admitted reference are constructed in Props. 3.163 and 3.169. The forced trial residual is treated in Prop. 3.120, and Prop. 3.194 produces the required homogeneous trial from coarse curvature. The proper curvature-data construction is proved in

Prop. 3.124, its tower admission in Cors. 3.130 and 3.131, and the response on the full first-order regular-pair domain in Prop. 3.174. The local gauge theorem itself remains an estimate for the given connection.

3.17. **The Landau precision on one physical block scale.** The full Feynman form controls every component of the divergence. The background precision retains only its projection by R. Subtracting the omitted component is therefore a substantive step. We first prove a gap for that projected flat form, uniform as the fine mesh tends to zero. We then compare the actual nonflat coefficients with the flat ones in a common small physical gauge. The result includes the nonlinear constraint Hessian and an inverse on the actual simultaneous constraint and Landau slice.

There is one physical block scale throughout this section. All coarse sites have the same assigned level, all rows are present, and the ambient lattice is periodic. Thus there are no outward rows, layer seams or proper-region boundary terms. The assumptions below do not replace those cases by a periodic problem.

3.17.1. *Operators and pairings.* Set the coarse spacing to one and the fine spacing to $h = L^{-k}$, where $L \geq 3$ is a fixed odd integer and $k \geq 0$. The periodic side length is an integer $M \geq 2$. Fine site, bond and plaquette norms use measure h^4; coarse site and bond norms use counting measure, which is their physical volume measure at this scale. The symbol $\sharp$ denotes the transpose for these pairings, and is the Hermitian adjoint when taking norms of real coefficients on their complexification.

At a flat connection choose a parallel frame on the universal cover. The resulting boundary twists are unitary. Write D for the fine gradient, d for its curl and $D^\sharp$ for its divergence adjoint. Let q be the arithmetic average on each centered fine block, and let Q be the physical straight bond derivative:

$$(q\lambda)(y) = h^4 \sum_{x \in B(y)} \lambda(x), \qquad (Qv)_\mu(y) = h^5 \sum_{x \in B(y)} \sum_{t=0}^{h^{-1}-1} v_\mu(x + the_\mu). \tag{3.dccxv}$$

These are the flat derivatives of the actual site and straightened field maps. Telescoping proves the exact identity

$$QD = \mathrm{d}_c q, \tag{3.dccxvi}$$

where d_c is the gradient with unit coarse step. In particular the site map in this identity is an average, not evaluation at the block center.

Put

$$L = D^\sharp D, \quad G = (L + q^\sharp q)^{-1}, \quad F = Gq^\sharp, \quad \mathcal{M} = F^\sharp F, \quad R = 1 - F\mathcal{M}^{-1}F^\sharp. \tag{3.dccxvii}$$

The positive coefficient multiplying $q^\sharp q$ can be changed without changing the range of F, hence without changing R. Indeed, for any $z \in \ker q$, $GLz = z$. Consequently

$$\operatorname{ran} R = L(\ker q), \qquad qGR = 0, \qquad LGR = R. \tag{3.dccxviii}$$

For the first assertion, $F^\sharp Lz = qz = 0$. Conversely, if $F^\sharp f = 0$, then $z = Gf$ satisfies $qz = 0$ and $Lz = f$. The other two identities follow from the same calculation.

The omitted projector is not $q^\sharp q$. The factor G in eq. 3.dccxvii is important. It makes R the projection onto $L(\ker q)$, rather than onto $\ker q$.

3.17.2. *A gap for the flat projected form.*

Proposition 3.48 (A flat Landau gap uniform in the fine mesh)**.** There is a constant $c_0 > 0$, independent of k, M and the real flat holonomies, such that

$$\|\mathrm{d}v\|_2^2 + \|RD^\sharp v\|_2^2 + \|Qv\|_2^2 \geq c_0(\|Dv\|_2^2 + \|v\|_2^2). \tag{3.dccxix}$$

Here Dv denotes all componentwise fine first differences. The assertion holds for the three real colour components and for their complexification. ■

Proof. We include the fine-mesh limiting argument. It avoids substituting a fixed-L estimate for a bound uniform in L^k.

Translation by one coarse unit commutes with all the flat operators. Bloch decomposition reduces the problem to one coarse block with quasiperiodic phase $\theta \in [-\pi, \pi]^4$. It is enough to prove one bound for every such phase. The allowed phases of any finite periodic torus form a subset. A flat adjoint holonomy merely shifts these phases after simultaneous diagonalization of its commuting unitary translations. It therefore suffices to treat one complex colour component.

On a Bloch block the coarse site space has dimension one. The site inequality from the block variance proof gives

$$\|u\|_2^2 \le C(\|Du\|_2^2 + |qu|^2), \tag{3.dccxx}$$

uniformly in h and θ: it uses only internal edges of the block, so no boundary phase enters its constant. Hence $\|G\| \le C$, $\|F\| \le C$ and $\|DF\| \le C$. Also $\|F\| \ge c > 0$ uniformly. To verify the last assertion, choose a fixed smooth function φ supported strictly inside the cell and of integral one. For all sufficiently fine meshes its sample has $|q\varphi| \ge 1/2$ and $\|(L + q^\sharp q)\varphi\|_2 \le C$. Then

$$\tfrac{1}{2} \le |q\varphi| = |\langle F, (L + q^\sharp q)\varphi\rangle| \le C\|F\|_2.$$

For the finitely many remaining values of $h = L^{-k}$, $L + q^\sharp q$ has operator norm at most $16h^{-2} + 1$ and $\|q^\sharp 1\| = 1$, which gives the same conclusion with a fixed smaller constant. The argument is uniform in θ.

Write $P = 1 - R$. Since P has range spanned by F, summation by parts gives

$$\|PD^\sharp v\|_2 = \frac{|\langle F, D^\sharp v\rangle|}{\|F\|_2} \le \frac{\|DF\|_2}{\|F\|_2}\|v\|_2 \le C\|v\|_2. \tag{3.dccxxi}$$

The exact flat Hodge identity thus yields the uniform Gårding inequality

$$\|Dv\|_2^2 \le \|\mathrm{d}v\|_2^2 + \|RD^\sharp v\|_2^2 + C\|v\|_2^2. \tag{3.dccxxii}$$

There is no fine-spacing loss in eq. 3.dccxxi; the derivative falls on the smoothed column F, not on an arbitrary bounded site function.

Suppose there were no uniform mass gap. Choose Bloch data with $\|v_n\|_2 = 1$ and with the left side of eq. 3.dccxix tending to zero. Pass to a subsequence with $\theta_n \to \theta$. If the corresponding integers h_n^{-1} remain bounded, all the matrices vary continuously in a fixed finite-dimensional space. A zero-energy limit would then contradict the kernel calculation below, applied on that finite lattice. We may therefore assume $h_n \to 0$.

Inequality eq. 3.dccxxii bounds every first difference. Here is a useful precise compactness realization. Interpolate a Bloch grid function by its trigonometric polynomial with frequencies $\theta_n + 2\pi\ell$ in the Brillouin cube. Parseval gives the same L^2 norm, and $4h_n^{-2}\sin^2(h_n k_\mu/2) \ge c|k_\mu|^2$ gives a uniform continuum H^1 bound. After multiplication by $e^{-i\theta_n x}$ these are periodic H^1 functions on a fixed cell. Rellich compactness gives strong L^2 convergence of a subsequence. The piecewise constant interpolation has the same limit. Indeed discrete orthogonality gives, for $|z| \le Ch_n$,

$$h_n^4 \sum_x |u^{\mathrm{trig}}(x + z) - u^{\mathrm{trig}}(x)|^2 \le |z|^2 \|\nabla u^{\mathrm{trig}}\|_2^2.$$

Integrating z over one fine cell shows that its L^2 difference from the piecewise constant interpolation is at most $Ch_n\|Du\|_2$. The limiting field v consequently has norm one and lies in the quasiperiodic H^1 space.

Ordinary differences converge weakly to the continuum differences, as is seen first on a fixed finite set of Fourier modes and then by their uniform L^2 bound. Thus $\mathrm{d}v = 0$. The site averages

converge to integration over the cell. The straight rows converge to

$$(Q_\theta v)_\mu = \int_B \int_0^1 v_\mu(x + te_\mu)\, dt\, dx. \tag{3.dccxxiii}$$

To check this convergence, rewrite the discrete row as $h_n \sum_t qT_{th_n} v_n$ on piecewise constant fields. Replacing th_n by t changes the result by at most $Ch_n \|Dv_n\|_2$, using the translation estimate just proved. Strong L^2 convergence handles the remaining integral. It follows that $Q_\theta v = 0$.

The smoothed columns F_n converge strongly as well. The equation $(L_n + q_n^\sharp q_n)F_n = q_n^\sharp 1$, its uniform energy bound, and the same compactness give a strong L^2 limit F_θ. Testing against sampled smooth Bloch functions identifies its equation

$$\langle \nabla\phi, \nabla F_\theta \rangle + \overline{q_\theta \phi}\, q_\theta F_\theta = \overline{q_\theta \phi}. \tag{3.dccxxiv}$$

The continuum block Poincaré inequality proves uniqueness. The uniform lower bound on $\|F_n\|$ passes to the limit. Therefore their rank-one orthogonal projections converge in operator norm under these interpolations. Since $D^\sharp v_n$ is weakly bounded and $R_n D^\sharp v_n \to 0$, we obtain $R_\theta \nabla^\sharp v = 0$. The continuum projector satisfies the same range identity as eq. 3.dccxviii; its proof uses the continuum resolvent and is unchanged.

We finish by identifying the zero kernel, both in the continuum and on each fixed mesh. Fourier decomposition of a curl-free Bloch field gives $v = D\lambda$ unless $\theta = 0$, in which case $v = D\lambda + c$ with c a constant vector. In the continuum D means ∇ and $\lambda \in H^2$; on a fixed mesh this is the same finite Fourier calculation. For each nonzero frequency the curl condition says that its vector coefficient is a scalar multiple of the gradient symbol. The only zero gradient symbol is the constant mode at $\theta = 0$.

At $\theta = 0$ the row of a constant vector is that vector, while $QD\lambda = \mathrm{d}_c q\lambda = 0$. Hence $Qv = 0$ forces $c = 0$. At $\theta \neq 0$, some component of d_c is nonzero, so $QD\lambda = 0$ forces $q\lambda = 0$. At $\theta = 0$ we obtain the same normalization by subtracting a scalar constant from λ. Now $D^\sharp v = L\lambda$ belongs to $L(\ker q)$, and eq. 3.dccxviii gives

$$0 = RD^\sharp v = L\lambda, \qquad D\lambda = 0.$$

Thus $v = 0$, contradicting its unit norm. This proves a uniform mass gap. Combine that gap with eq. 3.dccxxii to obtain the full estimate eq. 3.dccxix. □

The compactness proof determines a positive constant for the fixed four-dimensional cell geometry. It gives no claimed numerical optimal value. Its quantifiers include all k and every Bloch phase, hence every compatible periodic volume and flat holonomy.

3.17.3. *Actual nonflat coefficients in a common gauge.* For a real connection U, let D_U be its covariant site gradient. Let q_U be the actual hierarchical site average on each assigned pillar and let Q_U be the derivative of the actual straightened nonlinear field constraint $\mathcal{Q}_U$. These are the operators whose coefficients were obtained from the finite recursion in § 3.13. In particular

$$Q_U D_U = d_{\mathcal{M}^k U} q_U. \tag{3.dccxxv}$$

The derivative of the plain nonlinear average has a different site readout and is not substituted here. Define

$$G_U = (D_U^\sharp D_U + q_U^\sharp q_U)^{-1}, \quad F_U = G_U q_U^\sharp, \quad R_U = 1 - F_U (F_U^\sharp F_U)^{-1} F_U^\sharp. \tag{3.dccxxvi}$$

These are the actual site resolvent and Landau projector, with the physical pairings already declared.

Lemma 3.49 (Comparison of the actual rows and projector)**.** Let V be real and flat, and suppose in a common parallel frame

$$U_b = e^{iha_b} V_b, \qquad \|a\|_\infty \leq \delta. \tag{3.dccxxvii}$$

For a fixed sufficiently small $\delta_L > 0$, the actual regular mean branches are admitted. Uniformly in k and M,

$$\begin{aligned} \|D_U - D_V\|_{2\to 2} &\le C\delta, \\ \|q_U - q_V\|_{2\to 2} + \|Q_U - Q_V\|_{2\to 2} &\le C_L\delta, \\ \|R_U - R_V\|_{2\to 2} &\le C_L\delta, \\ \|(R_U D_U^\sharp - R_V D_V^\sharp)v\|_2 &\le C_L\delta(\|D_V v\|_2 + \|v\|_2). \end{aligned} \tag{3.dccxxviii}$$

There is also a right inverse E_U of Q_U with

$$\|E_U b\|_2 + \|\nabla_U E_U b\|_2 \le C_L\|b\|_2, \qquad \sup_c \sum_{b \text{ fine}} h^4 |E_U(b,c)| \le C_L. \tag{3.dccxxix}$$

■

Proof. The first comparison follows from $\|\mathrm{Ad}(e^{iha}) - 1\| \le Ch\delta$. The actual internal path transports over physical length at most one differ from those at V by $C_L\delta$ in this frame. For hierarchical transports, the perturbation at intermediate physical scale ξ_s is at most $C_L\delta\xi_s$, and $\sum_{s<k}\xi_s \le 1/(L-1)$. The site-row comparison follows by averaging their transported coefficients.

For the field rows use the actual finite analytic recursion and its row and column estimates in § 3.13. Its one-step relative error at scale s is $C_L\delta\xi_s$; their geometric sum is bounded by $C_L\delta$. This bounds both Schur sums for the declared physical measures by that amount; the fine column density retains its factor h^4. Schur's test gives the second line of eq. 3.dccxxviii. This is the row comparison for Q_U, including the differentiated straightening factors. It is not an infinity-norm estimate for a transported straight main term in place of Q_U.

The flat site gap and the first two comparisons make $D_U^\sharp D_U + q_U^\sharp q_U$ coercive on the physical site H^1 space, uniformly in volume. Its form differs from the flat form by at most $C_L\delta$ times the two H^1 norms. The resolvent identity in the H^1–H^{-1} pairings gives

$$\|G_U - G_V\|_{L^2\to H^1} \le C_L\delta, \qquad \|F_U - F_V\|_{2\to H^1} \le C_L\delta.$$

The flat Gram lower bound used in the Bloch proof, or equivalently the normalized site Gram estimate already proved for the actual pillars, implies $F_V^\sharp F_V \ge cI$. Hence its inverse and the inverse at U are uniformly bounded, and their difference is $O_L(\delta)$. Substitute these facts in eq. 3.dccxxvi. This proves the projector comparison. Its last stated line now follows by inserting and subtracting $R_U D_V^\sharp v$. It loses no factor h^{-1} because the remaining divergence is measured by the physical first-difference norm of v.

For the right inverse, use the compact signed two-moment row seeds of § 3.13. At one assigned scale their sum E^0 satisfies $Q_V E^0 = 1$ exactly. Every column is supported inside a physical block, has bounded amplitude and bounded first differences, and has physical L^1 norm at most a fixed constant. Their supports and gradient collars have bounded overlap. The field-row comparison therefore gives

$$S_U = Q_U E^0 = 1 + B_U, \qquad \|B_U\|_{\ell^1\to\ell^1} + \|B_U\|_{\ell^\infty\to\ell^\infty} \le C_L\delta.$$

Reduce δ_L so each norm is less than $1/2$. Then $E_U = E^0 S_U^{-1}$ is an exact right inverse. The Neumann series is bounded in both coarse Schur norms. The seed energy and column L^1 bounds prove eq. 3.dccxxix. The finitely many small block sizes, including a bare identity row, have the explicit finite seed inverses given in that construction. All constants are therefore independent of k. □

3.17.4. *The physical constraint curvature and the full form.* For a row multiplier ω, pair the Hessian of the actual per-length nonlinear constraint with the physical coarse measure:

$$B_\omega(v,w) = \sum_c \langle \omega(c), D^2\mathcal{Q}_{U,c}(0)[v,w]\rangle. \tag{3.dccxxx}$$

The two-leg coefficient moment of the actual recursion gives

$$|B_\omega(v,w)| \le C_L\|\omega\|_\infty\|v\|_2\|w\|_2. \tag{3.dccxxxi}$$

This is eq. 3.dciii at physical scale one. No Gaussian sample is required to lie in a holomorphic chart: the estimate is a bound on the resulting finite bilinear coefficient matrix.

Let a now denote a fixed positive row weight, with $0 < a_* \le a(c) \le a^* < \infty$. It is unrelated to the potential a_b in eq. 3.dccxxvii. Define the real form

$$\begin{aligned}\mathcal{K}_{U,\omega}(v,w) = D^2A_W(U)[v,w] - B_\omega(v,w)\\ + \langle R_U D_U^\sharp v, R_U D_U^\sharp w\rangle + \langle Q_U v, aQ_U w\rangle.\end{aligned} \tag{3.dccxxxii}$$

The action derivatives use physical left variations $e^{ihtv}U$. Thus the action Hessian has its physical L^2 normalization; no unscaled bond Hessian is inserted in this formula.

Proposition 3.50 (Uniform nonflat precision in a common small gauge)**.** Fix L, a_*, a^*. There are $\varepsilon_L > 0$ and $c_L, C_L > 0$ independent of k, M and the flat holonomies such that the following holds. Suppose eq. 3.dccxxvii holds relative to a real flat connection V,

$$\|F(U)\|_\infty \le \kappa, \qquad \|\omega\|_\infty \le \gamma, \qquad \delta + \kappa + \gamma \le \varepsilon_L. \tag{3.dccxxxiii}$$

Then, with $\|v\|_X^2 = \|\nabla_U v\|_2^2 + \|v\|_2^2$,

$$c_L\|v\|_X^2 \le \mathcal{K}_{U,\omega}(v,v) \le C_L\|v\|_X^2. \tag{3.dccxxxiv}$$

Consequently its full penalized inverse has $L^2 \to L^2$ norm at most c_L^{-1} and $X^* \to X$ norm at most c_L^{-1}.

If U is a critical point of the actual constrained action and its full physical stationarity equation is $J_A(U) = Q_U^\sharp\omega$, then

$$\|\omega\|_\infty \le C_L\|J_A(U)\|_\infty. \tag{3.dccxxxv}$$

Thus a sufficiently small bound on this actual current supplies the multiplier hypothesis. Criticality and that full stationarity identity are hypotheses, not conclusions of the coercivity estimate. ■

Proof. Apply Prop. 3.48, with the positive lower row weight, to the flat reference. It controls both the flat component gradient and the physical mass norm. The two gradient norms at U and V are equivalent for small δ by Lem. 3.49.

For the Wilson term use the exact plaquette Hessian and its curl comparison from § 3.13. In the common frame its linearized plaquette curl differs from the flat curl by at most $C\delta\|v\|_2$. Its remainder is bounded by $C\kappa\|v\|_2\|w\|_2$, since the two insertions contribute h^2, the plaquette defect contributes κh^2, and their product is the physical measure h^4. Thus

$$\left|D^2A_W(U)[v,w] - \langle \mathrm{d}_V v, \mathrm{d}_V w\rangle\right| \le C(\delta+\kappa)\|v\|_{X_V}\|w\|_{X_V}. \tag{3.dccxxxvi}$$

The gauge and row comparisons in eq. 3.dccxxviii, followed by expansion of the two squares, bound their form differences by $C_L\delta\|v\|_{X_V}\|w\|_{X_V}$. Equation eq. 3.dccxxxi bounds the actual constraint curvature by $C_L\gamma$ times these norms. Choose ε_L so the total relative error is below one half of the flat lower constant. This proves both inequalities in eq. 3.dccxxxiv. The inverse estimates are the ordinary finite-dimensional energy estimates in the stated physical norms.

Finally apply the exact right inverse in Lem. 3.49 to the full stationarity equation: $\omega = E_U^\sharp J_A(U)$. The last bound in eq. 3.dccxxix, with fine measure h^4 and unit coarse measure, proves eq. 3.dccxxxv. There is no factor h^{-4} in that readout. □

This proves positivity of a form with the actual projected gauge. It does not infer that positivity by monotonicity from the Feynman form. The flat projected gap was proved separately, before the nonflat perturbation was made.

3.17.5. *The actual constraint and Landau slice.* The positive extension in eq. 3.dccxxxii gives an inverse for the actual constrained Hessian as well. Let

$$X_L = \{v : R_U D_U^\sharp v = 0\}, \qquad X_0 = X_L \cap \ker Q_U, \qquad K_L = D^2 A_W(U) - B_\omega. \tag{3.dccxxxvii}$$

Give both subspaces the covariant X norm. On X_0 the two penalty terms vanish exactly, so $K_L(v,v) \geq c_L \|v\|_X^2$.

Corollary 3.51 (A uniform saddle inverse on the actual slice)**.** Under the assumptions of Prop. 3.50, the equations

$$K_L u - Q_U^\sharp \mu = f \quad \text{on } X_L, \qquad Q_U u = b \tag{3.dccxxxviii}$$

have a unique solution $u \in X_L$, μ in the actual coarse field-row space, and

$$\|u\|_X + \|\mu\|_2 \leq C_L(\|f\|_{X_L^*} + \|b\|_2). \tag{3.dccxxxix}$$

The constant is independent of fine spacing and compatible volume. ■□

Proof. First construct a bounded right inverse taking values in X_L. The exact site range identities in eq. 3.dccxviii also hold at U. Thus

$$S_U = 1 - D_U G_U R_U D_U^\sharp, \quad S_U X \subset X_L, \quad Q_U S_U = Q_U. \tag{3.dccxl}$$

The last identity uses eq. 3.dccxxv and $q_U G_U R_U = 0$.

We verify the energy bound, rather than treating $D_U^\sharp$ as a bounded operator on bare L^2. For $\lambda = G_U R_U D_U^\sharp v$, the range identity gives $q_U \lambda = 0$ and $D_U^\sharp D_U \lambda = R_U D_U^\sharp v$. The site gap gives $\|\lambda\|_2 + \|D_U\lambda\|_2 \leq C_L \|v\|_X$. The covariant Hodge identity applied to $D_U\lambda$ yields

$$\|\nabla_U D_U \lambda\|_2 \leq C_L(\|D_U^\sharp D_U \lambda\|_2 + \kappa\|\lambda\|_2 + \sqrt{\kappa}\|D_U\lambda\|_2).$$

Indeed the covariant curl of $D_U\lambda$ is a shift commutator bounded by $C\kappa\|\lambda\|_2$, and the Hodge remainder is $C\kappa\|D_U\lambda\|_2^2$. These are precisely the complete periodic plaquette stencils, so there is no boundary term. This proves $\|S_U v\|_X \leq C_L\|v\|_X$. Therefore $E_L = S_U E_U$ is a bounded right inverse of Q_U into X_L.

Write $u = E_L b + z$, $z \in X_0$. The coercive equation

$$K_L(z,w) = f(w) - K_L(E_L b, w) \quad (w \in X_0)$$

has a unique solution and bounds $\|z\|_X$ by $C_L(\|f\|_{X_L^*} + \|b\|_2)$. Define the row vector μ by $\langle \mu, b' \rangle = (K_L u - f)(E_L b')$ for every row vector b'; abbreviate this as $\mu = E_L^\sharp(K_L u - f)$. The functional $K_L u - f$ annihilates X_0, and every $w \in X_L$ decomposes as $w - E_L Q_U w + E_L Q_U w$. Hence it equals $Q_U^\sharp \mu$ on X_L, proving eq. 3.dccxxxviii. The boundedness of K_L and E_L proves the multiplier estimate. The same kernel coercivity and the surjectivity of $Q_U|_{X_L}$ give uniqueness. □

3.17.6. *Complex perturbations and localization.* On a physical first-order complex ball about the real reference, the already established coefficient estimates for the actual means, site resolvent and Gram projector give a form perturbation of size $C_L s$, where

$$\|E\|_\infty + \|\nabla_U E\|_\infty + \|\zeta\|_\infty \leq s, \qquad U_E = e^{ihE} U, \quad \omega_E = \omega + \zeta. \tag{3.dccxli}$$

The first derivative of E controls the complex plaquette change; its presence cannot be replaced by a fixed unscaled bond radius. For s smaller than a fixed fraction of the real lower constant, the full penalized inverse exists holomorphically by the normalized Neumann series. This statement uses analytic bilinear transposes for the continued coefficients; it asserts no Hermitian positivity at a complex field. A constrained inverse on a moving complex slice additionally requires a uniformly bounded holomorphic identification of that slice. Only the real-slice saddle estimate and the full penalized complex inverse are asserted here.

The common-gauge assumption in eq. 3.dccxxvii has global scope. The local gauge construction supplies it on bounded patches. The following localization argument combines those frames without

requiring one global small gauge; Prop. 3.56 proves the real curvature-small homogeneous periodic case.

To patch the estimates, one needs an operator comparison for the nonlocal R_U. For a scalar partition function χ, its gauge term contains

$$R_U D_U^\sharp(\chi v) - \chi R_U D_U^\sharp v = R_U[D_U^\sharp, \chi]v + [R_U, \chi]D_U^\sharp v. \tag{3.dccxlii}$$

An L^2 bound for $[R_U, \chi]$ alone leaves a fine derivative on v. The required composed bound and the sharper quadratic IMS estimate are proved in Lem. 3.54 using the smoothed projector's physical cell operators. The comparison between the global site inverse and the periodic extension is proved in Lem. 3.55. Both arguments use the exact actual site rows and Gram matrix, independently of the fine vector inverse.

Together these results close a real nonflat periodic one-scale energy inverse with the actual nonlinear constraint curvature. Different assigned scales, proper-region boundary forms, a moving complex slice and the independent-current completion remain distinct tasks. The equality with a separately specified absolute contour precision and the stronger pointwise response norms also require their own estimates.

3.18. **Localization of the one-scale Landau precision.** The common-gauge theorem leaves a nonlocal comparison: a local frame does not change the global projector into a projector computed on that patch. We prove the comparison using only the site inverse and its Gram matrix. The proof uses physical L^2 operators between unit cells. It requires neither pointwise mixed-derivative estimates nor a fine vector inverse as an input.

We retain the periodic, single-assigned-scale setting of § 3.17. The coarse spacing is one, the fine spacing is $h = L^{-k}$, and every site and field row is present. All constants below can depend on L and on the fixed upper and lower row weights, but not on h or the compatible periodic volume. The real curvature ceiling is fixed below the one for the actual site gap and normalized Gram gap already proved in § 3.13.

3.18.1. *Derivative bounds for the smoothed projector.* Let B_y be the fine cell belonging to coarse site y. A fine bond is assigned to the cell of its initial site. Distances between cells are physical coarse lattice distances, denoted by $d(y, z)$. Write

$$A_s = D_U^\sharp D_U + q_U^\sharp q_U, \quad G = A_s^{-1}, \quad F = G q_U^\sharp, \quad \mathcal{M} = F^\sharp F, \quad P = F\mathcal{M}^{-1}F^\sharp = 1 - R. \tag{3.dccxliii}$$

Here the q_U and all transports are the actual ones. In this homogeneous setting the site gap and Gram gap read

$$\langle u, A_s u\rangle \geq \beta\|u\|_2^2, \qquad m_0 I \leq \mathcal{M} \leq m_1 I, \tag{3.dccxliv}$$

with fixed positive constants. The first bound is the current-free site gap. We justify the second bound here without importing a site lift that requires differentiated background regularity.

Lemma 3.52 (A current-free energy lift and Gram lower bound)**.** At a fixed sufficiently small real curvature ceiling there is a right inverse E of the actual site average with

$$q_U E = 1, \qquad \|Eb\|_{A_s}^2 := \|D_U Eb\|_2^2 + \|q_U Eb\|_2^2 \leq C_E^2\|b\|_2^2. \tag{3.dccxlv}$$

It follows that the actual Gram matrix satisfies

$$C_E^{-4} I \leq F^\sharp F \leq \beta^{-2} I. \tag{3.dccxlvi}$$

No bound on the physical current or on a derivative of a local potential is used. ■

Proof. The site rows use disjoint pillars. Since each coefficient is a unitary adjoint transport with averaging weight h^4, their physical transpose obeys $q_U q_U^\sharp = 1$. Thus $\|q_U\| = \|q_U^\sharp\| = 1$.

First work on a periodic volume large enough to embed the fixed surrounding cubes used below. For each unit pillar choose a real comb frame on such a cube. Its potential has supremum at most $C_L\kappa$, using curvature only. In this frame every actual hierarchical internal transport differs

from one by $C_L\kappa$: the admitted intermediate open transports have size $C_L\kappa\xi_s$, and the physical scales obey $\sum_{s<k}\xi_s \le 1/(L-1)$. This is the current-free pillar transport estimate. It does not differentiate that potential.

Choose one fixed nonnegative smooth scalar bump ϕ supported strictly inside the centered unit cell, with $\phi(0) > 0$. Its sampled mean $m_h = h^4\sum_x \phi(x)$ has a uniform positive lower bound for $h = L^{-k}$. For fine meshes this follows from its positive integral; the finitely many larger meshes contain the center site and have a positive mean as well. Its physical L^2 norm and the physical L^2 norm of its first differences are uniformly bounded, by the smooth bounds and the fixed support.

On the pillar at y put $u^{(y)}(x) = \phi(x-y)\psi_y$ in this local frame and zero outside. The actual site readout there is $N_y\psi_y$, where $\|N_y - m_hI\| \le C_L\kappa m_h$. Decrease the curvature ceiling so that N_y is invertible with $\|N_y^{-1}\| \le 2/m_h$. Choose ψ_y to give the prescribed b_y, including the unitary coarse-frame rotation. No other site row sees this bump, so the sum of these fields is an exact right inverse E.

The first-difference product rule in its local frame gives

$$\|D_U u^{(y)}\|_2 \le C\big(\|D\phi\|_2 + \kappa\|\phi\|_2\big)|\psi_y|.$$

Only the potential's supremum enters. The first-difference collars of the bumps have bounded overlap, including the finitely coarse meshes. Sum over pillars and use $q_U E b = b$ to obtain eq. 3.dccxlv.

For a smaller torus perform this construction on a sufficiently large finite periodic cover. Average the resulting right inverse over the finite deck group, acting simultaneously on its fine output and coarse input. Every conjugate remains a right inverse and has the same energy bound, since the pulled-back coefficients commute with those unitary deck translations. Their average has the same bound and preserves the deck-invariant subspaces. It therefore descends to an exact right inverse on the original torus. Its squared input and output norms acquire the same number of sheets, so the constant in eq. 3.dccxlv is unchanged. This proves the energy lift even when a surrounding comb cube does not embed in the original small torus.

Finally $A_sFb = q_U^\sharp b$, and hence

$$\|b\|_2^2 = \langle A_sFb, Eb\rangle \le C_E\|Fb\|_{A_s}\|b\|_2, \qquad \|Fb\|_{A_s}^2 = \langle q_U^\sharp b, Fb\rangle \le \|b\|_2\|Fb\|_2.$$

For $b \neq 0$ these imply $\|Fb\|_2 \ge C_E^{-2}\|b\|_2$. The upper bound follows from $\|G\| \le \beta^{-1}$ and $\|q_U^\sharp\| = 1$. This proves eq. 3.dccxlvi. □

Lemma 3.53 (Exponential cell bounds with one derivative)**.** There are positive constants s_0 and C with the following property. The operators F, D_UF and $\mathcal{M}^{-1}$ have exponentially decreasing cell L^2 operator entries. In particular

$$\begin{aligned} T &= PD_U^\sharp = F\mathcal{M}^{-1}(D_UF)^\sharp, \\ K_s &= D_UPD_U^\sharp = (D_UF)\mathcal{M}^{-1}(D_UF)^\sharp \end{aligned} \tag{3.dccxlvii}$$

are bounded on their physical L^2 spaces, with

$$\|1_{B_y}T1_{B_z}\| + \|1_{B_y}K_s1_{B_z}\| \le Ce^{-s_0d(y,z)}. \tag{3.dccxlviii}$$

Every fixed polynomial cell moment of these bounds is finite uniformly in the fine mesh and volume. ■

Proof. Let ψ be bounded and physically one-Lipschitz on fine sites, and give coarse sites the sampled values $\psi(y)$. For $w = e^{s\psi}$, the fine-gradient commutator satisfies

$$\|wD_Uw^{-1} - D_U\|_{2\to2} \le C|s| \qquad (|s| \le 1).$$

The difference of weights across one fine bond is $O(|s|h)$; division by h therefore leaves a physical constant. Similarly $w_fq_U^\sharp w_c^{-1} - q_U^\sharp$ has norm $O_L(|s|)$, since the actual site-row carrier has physical

diameter bounded independently of k, and its physical Schur sums are bounded. Conjugating the site form changes it by at most $C_L|s|$ times the two site H^1 norms.

By eq. 3.dccxliv, for fixed sufficiently small $|s|$ the conjugated inverse is bounded from H^{-1} to H^1. Consequently

$$\|w_f F w_c^{-1}\|_{2\to 2} + \|w_f D_U F w_c^{-1}\|_{2\to 2} \le C_L. \tag{3.dccxlix}$$

For the derivative term, differentiate the weighted output and subtract the first commutator above. Thus only one site energy derivative is used. The same conjugation argument and resolvent identity give $\|w_c \mathcal{M} w_c^{-1} - \mathcal{M}\| \le C_L|s|$. Its inverse is uniformly bounded for smaller $|s|$ by the real Gram lower bound. This is the weighted Gram argument, now keeping the energy derivative in eq. 3.dccxlix.

Insert these weighted bounds in eq. 3.dccxlvii. The adjoint factors use the same bounds with $-\psi$. Choose ψ to be a truncated distance from the input cell; its values differ from cell distance by at most a fixed constant. This gives eq. 3.dccxlviii. Homogeneous four-dimensional cells have at most $C(n+1)^3$ neighbors at distance between n and $n+1$. Summing against the exponential proves every fixed polynomial moment.

All weights can be chosen on the finite periodic lattice. Truncated distance functions have the required physical Lipschitz bounds, independently of its size. □

The derivative in $PD_U^\sharp$ has fallen on the smoothed column F. Its boundedness here is not an order-zero L^∞ projection estimate. All the bounds in the lemma are physical L^2 cell bounds.

3.18.2. *Cutoffs and the nonlocal IMS bound.* Choose a smooth partition $\{\chi_i\}$ on the covering lattice, with supports of radius CR_0, where $R_0 \ge 2$ is an integer. It may be chosen so that

$$\begin{aligned} &\sum_i \chi_i(x)^2 = 1, \qquad \sum_i |D\chi_i(x)|^2 \le C R_0^{-2}, \\ &\sum_i |\chi_i(x) - \chi_i(z)|^2 \le C \min\{1, |x-z|^2/R_0^2\}. \end{aligned} \tag{3.dccl}$$

For instance translate one fixed smooth bump at every integer coarse site, scale its radius by R_0, and divide by the square root of the sum of its squared translates. This sum is comparable with R_0^4. The construction is invariant under integer translations and has the bounds displayed, including

$$\sum_i \sup_{x\in B_y} |\chi_i(x) - \chi_i(y)|^2 \le C R_0^{-2}. \tag{3.dccli}$$

The number of summands can grow with R_0; their squared derivative sum has the stated bound. Cutoffs on fine bonds are sampled at their initial sites.

Lemma 3.54 (A composed commutator and an IMS estimate)**.** For these cutoffs,

$$\sum_i \|[P, \chi_i] D_U^\sharp v\|_2^2 \le C R_0^{-2} \|v\|_2^2. \tag{3.dcclii}$$

The projected gauge form satisfies the sharper quadratic identity with error

$$\left| \sum_i \|R D_U^\sharp(\chi_i v)\|_2^2 - \|R D_U^\sharp v\|_2^2 \right| \le C R_0^{-2} \|v\|_2^2. \tag{3.dccliii}$$

The sums use the corresponding finite periodic cutoff family. ■

Proof. Put $B_i = D_U^\sharp \chi_i - \chi_i D_U^\sharp$, with the site and bond multiplications understood. The local product rule and eq. 3.dccl give $\sum_i \|B_i v\|_2^2 \le C R_0^{-2} \|v\|_2^2$. The exact algebra is

$$[P, \chi_i] D_U^\sharp = [T, \chi_i] - P B_i, \qquad T = P D_U^\sharp. \tag{3.dccliv}$$

To estimate $[T, \chi_i]$, first replace each cutoff on each cell by its center value. The input and output remainders satisfy the vector-valued bound $C R_0^{-1}$ by eq. 3.dccli and the L^2 bound on T.

For the center values, the cell entry of the commutator is $(\chi_i(z)-\chi_i(y))T_{yz}$. Let $t_{yz}=\|T_{yz}\|$ and $\rho_{yz}=1+d(y,z)$. Cauchy–Schwarz with weights $\rho_{yz}t_{yz}$ gives

$$\sum_i \left\| \sum_z (\chi_i(z)-\chi_i(y))T_{yz}v_z \right\|^2 \le \left(\sum_z \rho_{yz}t_{yz}\right)\sum_z \frac{t_{yz}}{\rho_{yz}}\sum_i |\chi_i(z)-\chi_i(y)|^2\|v_z\|^2.$$

Sum over y. The first row moment and first column moment are finite by Lem. 3.53; eq. 3.dccl supplies $C\rho_{yz}^2/R_0^2$. This proves eq. 3.dcclii.

For the quadratic estimate use

$$\|RD_U^\sharp v\|_2^2 = \|D_U^\sharp v\|_2^2 - \langle v, K_s v\rangle. \tag{3.dcclv}$$

The first term is the form of the local operator $D_U D_U^\sharp$. Its double-cutoff identity has error at most $CR_0^{-2}\|v\|_2^2$: its coefficients have range at most $2h$ and size at most Ch^{-2}, while the squared cutoff difference is $O(h^2/R_0^2)$.

We give the double-cutoff estimate for the smoothing term in eq. 3.dcclv, since an operator norm of a commutator alone would not give its quadratic improvement. For a cell entry K_{yz} of K_s, the contribution is

$$\sum_i \chi_i|_{B_y}\, K_{yz}\, \chi_i|_{B_z} - K_{yz}.$$

Write $\chi_i|_{B_y} = c_i(y)+\delta_i^y$, where $c_i(y)=\chi_i(y)$. Use $\sum_i(\chi_i|_{B_y})^2=1$ on each cell to expand it as minus one half of

$$\begin{aligned} &\sum_i (c_i(y)-c_i(z))^2 K_{yz} \\ &+2\sum_i (c_i(y)-c_i(z))(\delta_i^y K_{yz} - K_{yz}\delta_i^z) \\ &+\sum_i ((\delta_i^y)^2 K_{yz} - 2\delta_i^y K_{yz}\delta_i^z + K_{yz}(\delta_i^z)^2). \end{aligned} \tag{3.dcclvi}$$

The first line is bounded by $Cd(y,z)^2R_0^{-2}\|K_{yz}\|$. For the second line use Cauchy–Schwarz in i, eq. 3.dccl and eq. 3.dccli. Its bound is $C(1+d(y,z))R_0^{-2}\|K_{yz}\|$. For the last line use the squared within-cell bounds at both ends. Its bound is $CR_0^{-2}\|K_{yz}\|$. Thus the entry is at most $CR_0^{-2}(1+d(y,z))^2\|K_{yz}\|$ in operator norm. The exponential second moment and Schur's test prove eq. 3.dccliii. □

The same partition gives

$$\left| \sum_i \mathcal{K}_{U,\omega}(\chi_i v, \chi_i v) - \mathcal{K}_{U,\omega}(v,v) \right| \le CR_0^{-2}\|v\|_2^2. \tag{3.dcclvii}$$

Here $\mathcal{K}$ is exactly eq. 3.dccxxxii. For the Wilson Hessian the coefficient matrix has range $O(h)$ and physical size $O(h^{-2})$, so the same local double-cutoff calculation applies. The operator $Q_U^\sharp a Q_U$ has bounded physical Schur sums and bounded physical carrier diameter, by the actual row and column estimates. The actual constraint Hessian has the same properties, with an extra factor $\|\omega\|_\infty$, by its two-leg moment. Their double-cutoff errors are therefore $O(R_0^{-2})$ as well. This proves eq. 3.dcclvii without replacing either row by a straight main term.

3.18.3. *Shielding the projector from the exterior.*

Lemma 3.55 (Local comparison of the actual projector)**.** Consider two real admitted single-scale connections whose operators have the uniform site, Gram and weighted energy bounds above. They may live on different periodic volumes, with the common cubes embedded injectively in both.

Suppose, in common local frames, the connections and their actual site-row carriers agree on Q_{24R}, where R exceeds a fixed carrier-diameter constant. For fine sources supported in Q_{2R},

$$\|1_{Q_{2R}}(R_1 - R_2)1_{Q_{2R}}\|_{2\to 2} \le Ce^{-cR}. \tag{3.dcclviii}$$

The compression is identified by their common fine coordinates. ■

Proof. We separate the fine resolvent and coarse Gram inverse comparisons. All cutoffs below are supported in the common region. Their commutators use only coefficient stencils in that region.

First let f, g be fine sources supported in Q_{10R}. Choose $\theta = 1$ on Q_{12R} and supported in Q_{16R}. The geometric resolvent identity, with the cutoff embedding the two spaces, is

$$\theta G_1 - G_2\theta = G_2(A_{s,2}\theta - \theta A_{s,1})G_1. \tag{3.dcclix}$$

The middle operator is supported in an annulus separated from the source region. Its $H^1 \to H^{-1}$ norm is bounded uniformly: the gradient commutator contains a physical derivative of θ; the site-row commutator has bounded range and physical Schur sums. There is no subtraction of different connection coefficients outside this annulus. The weighted site energy bound makes both resolvent solutions exponentially small in the annulus. Pairing the identity with g proves a compressed resolvent difference Ce^{-cR}. The same energy argument gives its localized one-derivative version. The distances can be decreased by a fixed row-carrier radius without changing this conclusion.

Now put $\Lambda = \{y : B_y \subset Q_{6R}\}$ for coarse nodes. For a node vector supported in Λ, its source $q^\sharp b$ is supported in Q_{7R}, and the two actual $q^\sharp$ agree there. The just-proved comparison controls the difference of the two F outputs in Q_{10R}. Their tails outside Q_{10R} are exponentially small by the weighted F bound. Therefore

$$\|1_\Lambda(\mathcal{M}_1 - \mathcal{M}_2)1_\Lambda\| \le Ce^{-cR}. \tag{3.dcclx}$$

This is an operator bound for arbitrary vectors supported in Λ, not a sum of separate entry errors over its volume.

Each compressed Gram matrix $\mathcal{M}_{j,\Lambda} = 1_\Lambda \mathcal{M}_j 1_\Lambda$ retains the lower bound m_0. Its inverse is bounded by m_0^{-1}, so the resolvent identity bounds the difference of their inverses by Ce^{-cR}. For a node source b supported in Q_{3R}, compare that finite compression inverse with the global inverse. The exact identity is

$$\mathcal{M}_{j,\Lambda}^{-1} b - 1_\Lambda \mathcal{M}_j^{-1} b = \mathcal{M}_{j,\Lambda}^{-1} 1_\Lambda \mathcal{M}_j 1_{\Lambda^c} \mathcal{M}_j^{-1} b. \tag{3.dcclxi}$$

The global inverse has an exponentially small tail on Λ^c, by the weighted Gram estimate. The other two operators on the right are uniformly bounded. It follows that the compressions of $\mathcal{M}_1^{-1}$ and $\mathcal{M}_2^{-1}$ to Q_{3R} differ by Ce^{-cR}.

Finally write $P_j = F_j \mathcal{M}_j^{-1} F_j^\sharp$. If f is supported in Q_{2R}, $F_j^\sharp f$ has an exponentially small tail outside Q_{3R}. Their retained parts differ by Ce^{-cR} from the fine resolvent comparison. Insert these facts and the compressed Gram-inverse comparison into $\langle f, P_j g\rangle$. All uncompressed factors have uniform norms. We obtain eq. 3.dcclviii, since $R_j = 1 - P_j$. □

Only the existing site and Gram estimates entered this comparison. No fine vector Green function or lower bound for the full precision has been used in its proof.

3.18.4. *The nonflat periodic gap from local curvature bounds.*

Proposition 3.56 (A one-scale curvature-small Landau inverse)**.** Fix L and the row bounds a_*, a^*. There are positive constants κ_*, γ_*, c and C, independent of k, periodic volume and real holonomy, with the following property. Let U be real on a compatible periodic fine lattice, with every site and field row at the same assigned physical scale one. Suppose

$$\|F(U)\|_\infty \le \kappa_* \quad \text{and} \quad \|\omega\|_\infty \le \gamma_*. \tag{3.dcclxii}$$

Use the actual straightened nonlinear constraint and actual projected Landau gauge in eq. 3.dcclxxxii. Then

$$c(\|\nabla_U v\|_2^2 + \|v\|_2^2) \le \mathcal{K}_{U,\omega}(v,v) \le C(\|\nabla_U v\|_2^2 + \|v\|_2^2). \tag{3.dcclxiii}$$

The full penalized inverse and the real actual-slice saddle inverse have the uniform physical bounds stated in Prop. 3.50 and Cor. 3.51, with no common global small-gauge assumption. ■

Proof. Choose an integer R large enough for the carrier margins below. It will be fixed before the curvature ceiling is chosen. First assume that the periodic side is at least $512R$. At every coarse center use the local comb gauge and extension construction on a cube of radius $32R$. Apply the scaled version of Lem. 3.45 with its radius parameter $4R$. The resulting auxiliary periodic potential, on a torus of side $128R$, satisfies

$$\|A_i^{\mathrm{ext}}\|_\infty \le CR\kappa, \qquad \|F_i^{\mathrm{ext}}\|_\infty \le C\kappa, \tag{3.dcclxiv}$$

and agrees with the locally gauged original field on Q_{24R}, provided $R^2\kappa$ is sufficiently small. The estimates use curvature only. The current derivative bounds of the Coulomb gauge theorem are not needed for this coercivity step.

All operators in the present precision transform covariantly under this local frame change. For the nonlinear straightened constraint, both its internal means and its endpoint means are bi-equivariant; therefore its output logarithm is conjugated at the coarse initial site. Its first and second derivatives transform accordingly. Transform ω by that same unitary conjugation. The physical pairings and its supremum bound are unchanged. This covariance statement concerns the projected Landau form. It makes no assertion about the separately specified absolute soft contour gauge.

Take the cutoffs in eq. 3.dccl supported in cubes of radius R by a fixed rescaling of their defining bump. For $v_i = \chi_i v$, the full stencil of $D_U^\sharp v_i$ is in Q_{2R}. Extend ω and the row weights to the local torus, keeping their actual values on every row whose carrier meets that support, and keeping $\|\omega\|_\infty \le \gamma$ and $a_* \le a \le a^*$. The Wilson, row-mass and constraint-curvature forms of v_i then agree exactly with those in the local extension. The only difference is the projector.

For a real orthogonal projector, $\|Rf\|^2 = \langle f, Rf\rangle$. Consequently Lem. 3.55, with $f = D_U^\sharp v_i$, gives

$$|\mathcal{K}_U(v_i,v_i) - \mathcal{K}_i^{\mathrm{ext}}(v_i,v_i)| \le Ce^{-cR}\|v_i\|_X^2. \tag{3.dcclxv}$$

The coefficient values outside the common region have not been subtracted in a bare fine operator norm.

Choose γ_* smaller than the multiplier ceiling of Prop. 3.50. Once R is fixed, choose κ_* so that $R^2\kappa_*$ admits eq. 3.dcclxiv and $CR\kappa_* + C\kappa_* + \gamma_*$ is below the common-gauge ceiling in that proposition. Each auxiliary periodic precision then has the same lower constant $c_1 > 0$. It follows that

$$\mathcal{K}_U(v_i,v_i) \ge (c_1 - Ce^{-cR})\|v_i\|_X^2. \tag{3.dcclxvi}$$

The usual covariant gradient double-cutoff calculation also gives

$$\left|\sum_i \|v_i\|_X^2 - \|v\|_X^2\right| \le CR^{-2}\|v\|_2^2. \tag{3.dcclxvii}$$

The covariant shifts are unitary. Their fine denominator cancels the squared cutoff difference just as in the local term of Lem. 3.54. Sum eq. 3.dcclxvi, use eq. 3.dcclvii and eq. 3.dcclxvii, and first choose R so that $Ce^{-cR} \le c_1/4$ and the total CR^{-2} error is at most $c_1/4$. The constants used for these choices are uniform throughout a fixed initial small curvature and multiplier ceiling. The subsequent decrease of κ_*, γ_* does not change them. This proves the lower bound in eq. 3.dcclxiii. The upper bound follows from the local Wilson Hessian bound, $\|RD_U^\sharp v\| \le \|D_U^\sharp v\|$, and the actual row and two-leg Schur bounds.

For a smaller periodic volume, choose an integer t such that its t^4-sheeted periodic cover has side at least $512R$. Pull back the connection, the actual rows and the row multiplier to that finite

cover. The local averaging formulas and covariant differences commute with pullback, including every periodic path multiplicity. The same is true of their physical transposes. The site inverse preserves the deck-invariant subspace and equals the pullback of the smaller site's inverse there, by uniqueness of its gapped equation. The same argument applies successively to F, its Gram matrix and its Gram inverse. Consequently the actual R and the full form descend exactly. For a lifted vector, the full form and its squared X norm both multiply by t^4. Divide the already proved estimate on the cover by that factor. This proves the original finite-volume estimate without selecting a global nearly flat gauge or restricting its torus holonomies.

The actual one-scale row lift is constructed from the same compact two-moment seeds in local unit-cell gauges. The actual row/column comparison makes its coarse error $O_L(\kappa)$ in both Schur norms; its Neumann correction gives the bounds in eq. 3.dccxxix. There are no adjacent-level leakage terms in this homogeneous setting. The gauge-restoration energy argument in Cor. 3.51 uses only the site gap, curvature bound and full periodic covariant Hodge identity. It is therefore valid here as well. Repeating that corollary's kernel coercivity argument proves the actual-slice saddle assertion. □

At a physical critical background whose full stationarity equation is $J_A(U) = Q_U^\sharp \omega$, the column L^1 bound for this actual row lift again gives $\|\omega\|_\infty \le C_L \|J_A(U)\|_\infty$. Thus sufficiently small physical curvature and actual current supply the two numerical ceilings. This does not construct the critical background or infer the equation from criticality on an unidentified slice.

Restoring a common physical coarse spacing ξ replaces the mass norm by $\xi^{-2}\|v\|_2^2$, the curvature ceiling by $\xi^2\|F\|_\infty \le \kappa_*$, and the multiplier ceiling by $\xi^3\|\omega\|_\infty \le \gamma_*$. The full inverse then has $L^2 \to L^2$ norm at most $C\xi^2$. These powers follow from the declared physical pairings and do not depend on the number of fine bonds in a coarse cell.

3.18.5. *The scope of the recovered inverse.* The new conclusion is a real, unweighted Wilson/Lagrangian precision estimate at one assigned physical scale, with its actual straightened field rows and actual projected Landau gauge. The proof of the nonlocal localization used only the separately proved site and Gram package. In particular it does not assume the vector inverse in order to prove that inverse.

Several tasks remain in the general background problem. Different assigned scales change the cell metric and carrier bookkeeping. Proper-region inner-boundary forms have boundary terms in both Hodge and shielding identities. Independent analytic-current completions contain additional specified defects. An identification with the absolute contour precision has its own gauge-restoration terms. None of these is an equality supplied by the periodic one-scale result. The nonlinear trial residual and construction of the many-level critical orbit remain separate from the coercive linear inverse established here.

3.19. **Weighted site inverses on the actual determining region.** The projected gauge removes site directions with zero assigned average. Its inverse must therefore control these directions in the physical units of their own pillars. We prove that control on the actual active graph, including the outer boundary. We also prove a normalized Gram gap from curvature alone. A differentiated local potential and a physical-current bound are not premises of this Gram estimate.

The setting is the separated aligned sequence of § 3.11. The fine spacing is $\eta = L^{-k}$ and the assigned spacings are $\xi_j = L^{j-k}$. The pillars B_y partition Ω_0; write $\xi(x) = \xi_y$ on B_y. Outside Ω_0 put $\xi(x) = \eta$ for geometric purposes only. All operators below act on the original graph of sites and bonds inner to Ω_0. The action still contains precisely its inner plaquettes.

Fine scalar and vector norms use measure η^4. Top norms use the physical measure ξ_y^4, and field-row norms use ξ_c^4. The actual own-pillar site average is denoted by q. Thus q is the transported average in eq. 3.cdlxxx, not an unextended endpoint readout. Its physical transpose satisfies $qq^\sharp = 1$.

Let

$$L_U = D_U^\sharp D_U, \qquad A_s = L_U + q^\sharp a_s q, \qquad a_s(y) = c_y \xi_y^{-2}, \qquad 0 < c_* \le c_y \le c^* < \infty. \quad \text{(3.dcclxviii)}$$

The physical gradient is $D_U\lambda(b) = \eta^{-1}(\lambda(b_-) - \mathrm{Ad}\, U_b \lambda(b_+))$. Adjoints in real positivity statements are the Hilbert adjoints for these physical measures. All the estimates extend to the complexification of the real coefficient spaces.

Assume the actual means are on their regular branches and

$$\left\| \frac{1}{i\eta^2} \log U(\partial p) \right\| \le \kappa\, \mathsf{L}(p)^{-2} \quad (p \subset \Omega_0), \qquad \text{(3.dcclxix)}$$

with a fixed sufficiently small κ. The branch admission and the estimates on the actual pillar transports follow from the current-free comb comparison already proved in § 3.13. Constants below depend only on L, c_*, c^* and fixed geometric collar choices. We specify the additional lower bound on the separation ρ below. There is no dependence on depth, compatible volume or number of components. Enlarge the fixed C_{geom} once so it exceeds four times the chosen comb-cube radius in units of a pillar side.

3.19.1. *A slowly varying length comparable to the assigned scale.* The assigned scale jumps by a factor L at a layer boundary. Differentiating that step function would introduce a fine-mesh loss. We instead use a comparable Lipschitz length.

Lemma 3.57 (A smooth comparison length)**.** For $0 < \delta < 1$, define on the ambient torus

$$\ell(x) = \inf_z \{\xi(z) + \delta\, \mathrm{dist}_\infty(x, z)\}. \qquad \text{(3.dcclxx)}$$

If $\rho\delta \ge 1$, then

$$L^{-1}\xi(x) \le \ell(x) \le \xi(x), \qquad |\ell(x) - \ell(z)| \le \delta\, \mathrm{dist}_\infty(x, z). \qquad \text{(3.dcclxxi)}$$

On the bare layer and outside the active region, $\ell = \eta$. For $w = \ell^{-1}$, neighboring fine sites satisfy

$$|D\ell| \le \delta, \qquad |Dw| \le C\delta\ell^{-2}. \qquad \text{(3.dcclxxii)}$$

The site and bond choices of ℓ are equivalent with absolute constants. The actual bond scale $\mathsf{L}(b)$ is comparable to them with a constant depending only on L. ■

Proof. The upper bound follows by choosing $z = x$. Infima of functions with Lipschitz constant δ have that same Lipschitz bound. Suppose x belongs to layer j. If z has assigned level at least $j-1$, then $\xi(z) \ge \xi_j/L$. If its level is at most $j-2$, it lies outside Ω_{j-1}, whereas $x \in \Omega_j$. Separation gives $\mathrm{dist}_\infty(x, z) > \rho\xi_{j-1}$, so the distance term is at least ξ_j/L. The same argument includes exterior points, assigned the bare scale. For $j = 0$, the global lower bound $\xi(z) \ge \eta$ suffices. This proves the lower bound. At a bare point the lower bound $\ell \ge \eta$ and the upper bound $\ell \le \eta$ coincide.

The inverse-weight estimate follows by subtracting reciprocals. Since $\ell \ge \eta$ and its change over one fine step is at most $\delta\eta$, neighboring values have a fixed ratio. Fine neighbors can have assigned levels differing by at most one: otherwise they would cross the separated intervening layer in physical distance at most η. Thus their assigned scales, and the largest corner scale used on a bond or plaquette, differ by at most a fixed power of L. This proves the last assertion. □

The comparison metric obtained by integrating ds/ℓ is equivalent to the actual layer metric within a factor L. We will choose δ small using fixed block constants, and then choose $\rho \ge \max\{C_{\mathrm{geom}}L, \delta^{-1}\}$. These choices precede the depth and volume.

3.19.2. *Current-free block inequalities and a weighted site lift.* The real block argument gives two useful versions of Poincaré:

$$\begin{aligned}\|\xi^{-1}u\|_2^2 &\le C(\|D_U u\|_2^2 + \|\Xi^{-1}qu\|_{\mathrm{top}}^2),\\ \|u\|_2^2 &\le C(\|\ell D_U u\|_2^2 + \|qu\|_{\mathrm{top}}^2).\end{aligned} \tag{3.dcclxxiii}$$

Here Ξ is multiplication by ξ_y on tops. The first is the actual weighted site gap. For the second multiply each pillar's block inequality by ξ_y^2 before summing, and use Lem. 3.57. Only internal pillar bonds are used in either estimate, so crossing energies have a favorable sign. Both inequalities use curvature and unitarity, not a current. In particular A_s is strictly positive on its finite site space.

Lemma 3.58 (A weighted right inverse for the actual site average)**.** There is a real linear map E with $qE = 1$ such that, for each fixed $r \in \{-1, 0, 1\}$,

$$\|\ell^{-r}E\psi\|_2 \le C_r\|\Xi^{-r}\psi\|_{\mathrm{top}}, \qquad \|\ell^{-r}D_U E\psi\|_2 \le C_r\|\Xi^{-r-1}\psi\|_{\mathrm{top}}. \tag{3.dcclxxiv}$$

The constants are uniform over all layers and proper determining regions in this setting. ■

Proof. For a nonbare pillar use a comb frame on a fixed surrounding cube of radius $C_L\xi_y$. Separation places the required cube inside $\Omega_{j-1} \subset \Omega_0$ when the pillar has level $j \ge 1$. Its local potential has supremum at most $C_L\kappa\xi_y^{-1}$. The actual hierarchical internal transports in the pillar differ from one by $C_L\kappa$, by their geometric sum over intermediate physical scales. This comparison differentiates no potential.

Choose a fixed nonnegative smooth scalar bump supported strictly inside the unit centered cube, positive at its center, and sample its rescaling by ξ_y. Its mean m_y on the pillar has positive lower and finite upper bounds independent of its level. Fine meshes converge to the positive integral; the finitely coarse possibilities contain the center site. The actual readout of this bump times a constant colour is N_y times that colour, with $\|N_y - m_y I\| \le C_L\kappa m_y$. Normalize by N_y^{-1} and the unitary top-frame rotation. This gives the prescribed site value exactly. No other site row reads this bump.

The bump has amplitude $O(|\psi_y|)$ and first differences $O(\xi_y^{-1}|\psi_y|)$ in its local frame. The connection term has the same first-difference bound. Its physical support volume is $O(\xi_y^4)$. Multiplying by ℓ^{-r} and using eq. 3.dcclxxi gives exactly the two powers of Ξ in eq. 3.dcclxxiv. For a bare pillar take its one site value: q_0 is the identity. The first-difference collar of this seed has the same estimates, since $\xi_y = \eta$ and all transports are unitary. The collars of different pillars have bounded overlap; adjacent scales have ratio at most L. Summing proves the claims.

If a surrounding cube does not embed in the original torus, make the construction on a sufficiently large finite periodic cover and average E over the deck group, acting on its fine output and coarse input simultaneously. Pullback preserves the actual rows, Ξ and ℓ. Deck translations are unitary in each of the weighted norms above. The averaged map retains $qE = 1$ and all the bounds, preserves deck-invariant vectors and descends. The squared norms have the same sheet-count factor. This also handles nontrivial flat holonomies without a global gauge choice. □

3.19.3. *The normalized layered Gram matrix from weighted energy.* Put

$$G = A_s^{-1}, \qquad F = Gq^\sharp\Xi^{-2}, \qquad M = F^\sharp F. \tag{3.dcclxxv}$$

The normalization is the one in the actual site projector. It retains the physical top measures; an unweighted array transpose would give a different matrix.

Proposition 3.59 (A current-free normalized Gram gap)**.** For a sufficiently small fixed δ and the corresponding separation above, there are $m_*, m^* > 0$ such that

$$m_* I \le M \le m^* I. \tag{3.dcclxxvi}$$

They are independent of depth, region shape and compatible volume. Only eq. 3.dcclxix and the actual site geometry are required; no physical current or differentiated local-gauge bound is a premise. ■

Proof. Write $u = Fb$ and introduce

$$\mathcal{E}_+(u) = \|\ell D_U u\|_2^2 + \|qu\|_{\mathrm{top}}^2. \tag{3.dcclxxvii}$$

By eq. 3.dcclxxiii, $\|u\|_2^2 \le C\mathcal{E}_+(u)$. Test $A_s u = q^\sharp \Xi^{-2} b$ against $\ell^2 u$. The exact discrete product identity is

$$\mathrm{Re}\langle D_U u, D_U(\ell^2 u)\rangle = \|D_U(\ell u)\|_2^2 - \sum_b \eta^4 |D\ell(b)|^2 \,\mathrm{Re}\langle u(b_-), \mathrm{Ad}\, U_b u(b_+)\rangle. \tag{3.dcclxxviii}$$

Using $|D\ell| \le \delta$ and one more product rule bounds this from below by $\frac{1}{2}\|\ell D_U u\|_2^2 - C\delta^2\|u\|_2^2$.

Within one pillar the variation of ℓ is at most $C\delta\xi_y$, and $\ell(y) \ge \xi_y/L$. Therefore

$$\|\Xi^{-2}\{q(\ell^2 u) - \ell(y)^2 qu\}\|_{\mathrm{top}} \le C_L \delta \|u\|_2. \tag{3.dcclxxix}$$

This follows by Cauchy–Schwarz for each unitary transported average and the disjointness of pillars. The site-mass term in the tested equation is consequently bounded below by $c\|qu\|_{\mathrm{top}}^2 - C_L\delta^2\|u\|_2^2$, after a fixed Young inequality. Moreover,

$$\|\Xi^{-2} q(\ell^2 u)\|_{\mathrm{top}} \le \|u\|_2, \tag{3.dcclxxx}$$

because $\ell(x) \le \xi_y$ at every site in B_y and the absolute transported averaging operator is an L^2 contraction. We obtain

$$c\mathcal{E}_+(u) \le \|b\|_{\mathrm{top}}\|u\|_2 + C_L\delta^2\|u\|_2^2.$$

Choose δ so the last term is absorbed using eq. 3.dcclxxiii. Then

$$\mathcal{E}_+(Fb) \le C\|b\|_{\mathrm{top}}\|Fb\|_2, \qquad \|Fb\|_2 \le C\|b\|_{\mathrm{top}}. \tag{3.dcclxxxi}$$

This proves the Gram upper bound.

For the lower bound test the same equation against $\varphi = E\Xi^2 b$, with the exact lift from Lem. 3.58. Then $q\varphi = \Xi^2 b$ and $\|\ell^{-1} D_U \varphi\|_2 \le C\|b\|_{\mathrm{top}}$. Thus

$$\begin{aligned} \|b\|_{\mathrm{top}}^2 &= \langle A_s Fb, E\Xi^2 b\rangle \\ &\le (\|\ell D_U Fb\|_2 + C\|qFb\|_{\mathrm{top}}) C\|b\|_{\mathrm{top}}. \end{aligned} \tag{3.dcclxxxii}$$

Here the site-mass pairing is $\langle qFb, c_y b\rangle_{\mathrm{top}}$, with no extra length factor. For $b \ne 0$, the last display gives $\mathcal{E}_+(Fb) \ge c\|b\|_{\mathrm{top}}^2$. Combine this with eq. 3.dcclxxxi to obtain $\|Fb\|_2 \ge c\|b\|_{\mathrm{top}}$. Squaring proves the lower bound in eq. 3.dcclxxvi. □

This argument uses first differences of a compact site lift. It does not estimate $L_U E$ by differentiating a local connection. In particular the weighted Gram normalization has not introduced a hidden current premise.

3.19.4. *Two weighted derivatives on the zero-average directions.* Let $\lambda \in \ker q$. At every bare top it vanishes exactly, because the assigned zero-level average is the identity. Therefore

$$\lambda = 0 \quad \text{on } \Omega_0 \setminus \Omega_1. \tag{3.dcclxxxiii}$$

The separation of Ω_1 from Ω_0^c supplies more than the fixed number of fine layers needed by the following stencils. This fact concerns the actual assigned averages. It would fail for an arbitrary clipped average on an arbitrary subset of a block.

Proposition 3.60 (A weighted inverse on $\ker q$)**.** For every site vector λ with $q\lambda = 0$,

$$\|\xi^{-2}\lambda\|_2 + \|\mathsf{L}^{-1}D_U\lambda\|_2 + \|\nabla_U D_U\lambda\|_2 \le C\|L_U\lambda\|_2. \tag{3.dcclxxxiv}$$

The last norm is the full component-gradient norm after zero extension across the action boundary. Every nonzero stencil in that norm lies inside the action region. Thus it is an estimate for the true inner site operator, not a replacement by a compressed periodic Laplacian. ■

Proof. Put $f = L_U\lambda$ and $w = \ell^{-1}$. Apply the site gap in eq. 3.dcclxxiii to $w\lambda$. Since $q\lambda = 0$,

$$\|\Xi^{-1}q(w\lambda)\|_{\mathrm{top}} \le C_L\delta\|\ell^{-2}\lambda\|_2. \tag{3.dcclxxxv}$$

Indeed subtract $w(y)q\lambda$ in each pillar and use $|w(x) - w(y)| \le C_L\delta\xi_y^{-1}$. Since $\ell \ge \xi/L$, the left mass term in the site gap controls $\|\ell^{-2}\lambda\|_2$ up to L. Choose δ smaller if necessary and absorb eq. 3.dcclxxxv. We get

$$\|\ell^{-2}\lambda\|_2^2 \le C\|D_U(w\lambda)\|_2^2. \tag{3.dcclxxxvi}$$

Apply the weighted Green identity with weight w to the equation $L_U\lambda = f$. The weight difference in eq. 3.dcclxxii gives

$$\|D_U(w\lambda)\|_2^2 \le \|f\|_2\|\ell^{-2}\lambda\|_2 + C_L\delta^2\|\ell^{-2}\lambda\|_2^2.$$

Absorb its last term using eq. 3.dcclxxxvi. This proves the weighted mass bound. The product rule then proves $\|\ell^{-1}D_U\lambda\|_2 \le C\|f\|_2$. The comparison length converts them into the first two terms of eq. 3.dcclxxxiv.

For the last term extend λ by zero outside Ω_0 and extend the connection there by arbitrary unitary bonds. By eq. 3.dcclxxxiii, all nonzero two-step stencils are still inner to Ω_0, where the extended Laplacian agrees with $L_U\lambda$. The covariant curl of $D_U\lambda$ is a commutator of two shifts. Its coefficient is a conjugate of $(\mathrm{Ad}\,U_p - 1)/\eta^2$, so

$$\|\mathrm{d}_U D_U\lambda\|_2 \le C_L\kappa\|\xi^{-2}\lambda\|_2. \tag{3.dcclxxxvii}$$

The covariant Hodge calculation in eq. 3.dlxviii, applied to this zero-extended gradient, therefore gives

$$\|\nabla_U D_U\lambda\|_2^2 \le C(\|f\|_2^2 + \kappa^2\|\xi^{-2}\lambda\|_2^2 + \kappa\|\mathsf{L}^{-1}D_U\lambda\|_2^2). \tag{3.dcclxxxviii}$$

The corner scales in each plaquette are comparable within a fixed power of L. The unknown exterior curvature contributes nothing: the relevant field and its shifted values vanish in its collar. Substitute the first two estimates to finish the proof. □

No derivative of the curvature, of a gauge potential or of a current has entered this estimate. The extra boundary control comes from the actual zero-level site constraints.

3.19.5. *Gauge restoration and the actual outward rows.* Define the actual orthogonal projector and restoration map by

$$R = 1 - FM^{-1}F^\sharp, \qquad \Lambda = GRD_U^\sharp, \qquad S = 1 - D_U\Lambda. \tag{3.dcclxxxix}$$

The exact range identities are

$$\operatorname{ran} R = L_U(\ker q), \qquad qGR = 0, \qquad L_UGR = R. \tag{3.dccxc}$$

For $qz = 0$, $GL_Uz = z$ and $F^\sharp L_Uz = \Xi^{-2}qz = 0$. Conversely $F^\sharp f = 0$ implies $qGf = 0$ and $L_UGf = f$. This proves the range statement and the two identities.

For a field v define

$$\|v\|_X^2 = \|\nabla_U v^0\|_2^2 + \|\mathsf{L}^{-1}v\|_2^2, \tag{3.dccxci}$$

where v^0 is zero on all bonds outside the active graph. This comparison norm counts its boundary jumps; it does not add those jumps to the action. Its value is independent of an arbitrary unitary extension of the connection: when a difference has two nonzero field values its connecting bond is active, and otherwise unitarity fixes the norm of its single nonzero value.

Corollary 3.61 (Uniform restoration on every assigned scale)**.** The actual maps satisfy

$$\|\xi^{-2}\Lambda v\|_2 + \|D_U\Lambda v\|_X + \|Sv\|_X \le C\|v\|_X, \qquad RD_U^\sharp S = 0, \qquad QS = Q. \tag{3.dccxcii}$$

Here Q is the derivative of the actual straightened field map on the literal determining rows, including its outward rows. ■□

Proof. The site vector $\lambda = \Lambda v$ obeys $q\lambda = 0$ and $L_U\lambda = RD_U^\sharp v$. Since R is orthogonal and the inner divergence is bounded by the component-gradient comparison norm, Prop. 3.60 proves the estimates. The identity $RD_U^\sharp S = 0$ follows from $RL_UGR = R$.

The actual field intertwining is

$$QD_U = \bar{D}_{\mathrm{ext}}q. \tag{3.dccxciii}$$

At an outward endpoint of a level-j row, $\bar{D}_{\mathrm{ext}}$ averages the L^4 assigned level-$(j-1)$ top values in that whole outer block, with their actual mean transports. That is the exact extension in eq. 3.cdlxxxiii; it is not evaluation at one outer top. Hence $QD_U\Lambda = \bar{D}_{\mathrm{ext}}qGRD_U^\sharp = 0$. This proves $QS = Q$ on the true row spaces. □

Let $a_f(c) = d_c\xi_c^{-2}$, with fixed positive lower and upper bounds for d_c, and give data the norm

$$\|b\|_Y^2 = \sum_c \xi_c^4 a_f(c)|b(c)|^2. \tag{3.dccxciv}$$

The actual field-row construction in eq. 3.dcv supplies a right inverse E_Q with $\|E_Qb\|_X \le C\|b\|_Y$. Its compact seeds and adjacent-level Neumann correction are the actual ones; they include the identity seeds in the bare boundary layer. The zero-extension part of X adds only a bounded bare mass term to their stated inner energy estimate. Thus $E_L = SE_Q$ is an exact right inverse into $X_L = \ker(RD_U^\sharp)$ and

$$QE_L = 1, \quad \|E_Lb\|_X \le C\|b\|_Y, \quad \inf_{\mu\neq 0}\sup_{v\in X_L\setminus\{0\}} \frac{|\langle \mu, Qv\rangle_{\mathrm{rows}}|}{\|\mu\|_{Y^*}\|v\|_X} \ge C^{-1}. \tag{3.dccxcv}$$

The dual norm is $\|\mu\|_{Y^*} = \|a_f^{-1/2}\mu\|_{2,\mathrm{rows}}$. For the last inequality choose a unit data vector attaining the dual norm and apply E_L. This proves the uniform inf-sup part of the actual saddle problem. Coercivity on its simultaneous constraint kernel is a separate estimate.

3.19.6. *The explicit current correction has an energy bound.* For an independent current define $\mathcal{W}_U[J]$ and the symmetric correction $\mathcal{B}_U[J]$ by their actual explicit formulas eq. 3.cdlxiv and eq. 3.cdlxvii. Suppose

$$\gamma_J = \sup_b \mathsf{L}(b)^3|J(b)| < \infty. \tag{3.dccxcvi}$$

Then

$$|\langle u, \mathcal{B}_U[J]v\rangle| \le C\gamma_J\|u\|_X\|v\|_X. \tag{3.dccxcvii}$$

Indeed, the endpoint formula for $\mathcal{W}$ and comparable corner scales give

$$|\langle u, \mathcal{W}_U[J]\lambda\rangle| \le C_L\gamma_J\|\mathsf{L}^{-1}u\|_2\|\xi^{-2}\lambda\|_2.$$

Insert this inequality and Cor. 3.61 in the four undifferentiated-current pairings of eq. 3.cdlxix. This proves eq. 3.dccxcvii without a derivative of J. Likewise the actual quadratic constraint form satisfies

$$|\langle Su, \Delta^{(2)}[\omega]Sv\rangle| \le C\gamma_\omega\|u\|_X\|v\|_X, \qquad \gamma_\omega = \sup_c \xi_c^3|\omega(c)|,$$

by its already proved two-leg moment. The particular induced readout is bounded in Prop. 3.73 and eq. 3.mviii; the exact canonical current identification is Prop. 3.90.

The results in this section supply the current-free normalized site Gram gap, two weighted derivatives on the actual zero-average site directions, a uniformly bounded field restoration, and the inf-sup part of the all-layer proper-region saddle problem. They use the literal outward-row

extension and the actual bare boundary collar. The remaining mass estimate is a vector estimate, not another site gap.

3.20. **A flat regular decomposition on the determining regions.** The missing vector estimate is a div–curl estimate with the actual changing-scale averages. The outward rows are useful here: their outer endpoint average is taken over an entire block whose smaller internal rows are also prescribed. Those rows control the fluctuations hidden by the endpoint average. We first quantify this fact and then glue local scalar primitives. The construction retains holes, disconnected components and the true bare boundary layer.

Use the sites, active bonds and inner plaquettes of § 3.19. Let V be a real flat connection on this active cubical complex. Flatness means every inner plaquette is one. There is no assumption that V is a global pure gauge. In a convex fine box it can be put in a parallel frame, so all calculations there reduce to ordinary cochains. All norms and transposes have their previously declared physical measures. The field-row map Q is the actual straightened derivative; at a flat field it is the transported straight average, not the derivative of the plain average.

3.20.1. *What the outward endpoint average controls.* Make a graph with the assigned tops as vertices. Two vertices are joined when their pillars share a face containing a fine bond. Their levels are equal or adjacent. Let σ_{yz} be the larger of their two scales and let T_{yz} be the parallel transport between them inside the local one- or two-scale rectangle. The local rectangle is contractible in the active region, so flatness makes this transport independent of its chosen path there.

For a fixed real r define

$$\begin{aligned} J_r(\psi) &= \sum_{y\sim z} \sigma_{yz}^{2-2r} |\psi(y) - \operatorname{Ad} T_{yz}\psi(z)|^2, \\ D_r(\psi) &= \sum_{c\in\mathbf{B}} \xi_c^{4-2r} |\bar{D}_{\mathrm{ext}}\psi(c)|^2. \end{aligned} \tag{3.dccxcviii}$$

Count each unoriented graph edge once. The coarse difference in the second line has the exact averaged outer endpoint from eq. 3.cdlxxxiv.

Lemma 3.62 (Completion of the outward rows)**.** For every fixed r,

$$C_{L,r}^{-1} J_r \le D_r \le C_{L,r} J_r. \tag{3.dccxcix}$$

The constants have no depth or volume factor. The comparison is local: a graph edge uses only its associated determining row and the smaller internal rows in its outer endpoint block. ■

Proof. An equal-level graph edge is precisely an interior determining row, so the two differences coincide, with their length factor. For a face between a level-j pillar at y and smaller pillars, put $s = \xi_j$. The determining outward bond from y ends at the level-j grid point z across that face. Its entire block $B^j(z)$ is outside Ω_j and inside Ω_{j-1}. It consists of L^4 assigned level-$(j-1)$ pillars. Every level-$(j-1)$ bond internal to this block is an actual prescribed interior row. This is the no-inward-row geometry; it is not true for an arbitrary clipped block.

Choose a parallel frame on the two-block rectangle. Write a for the value at y, b_w for the smaller top values in $B^j(z)$, and $\bar{b} = L^{-4}\sum_w b_w$. The outward difference is $s^{-1}(a - \bar{b})$. For every smaller pillar on the face,

$$|a - b_w|^2 \le 2|a-\bar{b}|^2 + 2|b_w - \bar{b}|^2, \qquad \sum_w |b_w - \bar{b}|^2 \le CL^2 \sum_{\substack{w\sim w' \\ \text{internal}}} |b_w - b_{w'}|^2.$$

The last inequality is the finite L-grid path Poincaré inequality. Multiply by s^{2-2r} and sum over at most L^3 face neighbors. The smaller row weights differ by the fixed factor L^{2-2r}. This bounds the corresponding graph edges by the outward row and the smaller internal rows.

Conversely choose one smaller face neighbor w_0. Write $a-\bar{b} = (a-b_{w_0}) + L^{-4}\sum_w (b_{w_0}-b_w)$ and join w_0 to w by coordinate paths in the smaller block. Their length is at most $4L$. Cauchy–Schwarz gives the reverse bound. The same argument works after restoring the unitary parallel transports.

A top belongs to only one such outer large block at the next level. That block can be read by at most eight incident outward rows. Internal smaller edges and all the constructed local paths therefore have bounded overlap depending only on L. Summing the local inequalities proves eq. 3.dccxcix. □

In particular the kernel of $\bar{D}_{\mathrm{ext}}$ is the space of parallel sections of this pillar adjacency graph. Such a section lifts to a parallel fine site field by the actual own-pillar transport, and conversely every parallel fine field gives such a section. For a fine edge crossing a pillar face, this follows in the same two-block rectangle used in the proof. Thus the averaged outward endpoint does not introduce an extra coarse gauge kernel. This statement retains the actual holonomy conditions on each connected component.

3.20.2. *A local box estimate with its actual boundary adjoint.*

Lemma 3.63 (Local cochain Hodge decomposition)**.** Let D be a convex rectangular fine box of diameter comparable to $s \geq \eta$, with bounded aspect ratio. For any one-cochain v on all its inner bonds there is a site potential λ and a remainder $r = v - D_V\lambda$ such that

$$\|r\|_{2,D} \leq Cs\|\mathrm{d}_V v\|_{2,D}, \qquad \|\nabla_V r\|_{2,D'} \leq C\|\mathrm{d}_V v\|_{2,D}, \tag{3.dccc}$$

where D' is any fixed smaller concentric box. The potential is unique up to a parallel constant after its gradient is chosen. It may be normalized to have zero transported average on a specified centered pillar of scale comparable to s in D. The constants include only the fixed size ratios. They are independent of the number of fine sites in the box. ■

Proof. Choose a parallel frame on D. Let d_0 be the fine gradient on the path-product graph and d_1 its plaquette coboundary. Project v orthogonally onto $\operatorname{ran}\mathrm{d}_0$ and write $r = v - \mathrm{d}_0\lambda$. The projection equation is $\mathrm{d}_0^\sharp r = 0$, with the full graph adjoint, including its boundary vertices. Also $\mathrm{d}_1 r = \mathrm{d}_1 v$.

Here the required graph Hodge estimate is elementary and includes the boundary condition. In one direction with $N+1$ vertices, $\mathrm{d}_0^\sharp\mathrm{d}_0$ is the path Neumann matrix, whereas $\mathrm{d}_0\mathrm{d}_0^\sharp$ on its N edges is the tridiagonal matrix with diagonal $2\eta^{-2}$ and off-diagonal $-\eta^{-2}$. Their nonzero eigenvalues are

$$4\eta^{-2}\sin^2\frac{\pi m}{2(N+1)} \quad (1 \leq m \leq N).$$

The scalar matrix also has its constant zero mode. Tensor products give the one-cochain Hodge matrix $\mathrm{d}_0\mathrm{d}_0^\sharp + \mathrm{d}_1^\sharp\mathrm{d}_1$: in component μ its longitudinal factor is the edge matrix and its other factors are the scalar path matrices. Every component therefore has a nonzero longitudinal frequency and a gap at least cs^{-2}. Its quadratic form is the sum of the interior component first differences, with additional nonnegative longitudinal boundary edge terms. This follows either from those tensor factors or by expanding their squares.

It follows that $\|r\|_2 \leq Cs\|\mathrm{d}_1 r\|_2$, and that every first difference whose stencil is inside D' is bounded by $C\|\mathrm{d}_1 r\|_2$. This proves eq. 3.dccc. Changing the parallel constant in λ does not change r. The transported average of a parallel constant is that constant, so it gives the stated normalization. The local Poincaré inequality with a mean on the specified positive-volume pillar has a constant depending only on the size ratio. It includes a bare one-site pillar, whose physical volume is then s^4 up to that same fixed ratio. Restore the parallel frame to finish. □

The divergence in this lemma is the full adjoint on the finite box graph. An interior formula that discards its boundary vertex equations would allow additional harmonic gradients and would not prove the lemma.

3.20.3. *Adaptive patches and removal of the bare boundary collar.* Let C_{row} be a fixed physical carrier-radius constant for the flat rows and their completed outer blocks. Fix an integer $K \geq 64L^2(C_{\mathrm{row}}+1)$ and require $\rho \geq CKL$. A box of radius $K\xi_y$ about an assigned top can meet at most two adjacent assigned levels. Indeed it cannot reach level $j-2$ from a level-j top without crossing distance $\rho\xi_j/L$, nor level $j+2$ without crossing distance $\rho L\xi_j$. It cannot meet both levels $j-1$ and $j+1$, because those sets are separated by more than $\rho\xi_j$. Increase the fixed constant in the separation for the enlarged boxes used below.

Consequently these boxes have uniformly bounded overlap, and there is a partition $\sum_y \chi_y = 1$ on Ω_0 with

$$\operatorname{supp}\chi_y \subset Q_{2\xi_y}(y), \quad |D\chi_y| \leq C_L\xi_y^{-1}, \quad |D^2\chi_y| \leq C_L\xi_y^{-2}. \tag{3.dccci}$$

One construction uses a fixed smooth bump equal to one on a centered pillar, supported in its doubled cube, and divides by the sum of all such bumps. Pillars are disjoint; every overlapping scale has ratio at most L. Hence that sum is bounded above and below and its first two differences have the stated bounds. The same counting proves bounded overlap for the larger $K\xi_y$ boxes and the pair neighborhoods below. Whenever cutoff overlaps are used, include their two-fine-step collars as well; the same estimates apply since $\eta \leq \xi_y$.

We first remove a genuine boundary difficulty. Choose $H > 10K$ fixed and a scalar cutoff θ, equal to one within $H\eta$ of Ω_0^c, zero beyond $2H\eta$, with $|D\theta| \leq C\eta^{-1}$. Choose $\rho > 4H + C_L$. Every bond read by $v_b = \theta v$ is a bare determining row, and $Q_0 v = v$ on these bonds. The elementary finite-difference bound gives

$$\|v_b\|_X \leq C\|Qv\|_Y, \quad \|\mathrm{d}_V(v-v_b)\|_2 + \|Q(v-v_b)\|_Y \leq C(\|\mathrm{d}_V v\|_2 + \|Qv\|_Y). \tag{3.dcccii}$$

For the curl use the product rule; its cutoff term has size $C\eta^{-1}|v|$ in the bare collar. For Q use its bounded physical row and column sums, or note that the higher row carriers miss this collar. The norm X includes zero-extension boundary jumps, also bounded by $\eta^{-1}|v|$ there.

Put $w = v - v_b$. It vanishes in this boundary collar. Every nontrivial box used to decompose w is therefore inside Ω_0: nonbare boxes are inside by separation, and a bare box meeting the exterior lies entirely in the zero collar. For such a zero box choose potential and remainder zero. This convention never requires a flat extension across a hole.

3.20.4. *Gluing the normalized local potentials.*

Proposition 3.64 (A regular decomposition with the actual averages)**.** For every field v on the true active bonds there is a site potential λ_0 with $q\lambda_0 = 0$ and a field r_0 such that

$$v = D_V\lambda_0 + r_0, \qquad \|r_0\|_X \leq C(\|\mathrm{d}_V v\|_2 + \|Qv\|_Y). \tag{3.dcccciii}$$

The constant is independent of all assigned levels and the topology of the determining region. ■

Proof. First suppose every ambient period exceeds $8K\max_y \xi_y$, so all local boxes below embed. A finite-cover argument at the end removes this temporary restriction. It suffices by eq. 3.dcccii to decompose w. For every nonzero patch apply Lem. 3.63 on $D_y = Q_{K\xi_y}(y)$, choosing

$$w = D_V\lambda_y + r_y, \quad q_y\lambda_y = 0, \quad \|r_y\|_{2,D_y} \leq C_L\xi_y\|\mathrm{d}_V w\|_{2,D_y}, \quad \|\nabla_V r_y\|_{2,D_y/2} \leq C_L\|\mathrm{d}_V w\|_{2,D_y}. \tag{3.dccciv}$$

The local normalization uses the actual pillar average.

We spell out the comparison of constants on overlaps. If the cutoff supports, including the stated fine collars, meet at y, z, their scales have ratio at most L and their centers have distance at most $8\sigma_{yz}$. A coordinate route and every completed outer block lie in a rectangle of radius $C(C_{\mathrm{row}}+1)\sigma_{yz}$ about these centers, with the dimensional constant absorbed by the choice of K above. Since the smaller radius of $D_y/2, D_z/2$ is at least $K\sigma_{yz}/(2L)$, this rectangle lies in their intersection. Choose a convex pair neighborhood there containing the two central pillars and the following finite row route. Follow a coordinate fine path from one pillar to the other and record the pillars it crosses.

There are at most C_L of them because their scales are comparable. Replace each unequal-level face crossing by its determining outward row and the internal smaller rows in its full outer block, as in Lem. 3.62. All these carriers fit in the pair neighborhood when K is chosen large enough.

For $f_a = q_a\lambda_z$, the local intertwining gives $\bar{D}_{\mathrm{ext}} f = Q(w - r_z)$ on that route. Since $f_z = 0$, the finite-route version of the completion lemma implies

$$|q_y\lambda_z| \le C_L \left\{ \sum_{c\in\mathcal{C}_{yz}} \xi_c^2 |Qw(c)|^2 + \|\mathrm{d}_V w\|^2_{2,D_y\cup D_z} \right\}^{1/2} =: C_L e_{yz}. \tag{3.dcccv}$$

For the remainder term used here, a physical flat row has L^2 functional norm at most $C\xi_c^{-2}$: its coefficient sum is bounded and its largest fine coefficient is at most $C(\eta/\xi_c)^4$. Thus $\xi_c|Qr_z(c)| \le C_L\|\mathrm{d}_V w\|_{2,D_z}$, by eq. 3.dccciv. Only C_L rows enter.

On the pair neighborhood let $h_{yz} = \lambda_y - \lambda_z$. Its derivative is $r_z - r_y$ and its average at y is $-q_y\lambda_z$. Poincaré with that central pillar mean gives

$$\|h_{yz}\|_2 \le C_L\sigma_{yz}^2 e_{yz}, \qquad \|D_V h_{yz}\|_2 \le C_L\sigma_{yz} e_{yz}. \tag{3.dcccvi}$$

In particular the constants of the primitives have been estimated; a bound only on their gradient would not suffice. The pair neighborhoods and their routes have bounded overlap, so

$$\sum_{y,z} e_{yz}^2 \le C_L(\|\mathrm{d}_V w\|_2^2 + \|Qw\|_Y^2), \tag{3.dcccvii}$$

where only intersecting cutoff supports are summed.

Glue $\lambda = \sum_y \chi_y\lambda_y$ and put $r = w - D_V\lambda$. The exact product rule writes r as the sum of the cutoff remainders $\chi_y r_y$ and terms $D\chi_y$ times shifted primitive differences. The latter are differences because $\sum_y D\chi_y = 0$. A second product rule for its gradient, Cauchy–Schwarz and bounded overlap give

$$\begin{aligned} \|r\|_X^2 &\le C_L \sum_y (\|\nabla_V r_y\|^2_{2,D_y/2} + \xi_y^{-2}\|r_y\|^2_{2,D_y}) \\ &\quad + C_L \sum_{y,z} (\sigma_{yz}^{-4}\|h_{yz}\|_2^2 + \sigma_{yz}^{-2}\|D_V h_{yz}\|_2^2). \end{aligned} \tag{3.dcccviii}$$

All shifts in this formula remain in the specified interior boxes. Equations eq. 3.dccciv through eq. 3.dcccvii prove $\|r\|_X \le C_L(\|\mathrm{d}_V w\|_2 + \|Qw\|_Y)$.

The glued potential need not have zero assigned average. On B_y, subtract λ_y in its average and use its zero normalization. The averaging functional has norm ξ_y^{-2}, so eq. 3.dcccvi gives

$$\sum_y |q_y\lambda|^2 \le C_L(\|\mathrm{d}_V w\|_2^2 + \|Qw\|_Y^2). \tag{3.dcccix}$$

This is a counting norm of the site values, with no missing physical volume factor: the factor ξ_y^{-2} cancels the ξ_y^2 in the potential overlap estimate.

At a flat field the exact bump lift of the site averages can be chosen with the additional estimate

$$qE = 1, \qquad \|D_V E\psi\|_X^2 \le C_L \sum_y |\psi_y|^2. \tag{3.dcccx}$$

To verify it, use the same normalized compact scalar profiles in parallel frames. Their second differences are $O(\xi_y^{-2}|\psi_y|)$ and their physical volume is $O(\xi_y^4)$. The weighted first differences have that same squared counting bound. For a bare seed the two differences cost at most $C\eta^{-2}$, canceled by its physical volume η^4 after squaring. The two-step collars have bounded overlap. A large finite cover and deck averaging handle any nonembedded surrounding box, preserving these energy estimates.

Set $\lambda_0 = \lambda - Eq\lambda$. Its average is zero exactly. Add $D_V Eq\lambda$ to r and then add back v_b to the remainder. Equations eq. 3.dcccix, eq. 3.dcccx and eq. 3.dcccii prove eq. 3.dccciii on this large volume.

For an arbitrary smaller compatible torus, pull back the entire determining geometry, flat connection and input field to a finite periodic cover whose periods exceed $8K \max_y \xi_y$. Construct the potential λ_0 there by the preceding proof. Average it over the deck group. The lifted input is invariant, and the actual D_V, q, Q, all physical weights and the boundary collar commute with these translations. The averaged potential still has $q\lambda_0 = 0$. Its remainder is the average of the translated remainders, so its X norm obeys the same bound by the triangle inequality. It descends to the original torus. The squared remainder norm and both squared input norms multiply by the number of sheets under pullback; these factors cancel. This proves the full regular decomposition at every compatible volume, not only the auxiliary site lift. The argument does not require trivial holonomy on the original active complex. □

The argument uses local primitives on convex boxes and compares their constants through the actual determining rows. It therefore also controls closed fields with periods around holes: their constants can be glued only if the corresponding row information is retained. No assertion that the region has trivial first cohomology was made.

3.20.5. *The flat layered Landau gap.*

Proposition 3.65 (Flat coercivity on the true determining region)**.** For the separated aligned determining geometry, with separation larger than the fixed constants above, there are $c, C > 0$ such that

$$c\|v\|_X^2 \le \|\mathrm{d}_V v\|_{2,\Omega_0}^2 + \|RD_V^\sharp v\|_2^2 + \|Qv\|_Y^2 \le C\|v\|_X^2. \tag{3.dcccxi}$$

This is uniform in depth, compatible volume, region topology and real flat holonomies. The curl includes exactly the inner plaquettes, the divergence is the adjoint on the true active graph, and R, Q are the actual assigned-site projector and straightened determining rows. ■

Proof. Take the regular decomposition of Prop. 3.64. Since $q\lambda_0 = 0$, the actual range identity gives

$$L_V\lambda_0 = RL_V\lambda_0 = RD_V^\sharp v - RD_V^\sharp r_0.$$

The divergence is bounded by the X norm. Apply Prop. 3.60 to conclude

$$\|D_V\lambda_0\|_X \le C(\|RD_V^\sharp v\|_2 + \|r_0\|_X).$$

Add the remainder bound. This proves the lower estimate in eq. 3.dcccxi. The upper estimate follows from the local curl and divergence bounds and the physical row and column bounds for Q. The boundary part of X is a comparison norm only; no boundary plaquettes or crossing action bonds have been added in deriving its lower bound. □

At a flat field the physical Wilson Hessian is precisely the inner curl form. Hence the theorem proves the full flat projected-Landau precision gap on the actual multi-level region. Together with the actual-slice inf-sup estimate in eq. 3.dccxcv, it gives the flat constrained saddle inverse in the declared energy and dual-energy norms. The passage to a nonflat regular field still requires coefficient comparison and localization of this same geometry. It is not a consequence of a site gap alone.

3.21. **A nonflat Landau inverse on the determining regions.** We retain the same determining geometry in every comparison. A local comparison field equals the identity outside its gauge patch, but it has the original assigned averages, determining rows and inner action region. No periodic inner operator is substituted at a seam or an action boundary.

Use the hypotheses and physical spaces of §§ 3.19 and 3.20. All row weights are positive and comparable with the assigned inverse scale squared. The estimates concern the unweighted inner

Wilson action and actual straightened constraint. Signed profiles and separately specified current completions are not included by a change of notation.

3.21.1. *A common weighted gauge.* Let V be real and flat on the active graph and write

$$U_b = e^{i\eta A_b} V_b, \qquad \varepsilon = \sup_b \mathsf{L}(b)|A_b|. \tag{3.dcccxii}$$

The reference may have nontrivial holonomy around holes or torus cycles. Site and row spaces, Ξ, and ℓ are the same for both backgrounds.

Lemma 3.66 (Actual weighted coefficient comparison)**.** For sufficiently small fixed ε and curvature ceiling,

$$\begin{aligned}
\|\ell(D_U - D_V)u\|_2 &\le C\varepsilon\|u\|_2,\\
\|(q_U - q_V)u\|_{\mathrm{top}} + \|\Xi^{-2}(q_U - q_V)(\ell^2 u)\|_{\mathrm{top}} &\le C\varepsilon\|u\|_2,\\
\|a_f^{1/2}(Q_U - Q_V)v\|_{2,\mathrm{rows}} &\le C\varepsilon\|\mathsf{L}^{-1}v\|_2,\\
\|(F_U - F_V)b\|_2 + \|\ell(D_U F_U - D_V F_V)b\|_2 &\le C\varepsilon\|b\|_{\mathrm{top}},\\
\|R_U - R_V\|_{2\to 2} &\le C\varepsilon,\\
\|(R_U D_U^\sharp - R_V D_V^\sharp)v\|_2 &\le C\varepsilon\|v\|_{X_V}.
\end{aligned} \tag{3.dcccxiii}$$

The Q's are the actual straightened rows, including their node derivatives and extended outward endpoint averages. ■

Proof. The first bound follows from $\|\operatorname{Ad}(e^{i\eta A}) - 1\| \le C\eta|A|$. Each actual row carrier meets at most two adjacent assigned scales. In a local parallel frame for V, intermediate transports at physical scale ξ_s change by at most $C_L\varepsilon\xi_s/\xi_c$. Their geometric sum is bounded uniformly in the number of averaging levels. Differentiating the finite actual recursion gives both physical Schur sums for the field-row difference. This is the row comparison proved in § 3.13, including the straightening factors. The site-row comparison is the same transported-average calculation. Inserting ℓ^2/ξ_y^2, or the field mass weights on a two-scale carrier, preserves its $O_L(\varepsilon)$ bound. Thus the first three lines have no fine-density loss.

For completeness, the normalized resolvent comparison uses the weighted energy, rather than an unscaled fine matrix norm. Put $u = (F_U - F_V)b$. Then

$$A_{s,U}u = (q_U^\sharp - q_V^\sharp)\Xi^{-2}b - (A_{s,U} - A_{s,V})F_V b. \tag{3.dcccxiv}$$

Test against $\ell^2 u$. The real part on the left controls $\|\ell D_U u\|_2^2 + \|q_U u\|_{\mathrm{top}}^2$, and this energy controls $\|u\|_2^2$, by the proof of Prop. 3.59. The first right-hand term is bounded by $C\varepsilon\|b\|_{\mathrm{top}}\|u\|_2$. In the gradient-form difference, the factor $D_U - D_V$ has size $C\varepsilon\ell^{-1}$, while $D_U(\ell^2 u)$ is bounded by $C\ell(|\ell D_U u| + \delta|u|)$. The alternative placement of that difference is bounded by $C\varepsilon\|\ell D_V F_V b\|_2\|u\|_2$. The two site-mass differences are bounded by $C\varepsilon(\|F_V b\|_2 + \|q_V F_V b\|_{\mathrm{top}})\|u\|_2$. The weighted column energy bounds therefore give $\|u\|_2 + \|\ell D_U u\|_2 \le C\varepsilon\|b\|_{\mathrm{top}}$. This proves the fourth line after adding the gradient coefficient difference.

Consequently $M_U - M_V = O(\varepsilon)$ in normalized top norm. The Gram gaps give the same bound for the inverse difference. Insert these in $R = 1 - FM^{-1}F^\sharp$. For the last line insert and subtract $R_U D_V^\sharp v$. The remaining adjoint coefficient difference is bounded by $C\varepsilon\|\mathsf{L}^{-1}v\|_2$. No derivative of the potential is used. □

Pair the Hessian of the actual per-length nonlinear constraint by

$$B_\omega(v,w) = \sum_{c\in\mathbf{B}} \xi_c^4 \langle \omega(c), D^2\mathcal{Q}_{U,c}(0)[v,w]\rangle, \qquad \gamma_\omega = \sup_c \xi_c^3|\omega(c)|. \tag{3.dcccxv}$$

Its actual two-leg moment bounds it by $C\gamma_\omega\|\mathsf{L}^{-1}v\|_2\|\mathsf{L}^{-1}w\|_2$. Define the physical form

$$\begin{aligned} K_{U,\omega}(v,w) &= D^2A_{\Omega_0}(U)[v,w] - B_\omega(v,w) \\ &\quad + \langle R_U D_U^\sharp v, R_U D_U^\sharp w\rangle + \langle Q_U v, a_f Q_U w\rangle_{\mathrm{rows}}. \end{aligned} \tag{3.dcccxvi}$$

Action derivatives use physical left variations $e^{i\eta tv}U$.

Corollary 3.67 (Coercivity in the common gauge)**.** There are fixed $c_1, \epsilon_1 > 0$ such that

$$K_{U,\omega}(v,v) \geq c_1\|v\|_{X_U}^2 \quad \text{if} \quad \varepsilon + \kappa + \gamma_\omega \leq \epsilon_1. \tag{3.dcccxvii}$$

■□

Proof. The exact Wilson plaquette Hessian differs from its transported linearized curl form by $C\kappa$ times the mass norms. The curl differs from its flat reference by $C\varepsilon$ times the mass norm: each prefix transport changes by $O(\eta\varepsilon/\mathsf{L})$ before division by η. This is a local inner-plaquette calculation, including the action boundary. Thus

$$|D^2A_{\Omega_0}(U)[v,w] - \langle \mathrm{d}_V v, \mathrm{d}_V w\rangle| \leq C(\varepsilon+\kappa)\|v\|_{X_V}\|w\|_{X_V}.$$

Use Lem. 3.66 for the gauge and row squares and the two-leg estimate for the actual constraint form. Absorb the total error in Prop. 3.65. The two component-gradient norms are equivalent by their coefficient comparison. This proves eq. 3.dcccxvii. □

3.21.2. *Weighted cell kernels and IMS.* Let ψ be bounded and one-Lipschitz for $d_\ell = \inf\int ds/\ell$, with its sampled top values. Conjugate site and top vectors by $e^{s\psi}$. A derivative commutator has size $C_L|s|\ell^{-1}$, and a normalized site row changes by $C_L|s|$. Testing the conjugated equation against $\ell^2 u$ perturbs the coercive weighted-energy form by $C_L|s|$. The preceding weighted proof consequently gives, for a fixed $|s| \leq s_0$,

$$\|e^{s\psi_f}Fe^{-s\psi_t}\|_{2\to 2} + \|e^{s\psi_f}\ell D_U F e^{-s\psi_t}\|_{2\to 2} \leq C. \tag{3.dcccxviii}$$

The difference from the original column is $O(|s|)$. Therefore the conjugated normalized Gram matrix changes by $O(|s|)$, and its inverse stays bounded by the Gram gap. It follows that the normalized smoothing operator

$$\widetilde{K}_s = \ell D_U P D_U^\sharp \ell = (\ell D_U F)M^{-1}(\ell D_U F)^\sharp, \qquad P = 1 - R, \tag{3.dcccxix}$$

has exponential physical cell-L^2 entries. This is not a pointwise fine-kernel assertion.

The actual layer metric has cell growth bounded by $C_L(1+t)^5 e^{8t\log L/\rho}$. Since $d_\ell \geq d$, choose the separation so that

$$8\log L/\rho < s_0/2. \tag{3.dcccxx}$$

All fixed polynomial row and column moments of the smoothing entries are then bounded. This explicitly pays for the growth of the changing-scale metric.

Choose a large fixed R. A useful partition can be constructed without assumptions on boundary density. Select tops greedily in decreasing scale so that balls of radius $R\xi_y/(20L)$ are disjoint and the selection is maximal. If $\rho \geq C_L R$, intersecting enlarged balls have only adjacent scales. The larger balls of radius $R\xi_y$ cover the region, allowing a fixed enlargement for fine cells. Packing the smaller disjoint balls gives overlap at most C_L. Take bumps equal to one on the covering balls and supported in their doubles, and normalize their squared sum. They satisfy

$$\begin{aligned} &\sum_i \chi_i(x)^2 = 1, \qquad \sum_i |D\chi_i(x)|^2 \leq C_L R^{-2}\xi(x)^{-2}, \\ &\sum_i |\chi_i(x) - \chi_i(z)|^2 \leq C_L \min\{1, d_\ell(x,z)^2/R^2\}, \\ &\sum_i \sup_{x\in B_y} |\chi_i(x) - \chi_i(y)|^2 \leq C_L R^{-2}. \end{aligned} \tag{3.dcccxxi}$$

The pair difference follows by integrating the vector of cutoff gradients along a metric path. The supremum bound follows from bounded overlap and the bounded metric diameter of a pillar.

Lemma 3.68 (IMS for the actual layered form)**.** For the true inner form,

$$\left|\sum_i K_{U,\omega}(\chi_i v,\chi_i v)-K_{U,\omega}(v,v)\right|\le CR^{-2}\|\mathsf{L}^{-1}v\|_2^2. \tag{3.dcccxxii}$$

The same error bounds the difference between $\sum_i \|\chi_i v\|_X^2$ and $\|v\|_X^2$. ■

Proof. Split the gauge form as $\|D_U^\sharp v\|_2^2-\langle v,D_UPD_U^\sharp v\rangle$. For the smoothing term put $u=\ell^{-1}v$ and use eq. 3.dcccxix. The exact double-cutoff expansion eq. 3.dcclvi bounds its cell error by $CR^{-2}(1+d_\ell(y,z))^2$ times the entry norm, using the within-cell and pair estimates in eq. 3.dcccxxi. The exponential moments give $CR^{-2}\|u\|_2^2$ by Schur.

The remaining divergence matrix has fine range 2η and physical coefficients $C\eta^{-2}$. Its squared cutoff difference is $C\eta^2/(R^2\mathsf{L}^2)$, cancelling the fine denominator. The Wilson Hessian is a sum of the same kind of finite plaquette matrices, including at its true boundary. The row-mass and actual constraint-curvature matrices have bounded mass-normalized physical Schur sums and bounded carrier diameter in the layer metric. Their double-cutoff errors have the same mass bound. This proves eq. 3.dcccxxii. The local unitary-shift calculation gives the X identity. A zero-extension boundary jump has only one nonzero field value, so the identity $\sum_i \chi_i^2=1$ makes its contribution exact. No exterior cutoff extension or action bond is required. □

3.21.3. *Shielding on the same determining geometry.*

Lemma 3.69 (Localized comparison of the actual projector)**.** Let two admitted real backgrounds have the same determining geometry and agree in common local frames on $Q_{24R\xi_0}$. Suppose all assigned scales there are comparable to ξ_0 within a fixed factor depending on L. For its core $Q_{2R\xi_0}$,

$$\|1_{\mathrm{core}}(R_1-R_2)1_{\mathrm{core}}\|_{2\to2}\le Ce^{-cR}. \tag{3.dcccxxiii}$$

Only the current-free site and normalized Gram package is used. ■

Proof. Use a cutoff supported strictly inside the agreement cube in

$$\theta G_1-G_2\theta=G_2(A_{s,2}\theta-\theta A_{s,1})G_1. \tag{3.dcccxxiv}$$

The middle operator is a gradient or actual site-row commutator in a buffer annulus. Its energy-to-dual-energy norm has the physical scale. Weighted site estimates make the two solutions exponentially small there. The compressed fine inverse difference is consequently $C\xi_0^2e^{-cR}$, with the corresponding localized energy-derivative bound. No exterior connection coefficients have been subtracted.

Apply this comparison to $F=Gq^\sharp\Xi^{-2}$. All local scale factors are comparable to ξ_0, so its inverse-length factors cancel the site-inverse scale. The normalized cell-L^2 comparison is Ce^{-cR}. Compress the Gram matrices to an intermediate top box. Their difference is Ce^{-cR} in operator norm, by splitting the F outputs into the common interior and their tails. Both compressions retain the uniform positive gap.

Their inverse difference is therefore Ce^{-cR}. The exact compression-inverse identity eq. 3.dcclxi, applied to these normalized matrices with the physical top measures, compares each compressed inverse with its global inverse. The boundary term is exponentially small by the weighted Gram estimate. Insert this and the $F^\sharp$ source tails into $P=FM^{-1}F^\sharp$. This proves eq. 3.dcccxxiii. These are operator estimates on arbitrary supported vectors, not sums of separate errors over a patch volume. □

3.21.4. *Local fields and the bare action boundary.* For an interior patch of scale ξ_0, choose a comb frame on $Q_{32R\xi_0}$. At most two adjacent scales occur there when $\rho \geq C_L R$. The local potential is bounded by $C_L R\kappa\xi_0^{-1}$. Multiply it by a cutoff equal to one on $Q_{24R\xi_0}$, vanishing farther out while still inside Ω_0. On the original active graph put $U_i^{\mathrm{ext}} = e^{i\eta A_i^{\mathrm{ext}}}$, and put the identity connection elsewhere. The local logarithm and product rules give

$$\sup_b \mathsf{L}(b)|A_i^{\mathrm{ext}}(b)| \leq C_L R\kappa, \qquad \sup_p \mathsf{L}(p)^2|F_i^{\mathrm{ext}}(p)| \leq C_L(\kappa + R^2\kappa^2). \tag{3.dcccxxv}$$

The cutoff derivative contributes $(R\xi_0)^{-1}(R\kappa\xi_0^{-1})$, with the required curvature units. All its averages use the original geometry.

A nonbare center has the surrounding cube inside Ω_0 by separation. For a bare center either it is also interior, or its whole field support is in a bare outer collar. In that case $Q_0 v_i = v_i$, no higher row carrier reaches its support, and its nonlinear constraint Hessian vanishes. The true inner Wilson lower bound and positive gauge give

$$K_{U,\omega}(v_i, v_i) \geq (d_* - C\kappa)\eta^{-2}\|v_i\|_2^2 \geq c_b\|v_i\|_X^2. \tag{3.dcccxxvi}$$

Here $d_* = \inf_c \xi_c^2 a_f(c) > 0$ is the lower field-row weight. The last inequality uses only the fine finite-difference bound $\|\nabla v_i^0\|_2 \leq C\eta^{-1}\|v_i\|_2$. This is a boundary estimate for the actual inner action.

3.21.5. *The real all-layer precision and saddle inverse.*

Proposition 3.70 (Uniform nonflat precision on the determining region)**.** There are fixed positive constants ρ_*, κ_*, γ_*, c and C such that, for every depth, compatible volume and separated aligned determining geometry with $\rho \geq \rho_*$, a real field with

$$\sup_{p\subset\Omega_0} \mathsf{L}(p)^2|F_U(p)| \leq \kappa_*, \qquad \sup_{c\in\mathbf{B}} \xi_c^3|\omega(c)| \leq \gamma_* \tag{3.dcccxxvii}$$

satisfies

$$c\|v\|_X^2 \leq K_{U,\omega}(v, v) \leq C\|v\|_X^2. \tag{3.dcccxxviii}$$

The constants depend only on L and the positive weight bounds. The form uses the actual inner Wilson Hessian, projected gauge and nonlinear straightened-constraint curvature. ■

Proof. Initially pass to a finite periodic cover large enough for the patches. Fix the initial curvature ceiling for the site estimates. It gives fixed normalized column and Gram constants and a rate s_0. The flat gap gives a fixed lower constant. Choose R large enough that CR^{-2} and Ce^{-cR} are smaller than a quarter of the common-gauge lower constant. Choose ρ to satisfy the flat patch conditions, eq. 3.dcccxx, and every fixed $C_L R$ collar inequality. These prior constants are uniform above their initial separation thresholds. Finally reduce κ_*, γ_* so eq. 3.dcccxxv admits every local mean and meets eq. 3.dcccxvii. This order does not use the depth.

Use eq. 3.dcccxxi. For an interior $v_i = \chi_i v$, change to its local comb frame and retain ω, a_f on every carrier meeting its support. Extend those coefficients elsewhere with the same bounds. Fixed gauge changes conjugate the actual means, their first and second derivatives and the site projector by the matching unitary fine and top rotations. The forms are unchanged. All local terms of the comparison field therefore agree exactly on v_i. Only R differs.

For a real orthogonal projector, $\|Rf\|^2 = \langle f, Rf\rangle$. Apply Lem. 3.69 to $f = D_U^\sharp v_i$; its support is inside the core. Thus

$$|K_{U,\omega}(v_i, v_i) - K_{U_i^{\mathrm{ext}},\omega_i}(v_i, v_i)| \leq Ce^{-cR}\|v_i\|_X^2.$$

The extension has a global small weighted potential relative to the identity on the same active graph, so Cor. 3.67 applies. Boundary patches have the direct estimate eq. 3.dcccxxvi. Sum these local lower bounds and use Lem. 3.68; the chosen errors are absorbed. The upper bound follows

from the local Wilson coefficient estimate, orthogonality of R, physical row bounds and the two-leg constraint moment.

On a smaller original torus the actual local rows, physical transposes and Ξ commute with pullback to the finite cover. Uniqueness of the gapped site equation and then the normalized Gram equation makes their inverses preserve deck-invariant subspaces. Thus the actual projector descends exactly. The full form and the squared X norm have the same sheet-count factor. Divide the cover estimate by that factor. No global almost-flat gauge or topology restriction is used. □

Let $X_L = \ker(R_U D_U^\sharp)$ and $K_L = D^2 A_{\Omega_0}(U) - B_\omega$. On $X_L \cap \ker Q_U$, both positive penalties vanish exactly. Coercivity there and the true-row inf-sup eq. 3.dccxcv prove the actual saddle estimate

$$K_L u - Q_U^\sharp \mu = f \text{ on } X_L, \qquad Q_U u = b, \qquad \|u\|_X + \|\mu\|_{Y^*} \le C(\|f\|_{X_L^*} + \|b\|_Y). \tag{3.dcccxxix}$$

Explicitly write $u = E_L b + z$, solve the coercive kernel equation for z, and define $\langle \mu, b' \rangle = (K_L u - f)(E_L b')$. Every $w \in X_L$ splits as $w - E_L Q_U w + E_L Q_U w$, proving the full equation. Kernel coercivity and surjectivity give uniqueness. This bounds a linearized saddle with its actual small multiplier; it does not construct the critical background.

3.21.6. *Exponential energy kernels in the physical layer metric.* The energy inverse also has a quantitative spatial consequence. Let $G_f = K_{U,\omega}^{-1}$, and let 1_y restrict fields to an assigned cell. With d the original physical layer metric,

$$\begin{aligned} \|1_y G_f 1_z\|_{2\to 2} &\le C\xi_y \xi_z e^{-md(y,z)}, \\ \|1_y \nabla_U G_f 1_z\|_{2\to 2} &\le C\xi_z e^{-md(y,z)}, \\ \|1_y G_f \nabla_U^\sharp 1_z\|_{2\to 2} &\le C\xi_y e^{-md(y,z)}, \\ \|1_y \nabla_U G_f \nabla_U^\sharp 1_z\|_{2\to 2} &\le C e^{-md(y,z)}. \end{aligned} \tag{3.dcccxxx}$$

Here ∇_U is the comparison component gradient defining X; its adjoint in the last two lines is the corresponding typed force source. The norms include all physical cell measures. These are cell operator estimates, not pointwise bounds at the fine Green singularity.

To prove them, conjugate by $w = e^{s\psi}$ for bounded one-Lipschitz ψ in d_ℓ. A local derivative commutator has size $C|s|\ell^{-1}$, so the local Wilson and divergence forms change by $C|s|$ in the two X norms. The normalized nonlocal term in eq. 3.dcccxix has conjugated difference $C|s|$ in physical L^2 norm, by the weighted column and Gram resolvent arguments. The row and constraint terms have bounded normalized Schur sums and fixed metric carrier radius; their differences have that same $C|s|$ bound. Thus

$$\|w K_{U,\omega} w^{-1} - K_{U,\omega}\|_{X \to X^*} \le C|s|. \tag{3.dcccxxxi}$$

The real lower bound and a normalized Neumann series imply $\|w G_f w^{-1}\|_{X^* \to X} \le C$ for a fixed small s. Converting a force supported in B_z to the dual energy norm costs at most $C\xi_z$; converting output energy to $L^2(B_y)$ costs at most $C\xi_y$. Choose ψ to be a truncated distance from the source cell. Its within-cell oscillation is bounded. This proves the first two lines of eq. 3.dcccxxx. A gradient-adjoint source has dual norm bounded by its L^2 norm, with no scale factor. The same argument proves the last two lines, including the single-step support enlargement of that source.

After increasing the fixed separation once more so that $8 \log L/\rho < m/2$, the metric ball count makes their normalized row and column sums finite. In particular, if $\sup_z \xi_z \|f\|_{2,B_z} \le B$, then

$$\sup_y \left\{ \xi_y^{-1} \|G_f f\|_{2,B_y} + \|\nabla_U G_f f\|_{2,B_y} \right\} \le CB. \tag{3.dcccxxxii}$$

Indeed the scale factors in the first two kernel lines cancel these input and output amplitudes before the exponential cell sum is taken. This is an energy response estimate uniform in the number of fine bonds in each pillar.

3.21.7. *The scope of the current extension.* The explicit current bound eq. 3.dccxcvii also makes

$$\widetilde{K}[J,\omega] = D^2 A_{\Omega_0}(U) - \mathcal{B}_U[J] + D_U R_U D_U^\sharp + Q_U^\sharp a_f Q_U - S^\sharp \Delta^{(2)}[\omega] S \tag{3.dcccxxxiii}$$

coercive for sufficiently small $\sup_b \mathsf{L}(b)^3|J(b)|$ and $\sup_c \xi_c^3|\omega(c)|$. First apply eq. 3.dcccxxviii at zero multiplier and then absorb the two explicit relative form estimates. On X_L, S is the identity and every term in $\mathcal{B}_U[J]$ has a zero horizontal gauge factor. Its restriction to the constraint kernel is therefore the same Lagrangian Hessian when ω is the actual multiplier.

Prop. 3.90 identifies this completion with the specified canonical current correction. Prop. 3.73 supplies the induced readout, and Props. 3.92, 3.171 and 3.174 supply the strong outputs, carrier families and nonlinear response. The absolute soft contour precision retains its separate gauge-restoration comparison.

3.22. **Coarse Schur kernels and the induced current.** The current in the second explicit precision is obtained by transposing a minimizing field lift. An energy bound for that lift alone would charge the whole volume of a bounded current. We prove exponential energy columns and sum them in the actual layer metric. This gives the required weighted supremum bound for the induced row multiplier without a fine pointwise Green estimate.

Keep the real background and determining geometry of Prop. 3.70. Currents below may be complex, but the background is real. Every transpose in an analytic formula is the physical bilinear transpose. Hilbert norms use the complexification of the real physical spaces. Let

$$\begin{aligned} \mathcal{K}_0 &= D^2 A_{\Omega_0}(U) + D_U R D_U^\sharp + Q^\sharp a_f Q, \\ \mathcal{K}_J &= \mathcal{K}_0 - \mathcal{B}_U[J], \qquad G_J = \mathcal{K}_J^{-1}, \\ \gamma_J &= \sup_b \mathsf{L}(b)^3 |J(b)|. \end{aligned} \tag{3.dcccxxxiv}$$

This is the displayed symmetric current extension, with $\mathcal{B}_U[J]$ defined by its endpoint formula. It is not identified here with another named completion.

The field-row Hilbert space $\mathcal{H}_\Gamma$ has measure ξ_c^4. Write $\Xi_\Gamma b(c) = \xi_c b(c)$, so that $\mathcal{U}_\Gamma = \Xi_\Gamma^2$ is unitary from $\mathcal{H}_\Gamma$ to the counting ℓ^2 space. This is a field-row scale. At an outward row it is the row's assigned level, even when one endpoint is a top of the smaller level. It is not the site-scale operator Ξ.

3.22.1. *Weighted restoration for the current correction.*

Lemma 3.71 (Restoration with a spatial exponential weight)**.** For a fixed small $s_* > 0$, a bounded one-Lipschitz function ψ for d_ℓ, and $w = e^{s\psi}$, $|s| \le s_*$, the actual maps satisfy

$$\|\ell^{-2} w \Lambda w^{-1} v\|_2 + \|w D_U \Lambda w^{-1} v\|_X + \|w S w^{-1} v\|_X \le C \|v\|_X. \tag{3.dcccxxxv}$$

Consequently

$$\|w \mathcal{B}_U[J] w^{-1}\|_{X \to X^*} \le C \gamma_J. \tag{3.dcccxxxvi}$$

No derivative of J or second derivative of ψ is a premise. ■

Proof. For $\lambda = \Lambda w^{-1} v$, put $f = L_U \lambda = R D_U^\sharp w^{-1} v$. The weighted site projector bound and the first derivative commutator give $\|wf\|_2 \le C\|v\|_X$. Also $q\lambda = 0$, including the bare collar.

Repeat the zero-average proof with the combined scalar weight $h_w = \ell^{-1} e^{s\psi}$. Its relative first difference is bounded by $C(\delta + |s|)/\ell$. Subtract $h_w(y) q\lambda = 0$ in each pillar. The site-gap average error is now at most

$$C_L(\delta + |s|)\|\ell^{-2} w \lambda\|_2.$$

Testing $L_U \lambda = f$ against $h_w^2 \lambda$ and using the exact weighted Green identity proves

$$\|\ell^{-2} w \lambda\|_2 + \|\ell^{-1} w D_U \lambda\|_2 \le C \|wf\|_2,$$

after reducing s_*. The weighted Hodge calculation for $wD_U\lambda$ contains only first weight differences. Its divergence is wf plus $O(|s|\ell^{-1}wD_U\lambda)$; its curl is weighted curvature times λ, plus that same first-weight error. Thus its component-gradient energy is bounded by $C\|wf\|_2^2$. The zero-average bare collar keeps every nonzero stencil inside the action region, exactly as before. This proves eq. 3.dcccxxxv.

Use the four undifferentiated-current pairings in eq. 3.cdlxix. Apply the restoration bounds with both signs of s. The endpoint ratios of w in $\mathcal{W}_U[J]$ are bounded uniformly, since an endpoint step has bounded metric length. Each pairing is therefore bounded by $C\gamma_J\|u\|_X\|v\|_X$. This proves eq. 3.dcccxxxvi. □

The weighted inverse of $\mathcal{K}_0$ is bounded from X^* to X by the already proved field Combes argument. For sufficiently small γ_J, the normalized Neumann series using eq. 3.dcccxxxvi gives

$$\|wG_Jw^{-1}\|_{X^*\to X}\le C. \tag{3.dcccxxxvii}$$

This proof applies to complex currents. It invokes positivity only at the real zero-current reference; it asserts no Hermitian positivity at a complex current.

3.22.2. *The normalized coarse Schur matrix.* Define

$$S_J=QG_JQ^\sharp,\quad T_J=a_f^{1/2}S_Ja_f^{1/2},\quad T_J^{\mathrm{n}}=\Xi_\Gamma^2T_J\Xi_\Gamma^{-2}. \tag{3.dcccxxxviii}$$

The last matrix acts in counting orthonormal coordinates. Give a row c the metric location of one incident top at its row level. Its carrier is within bounded layer-metric distance of that top, and at most eight rows are assigned to a top. The row ball count has the same growth rate as the top count.

Proposition 3.72 (Uniform normalized Schur inverse)**.** For sufficiently small γ_J, S_J is invertible and

$$|(T_J^{\mathrm{n}})^{-1}(c,d)|\le Ce^{-md(c,d)}. \tag{3.dcccxxxix}$$

The constants are independent of depth, compatible volume and the current. After increasing the fixed separation so the metric growth rate is less than $m/2$, this inverse is bounded on counting ℓ^∞. Equivalently T_J^{-1} is bounded in the coarse amplitude norm $\sup_c\xi_c^2|\beta(c)|$. ■

Proof. At $J=0$, T_0 has a positive lower and upper bound. For the lower bound take the exact field-row right inverse E_Q, or $E_L=SE_Q$, and put $v=E_Qa_f^{-1/2}\beta$. Its $\mathcal{K}_0$ energy is at most $C\|\beta\|_{\mathcal{H}_\Gamma}^2$. Since $Qv=a_f^{-1/2}\beta$,

$$\begin{aligned}\|\beta\|_{\mathcal{H}_\Gamma}^2&=\langle Q^\sharp a_f^{1/2}\beta,E_Qa_f^{-1/2}\beta\rangle\\&\le C\langle\beta,T_0\beta\rangle^{1/2}\|\beta\|_{\mathcal{H}_\Gamma}.\end{aligned} \tag{3.dcccxl}$$

The upper bound follows from the energy inverse and the bounded trace $a_f^{1/2}Q:X\to\mathcal{H}_\Gamma$. No positivity of a different effective coarse action has been used.

Let w_Γ sample $e^{s\psi}$ at the row locations. The finite metric carriers of the actual rows imply

$$\|w_\Gamma a_f^{1/2}Qw^{-1}-a_f^{1/2}Q\|_{X\to\mathcal{H}_\Gamma}\le C|s|.$$

The weighted base inverse differs from its original value by $C|s|$. Its current perturbation differs from the weighted base inverse by $C\gamma_J$, by the same normalized Neumann series as in eq. 3.dcccxxxvii. Therefore

$$\|w_\Gamma T_Jw_\Gamma^{-1}-T_0\|\le C(|s|+\gamma_J). \tag{3.dcccxli}$$

Choose s and the current ceiling so the right side is less than half the real lower constant of T_0. The inverse of the conjugated T_J is uniformly bounded. Truncated distance weights give exponential entries between physical orthonormal row cells, which are precisely $(T_J^{\mathrm{n}})^{-1}(c,d)$. The cell count and a strict rate reserve give the stated ℓ^∞ bound. □

For reference, these normalizations imply the counting-array and physical-kernel bounds

$$|S_J^{-1}(c,d)|_{\text{array}} \le C\xi_c^{-3}\xi_d e^{-md(c,d)}, \qquad |S_J^{-1}(c,d)|_{\text{physical}} \le C\xi_c^{-3}\xi_d^{-3}e^{-md(c,d)}. \tag{3.dcccxlii}$$

Indeed $S_J^{-1} = a_f^{1/2}T_J^{-1}a_f^{1/2}$, and converting its array to a physical kernel divides by the input measure ξ_d^4. These are different conventions for the same operator.

3.22.3. *The actual minimizing lift and the induced multiplier.* Define the actual first-variant lift by

$$\widehat{H}_J = G_J Q^\sharp S_J^{-1}, \qquad Q\widehat{H}_J = 1. \tag{3.dcccxliii}$$

It has the useful normalized representation

$$\widehat{H}_J a_f^{-1/2} = G_J Q^\sharp a_f^{1/2} T_J^{-1}. \tag{3.dcccxliv}$$

The weighted inverse, trace and normalized Schur bounds make this a bounded weighted operator from $\mathcal{H}_\Gamma$ to X. In particular, with X_y the cell component energy and a fixed one-fine-step collar for its derivatives,

$$\|1_y\widehat{H}_J 1_c b\|_{X_y} \le Ce^{-md(y,c)}\|1_c b\|_Y. \tag{3.dcccxlv}$$

This follows directly by a distance weight centered at c; it does not require summing an unnormalized fine kernel.

Proposition 3.73 (The actual induced row current has its physical amplitude)**.** For the displayed first precision and its actual lift, put

$$\omega_J = \widehat{H}_J^\sharp J. \tag{3.dcccxlvi}$$

For sufficiently small γ_J,

$$\sup_c \xi_c^3|\omega_J(c)| \le C\gamma_J. \tag{3.dcccxlvii}$$

This holds uniformly over all assigned scales, determining regions and compatible volumes, including bare and outward rows. It is valid for complex independent currents on the stated small ball. ■

Proof. Fix a row c and a unit colour e. Take the datum $b^{(c)}(c) = \xi_c^{-1}e$, zero elsewhere. Its squared Y norm is $\xi_c^2 a_f(c)$, bounded above and below by fixed constants. Physical transposition gives the exact dimensional identity

$$\xi_c^3\langle e, \omega_J(c)\rangle = \langle \widehat{H}_J b^{(c)}, J\rangle_{\text{fine}}. \tag{3.dcccxlviii}$$

On a cell of side ξ_y, the current assumption implies

$$\|\xi J\|_{2,B_y} \le C_L\gamma_J. \tag{3.dcccxlix}$$

Indeed its physical volume is ξ_y^4, while the current amplitude is at most $C_L\gamma_J\xi_y^{-3}$. Pair cell by cell in eq. 3.dcccxlviii:

$$|\xi_c^3\langle e, \omega_J(c)\rangle| \le \sum_y \|\xi J\|_{2,B_y}\|\xi^{-1}\widehat{H}_J b^{(c)}\|_{2,B_y} \le C\gamma_J \sum_y e^{-md(y,c)}.$$

Increase the fixed separation, if necessary, so that its growth rate is below $m/2$. The last sum is uniform. Taking the three colour components proves eq. 3.dcccxlvii. For complex currents the same bilinear identity and absolute Cauchy–Schwarz bound apply; no current was replaced by the Wilson gradient. □

At a bare row this proof is still dimensionally exact. The cell force norm is $\eta\|J\|_2 = O(\gamma_J)$, the unit energy datum has size η^{-1}, and its physical row dual has size $\eta^3\omega$. No ultraviolet factor was discarded.

3.22.4. *Exponential coupled kernels.* The full penalized saddle equations have an explicit inverse:

$$\begin{aligned} \mathcal{K}_J u - Q^\sharp \mu = f, \qquad Qu = b, \\ u = (G_J - \widehat{H}_J Q G_J) f + \widehat{H}_J b, \\ \mu = S_J^{-1}(b - Q G_J f). \end{aligned} \tag{3.dcccl}$$

All normalized factors on the right have uniformly bounded weighted energy norms. The same holds for the resulting block inverse. It consequently has exponential cell kernels with the physical force and datum normalizations: a force cell costs $\xi_z \|f\|_{2,B_z}$, a datum row costs $\|b\|_{Y_c}$, a field output is measured in X_y, and a multiplier output is measured by $\xi_c^3 |\mu(c)|$, up to its fixed weight constant. In particular

$$\|u\|_X + \|\mu\|_{Y^*} \le C(\|f\|_{X^*} + \|b\|_Y). \tag{3.dcccli}$$

Removing the artificial row-mass term from the first equation changes its multiplier to $\mu - a_f b$, a local bounded map in Y^*. It preserves these bounds and spatial kernels.

For an independent current the minimizing lift is not asserted to lie in the Landau slice. Its exact off-current slice defect is the one in eq. 3.cdlxxiv. The coupled formula above keeps the displayed gauge penalty.

3.22.5. *The second explicit variant is admitted.* Now define, in the prescribed order,

$$\mathcal{K}_{1,J} = \mathcal{K}_J - S^\sharp \Delta^{(2)}[\omega_J] S, \qquad \omega_J = \widehat{H}_J^\sharp J. \tag{3.dcccllii}$$

The lift inside ω_J is the first-variant lift in eq. 3.dcccxliii. Replacing it by the lift formed from $\mathcal{K}_{1,J}$ would be a different definition.

The new term has energy norm at most $C\gamma_J$, by eq. 3.dcccxlvii and the actual two-leg constraint estimate. Its conjugated norm has that same bound: the row carrier has fixed metric radius and the two restoration factors have eq. 3.dcccxxxv. Thus a further fixed decrease of the current ceiling makes $\mathcal{K}_{1,J}$ invertible with the same weighted energy bounds. Its normalized coarse Schur matrix, lift and coupled inverse satisfy the same conclusions. This proves admission of the second displayed variant, rather than merely bounding a constraint form at a freely chosen small multiplier.

The maps are holomorphic in the independent current ball. The first inverse, normalized Schur inverse and lift are convergent analytic inverses there; the readout $\widehat{H}_J^\sharp J$ is consequently holomorphic, and so is the second precision and its inverse. The transpose is bilinear throughout this continuation.

3.22.6. *The physical slice.* If $J = j_U$ is the actual Wilson current, the inner-action Ward identity and the displayed current correction give

$$G_J D_U R = D_U G R. \tag{3.dcccliii}$$

The second subtraction annihilates $D_U G R$, since $S D_U G R = 0$, so this identity also holds for $G_{1,J} = \mathcal{K}_{1,J}^{-1}$. Transposition and $Q D_U G R = \bar{D}_{\mathrm{ext}} q G R = 0$ imply that its row lift is horizontal. With that second lift $\widehat{H}_{1,J}$, set $C_1 = G_{1,J} - \widehat{H}_{1,J} Q G_{1,J}$. Then $C_1 S^\sharp f$ is both horizontal and in $\ker Q$: the gauge cancellation is $(S D_U G R)^\sharp = 0$. These identities use the actual extended outward difference.

At an actual constrained critical point, full stationarity is $j_U = Q^\sharp \omega_{\mathrm{phys}}$. Since $Q\widehat{H}_J = 1$, it follows exactly that $\omega_J = \omega_{\mathrm{phys}}$. In particular the induced-current theorem bounds the actual multiplier at every layer if the actual current has its stated small amplitude. The full stationarity equation can be deduced from criticality on the actual horizontal constraint kernel: S preserves Q, and the Ward identity annihilates the gauge part $1 - S$. It is not inferred from criticality on an unidentified slice.

On horizontal vectors the Ward correction vanishes and $S = 1$. Therefore the second form restricts to the actual Lagrangian Hessian plus the row-mass term. The formula

$$u = C_1 S^\sharp f + \widehat{H}_{1,J} b$$

is the physical horizontal saddle solution, with its multiplier adjusted by $-a_f b$ when the row mass is removed. Its exponential energy kernels follow from the weighted factors already proved. No fine pointwise inverse has been used to obtain this physical slice statement.

The conclusions concern the two displayed current extensions. They do not identify another independently named $\Delta'_\pi[J]$, nor a signed-profile precision or the absolute contour precision. Fine pointwise and Hölder responses, moving complex background slices and the nonlinear trial-field construction remain further tasks.

3.23. **A complex inverse on the moving Landau slice.** The real proper-region estimate has a uniform complex neighbourhood. The relevant slice moves because its site projection and covariant divergence depend on the background. We first continue the site operators by a balanced physical form. We then solve a saddle problem with a fixed target space for both constraints. Its zero gauge datum is exactly the moving Landau condition.

The geometry, scales, bare collars and outward rows remain those of Prop. 3.70. Fix a real background U_0 with the curvature ceiling there reduced by a factor of two. All comparison norms and ℓ in this section refer to this fixed geometry and real frame. Write

$$U_A(b) = e^{i\eta A(b)} U_0(b), \qquad \|A\|_{\mathcal{T}} = \sup_b \ell(b)|A(b)| + \sup \ell^2 |\nabla_{U_0} A| < \varepsilon_*. \tag{3.dcccliv}$$

The comparison derivatives use the same zero-extension convention as X. At the bare boundary $\ell = \eta$, so the boundary step also has this scale. The field A may be complex. Transposes of analytic operators are bilinear physical transposes, not conjugate transposes.

3.23.1. *Uniform continuation of the actual site projection.* For this section use a subscript A for actual objects at U_A, and a subscript 0 for the real reference. In particular

$$\begin{aligned} A_{s,A} &= D_A^\sharp D_A + q_A^\sharp a_s q_A, \qquad G_{s,A} = A_{s,A}^{-1}, \\ F_A &= G_{s,A} q_A^\sharp \Xi^{-2}, \qquad M_A = F_A^\sharp F_A, \qquad R_A = 1 - F_A M_A^{-1} F_A^\sharp. \end{aligned} \tag{3.dccclv}$$

Here Ξ is the site-top scale, not the field-row scale.

Lemma 3.74 (Balanced complex site form)**.** For a fixed small ε_*, all operators in eq. 3.dccclv are defined and holomorphic throughout eq. 3.dcccliv. With physical Hilbert operator norms,

$$\|F_A - F_0\| + \|\ell D_0 (F_A - F_0)\| + \|M_A - M_0\| + \|R_A - R_0\| \le C\|A\|_{\mathcal{T}}. \tag{3.dccclvi}$$

Moreover $R_A^\sharp = R_A$, $R_A^2 = R_A$, and

$$q_A G_{s,A} R_A = 0, \qquad D_A^\sharp D_A G_{s,A} R_A = R_A. \tag{3.dccclvii}$$

No complex orthogonality is claimed. ■

Proof. The actual transport paths have length at most a fixed multiple of their row scale. On their carriers ℓ is comparable to that scale. Telescoping their transports therefore gives, for each of the finitely many powers $r = -2, -1, 0, 1, 2$,

$$\begin{aligned} \|\Xi^{-r}(q_A - q_0)\ell^r\| &\le C\|A\|_{\mathcal{T}}, \\ \|\ell(D_A - D_0)u\|_2 &\le C\|A\|_{\mathcal{T}}\|u\|_2, \\ \|a_f^{1/2}(Q_A - Q_0)v\|_{\mathcal{H}_\Gamma} &\le C\|A\|_{\mathcal{T}}\|\ell^{-1}v\|_2. \end{aligned} \tag{3.dccclviii}$$

The same estimates follow for the transposes. Physical carrier Schur sums, rather than the number of fine sites in a carrier, are used. The local logarithms remain in their common analytic charts after a fixed decrease of ε_*. The geometric sum of path lengths through successive homogeneous subscales is bounded by the final path scale. Thus these comparisons are independent of depth. They include completed outward rows; the identity $Q_A D_A = \bar{D}_{\mathrm{ext},A} q_A$ is kept with its actual extension.

Put

$$\|u\|_{Z_+}^2 = \|\ell D_0 u\|_2^2 + \|q_0 u\|_{\mathrm{top}}^2.$$

The real block inequality gives $\|u\|_2 \le C\|u\|_{Z_+}$. Consider the sesquilinear testing form $\mathfrak{a}_A(u,v) = \langle A_{s,A}u, \ell^2\overline{v}\rangle_{\mathrm{bil}}$. At the real reference its weighted Green identity, and the $O(\delta)$ average commutator, give

$$\mathrm{Re}\,\mathfrak{a}_0(u,u) \ge c\|u\|_{Z_+}^2, \qquad |\mathfrak{a}_A(u,v) - \mathfrak{a}_0(u,v)| \le C\|A\|_{\mathcal{T}}\|u\|_{Z_+}\|v\|_{Z_+}. \tag{3.dccclix}$$

Indeed a derivative error is $O(\varepsilon_*\ell^{-1}u)$ before multiplication by ℓ; the row errors in the test $q_A(\ell^2 v)$ are cancelled by the Ξ^{-2} site mass. The first differences of ℓ cost $O(\delta)$. Choose δ as in the real proof and then ε_* small. This is a coercive perturbation on Z_+.

The source for $F_A b$ obeys

$$|\langle q_A^\sharp \Xi^{-2} b, \ell^2\overline{v}\rangle_{\mathrm{bil}}| \le C\|b\|_{\mathrm{top}}\|v\|_{Z_+}.$$

Its difference from the real source is $O(\|A\|_{\mathcal{T}})$ in that dual norm. Solving the balanced form and subtracting the two equations proves the first two bounds in eq. 3.dccclvi. This also proves holomorphy by a form Neumann series on fixed spaces; the testing weight does not depend on A.

The real normalized Gram lower bound implies M_0^{-1} is uniformly bounded. The L^2 bound for $F_A - F_0$ gives $M_A - M_0 = O(\|A\|_{\mathcal{T}})$. Its inverse and the last bound in eq. 3.dccclvi follow by another Neumann series. The projection algebra in eq. 3.dccclv is bilinear algebra, so it continues exactly. Since $F_A^\sharp R_A = 0$ and $G_{s,A}^\sharp = G_{s,A}$, the first identity in eq. 3.dccclvii follows. Apply $A_{s,A}G_{s,A} = 1$ to obtain the second. □

3.23.2. *Two physical derivatives in the complex zero-average space.*

Lemma 3.75 (Complex gauge restoration)**.** If $q_A\lambda = 0$ and $D_A^\sharp D_A\lambda = f$, then

$$\|\ell^{-2}\lambda\|_2 + \|\ell^{-1}D_0\lambda\|_2 + \|\nabla_0 D_A\lambda\|_2 \le C\|f\|_2. \tag{3.dccclx}$$

Consequently

$$\Lambda_A = G_{s,A}R_A D_A^\sharp, \qquad S_A = 1 - D_A\Lambda_A \tag{3.dccclxi}$$

are bounded holomorphic maps in their physical norms, with $\|D_A\Lambda_A v\|_X + \|S_A v\|_X \le C\|v\|_X$. Exactly

$$R_A D_A^\sharp S_A = 0, \qquad Q_A S_A = Q_A. \qquad \blacksquare$$

Proof. Apply the real weighted site gap to $\ell^{-1}\lambda$. In its average term insert $q_A\lambda = 0$. The weight commutator costs $C\delta\|\ell^{-2}\lambda\|_2$, and eq. 3.dccclviii costs $C\varepsilon_*\|\ell^{-2}\lambda\|_2$. After absorption,

$$\|\ell^{-2}\lambda\|_2 \le C\|D_0(\ell^{-1}\lambda)\|_2.$$

Test the complex equation against $\ell^{-2}\overline{\lambda}$, and compare its bilinear form with the real reference form. The exact real weighted Green identity has an $O(\delta^2)\|\ell^{-2}\lambda\|_2^2$ error. Each complex derivative perturbation contributes at most

$$C\varepsilon_*(\|\ell^{-1}D_0\lambda\|_2 + \|\ell^{-2}\lambda\|_2)^2.$$

Absorb these errors using the preceding gap. The forcing pairing is bounded by $\|f\|_2\|\ell^{-2}\lambda\|_2$. This proves the first two terms of eq. 3.dccclx, without a derivative of A.

For the last term the C^1 part of the tube is used. Expanding the actual covariant stencils gives

$$\|(D_0^\sharp D_0 - D_A^\sharp D_A)\lambda\|_2 + \|\nabla_0(D_A - D_0)\lambda\|_2 \le C\varepsilon_*(\|\ell^{-1}D_0\lambda\|_2 + \|\ell^{-2}\lambda\|_2). \tag{3.dccclxii}$$

The differentiated transport difference contains $\nabla_0 A$, $AD_0\lambda$, and $A^2\lambda$. Its two explicit tube powers are respectively ℓ^{-2}, ℓ^{-1}, and ℓ^{-2}; there is no second derivative of A. The bare row is still the identity, so $\lambda = 0$ on the same bare collar. Extend it by zero and apply the real covariant Hodge estimate eq. 3.dlxviii to $D_0\lambda$. Every nonzero second-derivative stencil stays inside the inner-plaquette region. Equation eq. 3.dccclxii and the first two bounds give the final term in eq. 3.dccclx.

Take $\lambda = G_{s,A} R_A D_A^\sharp v$. Its source has norm at most $C\|v\|_X$, and eq. 3.dccclvii supplies both equations just used. The mass term of $D_A\lambda$ follows from the same comparison. This proves the norm assertions. All maps are holomorphic in the finite coordinate system, and their uniform estimates are in the displayed spaces. Finally eq. 3.dccclvii and the actual intertwining give the two exact identities. □

3.23.3. *The combined constraint has a fixed target.* Let $Z_0 = \operatorname{ran} R_0$, with its physical L^2 norm. Define the combined constraint on the fixed field space X by

$$\mathcal{C}_A u = (Q_A u,\ R_0 R_A D_A^\sharp u) \in Y \oplus Z_0. \tag{3.dccclxiii}$$

This use of R_0 fixes the target only. It does not replace the moving projection R_A.

Lemma 3.76. The reference constraint has a bounded exact right inverse

$$\mathcal{E}_0(b,\rho) = E_{L,0} b + D_0 G_{s,0} R_0 \rho. \tag{3.dccclxiv}$$

Also

$$\|\mathcal{C}_A - \mathcal{C}_0\|_{X \to Y \oplus Z_0} \le C\|A\|_{\mathcal{T}}. \tag{3.dccclxv}$$

Thus $\mathcal{C}_A$ is onto with a uniform right inverse. Its second component is zero if and only if $R_A D_A^\sharp u = 0$. ■

Proof. The first summand of eq. 3.dccclxiv has row value b and zero reference divergence. The second has zero row value by $Q_0 D_0 G_{s,0} R_0 = \bar{D}_{\mathrm{ext},0} q_0 G_{s,0} R_0 = 0$. Its reference projected divergence is ρ, by eq. 3.dccclvii. Its energy bound is the real zero-average restoration estimate. This proves the right-inverse assertion.

For the comparison use eq. 3.dccclviii, eq. 3.dccclvi, and $\|D_0^\sharp u\|_2 \le C\|u\|_X$. Then $\mathcal{C}_A\mathcal{E}_0 = 1 + O(\varepsilon_*)$; inverting it gives a right inverse for $\mathcal{C}_A$.

If $z \in \operatorname{ran} R_A$ and $R_0 z = 0$, then $z = (R_A - R_0)z$, so $z = 0$. Also $R_0 R_A : Z_0 \to Z_0$ is $1 + O(\varepsilon_*)$. It follows that $R_0 : \operatorname{ran} R_A \to Z_0$ is an isomorphism. Apply its injectivity to $z = R_A D_A^\sharp u$ to prove the final equivalence. □

3.23.4. *The full complex saddle and its actual slice.* Let ω be a complex field-row multiplier with $\gamma_\omega = \sup_c \xi_c^3 |\omega(c)|$, and define the displayed Lagrangian Hessian

$$H_{A,\omega} = D^2 A_{\Omega_0}(U_A) - \Delta_A^{(2)}[\omega]. \tag{3.dccclxvi}$$

No current extension is part of this definition.

Proposition 3.77 (Complex saddle inverse)**.** There are depth- and volume-independent constants $\varepsilon_* > 0$ and $\gamma_* > 0$. If eq. 3.dcccliv holds and $\gamma_\omega < \gamma_*$, the system

$$\begin{aligned} H_{A,\omega} u - Q_A^\sharp \mu - D_A R_A R_0 \nu &= f, \\ Q_A u = b, \qquad R_0 R_A D_A^\sharp u &= \rho \end{aligned} \tag{3.dccclxvii}$$

has a unique solution $(u, \mu, \nu) \in X \oplus Y^* \oplus Z_0$ and

$$\|u\|_X + \|\mu\|_{Y^*} + \|\nu\|_2 \le C(\|f\|_{X^*} + \|b\|_Y + \|\rho\|_2). \tag{3.dccclxviii}$$

Its inverse is holomorphic in (A, ω) on this fixed product of spaces. At $\rho = 0$ it gives exactly the actual moving-slice saddle

$$\begin{aligned} X_L(A) = \ker(R_A D_A^\sharp), \qquad Q_A u = b, \\ H_{A,\omega} u - Q_A^\sharp \mu = f \quad \text{on } X_L(A). \end{aligned} \tag{3.dccclxix}$$

This saddle has a unique (u, μ) with the bound

$$\|u\|_X + \|\mu\|_{Y^*} \le C(\|f\|_{X_L(A)^*} + \|b\|_Y). \tag{3.dccclxx}$$

■

Proof. At $A = 0, \omega = 0$, the real proper-region gap gives coercivity of $H_{0,0}$ on $\ker \mathcal{C}_0 = X_L(0) \cap \ker Q_0$. Its full form is bounded on X. The right inverse eq. 3.dccclxiv then proves invertibility of the full reference saddle. For completeness, lift (b, ρ), solve the coercive equation on $\ker \mathcal{C}_0$, and recover the multiplier by evaluating the remaining functional on the same right inverse. This gives the full estimate, with no positivity assertion off the constraint kernel.

The actual plaquette expansion implies

$$\|H_{A,\omega} - H_{0,0}\|_{X \to X^*} \le C(\|A\|_{\mathcal{T}} + \gamma_\omega). \tag{3.dccclxxi}$$

To check the scale, the curl-row difference is bounded by $C\|A\|_{\mathcal{T}}\|\ell^{-1}v\|_2$. The physical plaquette-curvature difference is bounded by $C\|A\|_{\mathcal{T}}\ell^{-2}$, from the first covariant differences of A and the quadratic A term. The exact Wilson Hessian remainder is consequently a bounded mass-form perturbation. This is a local inner-plaquette calculation and has no boundary integration-by-parts term. The actual constraint two-leg estimate bounds the last term of eq. 3.dccclxvi by $C\gamma_\omega$ in the two energy norms. Its carrier estimates continue on the same complex charts with a uniform constant.

The transpose of the second component of $\mathcal{C}_A$ is $D_A R_A R_0$, because R_A is bilinearly symmetric. The whole operator in eq. 3.dccclxvii therefore differs from the reference saddle by $C(\|A\|_{\mathcal{T}} + \gamma_\omega)$ between fixed energy and dual-energy product spaces. The reference inverse and a Neumann series prove the first assertion and eq. 3.dccclxviii. Every entry is holomorphic, so its inverse is holomorphic there as well. Complex orthogonality and a parametrization of the moving field slice were not used.

Set $\rho = 0$. The previous lemma identifies its kernel with the actual $X_L(A)$. Testing the first equation there eliminates ν, proving eq. 3.dccclxix. Conversely, any solution of that restricted equation extends to eq. 3.dccclxvii by a unique gauge multiplier. Indeed $R_0 R_A D_A^\sharp : X \to Z_0$ is onto, and the annihilator of its kernel is its transpose range. The transpose is injective by the same right-inverse bound. Full saddle uniqueness therefore proves restricted uniqueness.

For a functional given only on $X_L(A)$, take a norm-preserving Hahn–Banach extension to X. The full bound gives eq. 3.dccclxx. Another extension changes only the eliminated gauge multiplier, so the field and physical row multiplier are independent of that choice. Holomorphic dependence is asserted for fixed-space source extensions, and requires no holomorphic choice of Hahn–Banach extensions. □

On any smaller fixed tube, Cauchy's inequality gives uniform operator jets in the displayed physical energy norms, with factorial bounds in the tube norm and in γ_ω. The result permits complex backgrounds and the actual moving Landau constraint at all assigned scales on proper determining regions. Strong outputs and the regular-pair nonlinear response are proved in Props. 3.92, 3.171 and 3.174. The C^1 background tube itself does not bound the physical Wilson current; the current is independent in these constructions.

3.24. **Uniform discrete singular-integral estimates.** The strong proper-region estimates require finite-p bounds for second derivatives of a scalar inverse. Supremum-norm bounds for these order-zero operators would be false. We extend Lem. 3.42 to arbitrary masses and periods, and derive the local heat embeddings needed for the response bootstrap. The singular-integral proof itself was given in that lemma, including the physical measure at the last atomic scale; only its new uniform parameters are checked here.

Let $\Gamma_h = h\mathbb{Z}^4$, $0 < h \le 1$, with measure h^4 times counting measure. Put

$$D_i^+ u(x) = h^{-1}(u(x + he_i) - u(x)), \qquad D_i^- u(x) = h^{-1}(u(x) - u(x - he_i)), \qquad L_h = -\sum_i D_i^- D_i^+.$$

Either sign of a difference will be allowed below. The notation $\|D^2 u\|_p$ includes all ordered component second differences. Replacing a forward by a backward difference only shifts its location and

changes fixed constants. All convolutions use physical measure:

$$(k * u)(x) = h^4 \sum_y k(x-y)u(y).$$

3.24.1. *The scalar kernels.* Let p_t^h be the physical heat density of e^{-tL_h}. The differentiated heat estimates already proved in eq. 3.dclxxxv imply, for every derivative order $a \geq 0$ and every integer N,

$$|D^a p_t^h(x)| \leq C_{a,N}(t+h^2)^{-(4+a)/2}\left(1+\frac{|x|}{\sqrt{t+h^2}}\right)^{-N}. \tag{3.dccclxxii}$$

The quoted local-time estimate extends to $t \geq 1$ on the infinite lattice by the exact scaling

$$p_t^h(x) = t^{-2} p_1^{h/\sqrt{t}}(x/\sqrt{t}).$$

Each derivative contributes a further $t^{-1/2}$. The rescaled mesh is still at most one, so the same pointwise estimate holds at every time. They also give

$$\|D^a p_t^h\|_{r,h} \leq C_{a,r}(t+h^2)^{-a/2-2(1-1/r)}, \qquad 1 \leq r \leq \infty. \tag{3.dccclxxiii}$$

For finite r, sum eq. 3.dccclxxii with $Nr > 4$; the lattice sum of the spatial factor is at most $C(t+h^2)^2$. The case $r = \infty$ is the pointwise bound. Thus these estimates include $t < h^2$.

For $\mu \geq 0$, define the second-resolvent kernel

$$k_{ij}^{h,\mu}(x) = \int_0^\infty e^{-\mu^2 t} D_i^\sigma D_j^\tau p_t^h(x)\, dt, \qquad \sigma,\tau \in \{+,-\}. \tag{3.dccclxxiv}$$

This integral converges at every lattice point, including zero: the mesh is fixed at the lower limit, and the large-time derivative bound is Ct^{-3}. For compactly supported input, its convolution is the Fourier multiplier

$$\frac{\mathrm{d}_i^\sigma(\theta)\mathrm{d}_j^\tau(\theta)}{\lambda_h(\theta)+\mu^2}, \qquad \lambda_h(\theta) = 4h^{-2}\sum_i \sin^2(h\theta_i/2), \quad \theta \in [-\pi/h, \pi/h]^4.$$

At $\mu = 0, \theta = 0$ the value of the multiplier can be assigned arbitrarily on the infinite lattice. Since $|\mathrm{d}_i^\sigma \mathrm{d}_j^\tau| \leq \lambda_h$, its L^2 operator norm is at most one.

Lemma 3.78. Uniformly in h, μ, these kernels satisfy

$$|k_{ij}^{h,\mu}(x)| \leq C(|x|+h)^{-4}, \qquad |D_\ell^\pm k_{ij}^{h,\mu}(x)| \leq C(|x|+h)^{-5}. \tag{3.dccclxxv}$$

In particular, for a lattice displacement y,

$$h^4 \sum_{|x| \geq C_0(|y|+h)} |k_{ij}^{h,\mu}(x-y) - k_{ij}^{h,\mu}(x)| \leq C \tag{3.dccclxxvi}$$

with a fixed sufficiently large C_0. ■

Proof. The mass factor can be omitted for these upper bounds. For $|x| = r \geq h$, integrate eq. 3.dccclxxii with $a = 2$, using $v = t + h^2$. For $v \leq r^2$, its bound is $Cr^{-N}v^{N/2-3}$, which has integral Cr^{-4} if $N > 4$. For $v \geq r^2$, the integral of Cv^{-3} has the same bound. At $r \leq h$ the full integral is Ch^{-4}. Using $a = 3, N > 5$ proves the derivative bound.

Join 0 to y by coordinate steps. On the region in eq. 3.dccclxxvi, all intermediate arguments are comparable in distance to x. Telescoping the derivative bound gives

$$|k(x-y) - k(x)| \leq C|y|\,|x|^{-5}.$$

On the dyadic annulus with radius $2^q(|y|+h)$, the physical number of lattice points is at most $C[2^q(|y|+h)]^4$. Summing the resulting $C|y|/[2^q(|y|+h)]$ proves the assertion. For $y = 0$ the difference is zero. □

3.24.2. *Weak type and finite-p bounds.*

Proposition 3.79 (Uniform finite-p scalar estimate)**.** For every $1 < p < \infty$,

$$\|D_i^\sigma D_j^\tau (L_h + \mu^2)^{-1} f\|_{p,h} \le C_p \|f\|_{p,h}, \qquad \mu \ge 0. \tag{3.dccclxxvii}$$

At zero mass on a finite periodic lattice the inverse is the inverse on constants' orthogonal complement; the second derivative annihilates its constant mode. The same constant is valid on every compatible periodic torus, independently of its size. ■

Proof. Write T for the infinite-lattice multiplier above. The proof of eq. 3.dclxxxix uses only the L^2 bound and its displayed kernel cancellation condition. Both have just been established for T, with constants independent of h, μ. On the infinite lattice take dyadic cubes of sides $2^n h$, $n \ge 0$. For compactly supported input their averages eventually tend to zero, so the same maximal-cube decomposition exists at every positive threshold. A parent has sixteen children of equal physical volume, which improves its average bound to 16λ. The bad part of a single-site cube is zero. Its good-part estimate and the cancellation sum outside enlarged cubes are therefore exactly the two estimates in that proof. They give weak-$(1,1)$ with the same uniform parameters. The distribution-function interpolation and adjoint duality proved there apply unchanged, giving every $1 < p < \infty$. Density defines these operators on L^p. This step reuses the proof rather than assuming a continuous singular-integral theorem for the lattice.

For $\mu > 0$, the kernel is absolutely summable at every fixed mesh and mass: by eq. 3.dccclxxiii,

$$\|k^{h,\mu}\|_{1,h} \le C \int_0^\infty e^{-\mu^2 t} (t + h^2)^{-1}\, dt < \infty.$$

Periodize that kernel. To transfer its L^p bound, truncate a periodic input to an increasing union of fundamental cells. Absolute summability makes the truncated convolution converge to the periodic one on cells a large fixed distance from the truncation boundary. Apply the infinite-lattice estimate, divide its p-th power by the number of cells, and let the truncation grow. The proportion of boundary cells tends to zero; a further limit of the fixed distance removes the summable tail. This proves the same periodic bound. Finally, on any fixed finite torus let $\mu \downarrow 0$. Every nonconstant Fourier mode converges to the massless second-resolvent multiplier and the constant second-derivative mode is zero. The uniform bound passes to this finite matrix limit. □

No assertion at $p = \infty$ follows from this proposition. The proof uses cancellation of the bad parts, precisely where an absolute supremum-norm kernel estimate would fail.

3.24.3. *Interior second derivatives and the flat Hodge estimate.* Let $Q_r \subset Q_R$ be concentric physical fine boxes, and assume that their distance is large enough to contain the fixed two-step stencils. Choose a sampled smooth cutoff $\chi = 1$ on Q_r, supported strictly inside Q_R, with $|D\chi| \le C(R-r)^{-1}$ and $|D^2\chi| \le C(R-r)^{-2}$. Extend χu by zero to the full lattice. The product rule and Prop. 3.79 give the following precise local estimate.

Corollary 3.80. For $1 < p < \infty$,

$$\begin{aligned}\|D^2 u\|_{p,Q_r} \le C_p \{ &\|L_h u\|_{p,Q_R} + (R-r)^{-1} \|Du\|_{p,Q_R} \\ &+ (R-r)^{-2} \|u\|_{p,Q_R} \}.\end{aligned} \tag{3.dccclxxviii}$$

The constants are independent of the fine mesh. ■□

Proof. For a compactly supported v, $D_i^\sigma D_j^\tau v = D_i^\sigma D_j^\tau L_h^{-1} (L_h v)$ as Fourier multipliers. Thus $\|D^2 v\|_p \le C_p \|L_h v\|_p$. Apply this to $v = \chi u$. The exact product rule for $L_h(\chi u)$ has the term $\chi L_h u$, terms containing one difference of χ and one of u, and terms containing two differences of χ and a shifted value of u. Their indicated supports lie in Q_R. This proves the estimate. □

For a compactly supported one-cochain v, the flat operator identity

$$\mathrm{d}^\sharp \mathrm{d} + DD^\sharp = L_h I$$

and Prop. 3.79 imply

$$\|Dv\|_p \le C_p(\|\mathrm{d}v\|_p + \|D^\sharp v\|_p). \tag{3.dccclxxix}$$

To see the operator types, write $v = L_h^{-1}(\mathrm{d}^\sharp \mathrm{d}v + DD^\sharp v)$ and differentiate. Each resulting coefficient is a second-resolvent multiplier of Prop. 3.79; there are only finitely many component pairs. Applying this to χv proves

$$\|Dv\|_{p,Q_r} \le C_p\{\|\mathrm{d}v\|_{p,Q_R} + \|D^\sharp v\|_{p,Q_R} + (R-r)^{-1}\|v\|_{p,Q_R}\}. \tag{3.dccclxxx}$$

These are full-lattice cutoff identities. They impose no boundary condition on an arbitrary proper determining region.

3.24.4. *Finite-time heat Sobolev and Morrey estimates.* We state the strict-exponent estimates needed for bootstrap, so no critical endpoint is used implicitly. For compactly supported u put $g = L_h u$. The exact finite-time identity is

$$u = P_1 u + \int_0^1 P_t g \, dt, \qquad P_t = e^{-tL_h}.$$

Young's inequality and eq. 3.dccclxxiii give the following consequences.

Proposition 3.81. Let $1 < p \le q \le \infty$. If $2(1/p - 1/q) < 1$, then

$$\|u\|_q \le C_{p,q}(\|u\|_p + \|L_h u\|_p). \tag{3.dccclxxxi}$$

If $1/2 + 2(1/p - 1/q) < 1$, then

$$\|Du\|_q \le C_{p,q}(\|u\|_p + \|L_h u\|_p). \tag{3.dccclxxxii}$$

The constants are uniform in h. The corresponding interior estimates follow by a cutoff, with the commutator terms of eq. 3.dccclxxviii. ■

Proof. The fixed-time operators P_1, DP_1 map L^p to L^q with a uniform bound. The integrals of their variable-time bounds are respectively

$$\int_0^1 (t+h^2)^{-2(1/p-1/q)}\, dt, \qquad \int_0^1 (t+h^2)^{-1/2-2(1/p-1/q)}\, dt.$$

The stated strict inequalities make both integrals bounded independently of h. The cutoff product rule proves the local version. □

Proposition 3.82 (Uniform gradient Morrey estimate)**.** If $4 < p < \infty$, then

$$\|u\|_\infty + \|Du\|_\infty + [Du]_{1-4/p,\mathrm{loc}} \le C_p(\|u\|_p + \|L_h u\|_p). \tag{3.dccclxxxiii}$$

The seminorm uses distinct fine lattice points at physical distance at most one. This estimate also has the cutoff interior version. ■

Proof. The two supremum bounds follow from Prop. 3.81. For a fine lattice translation z, the derivative kernel obeys

$$\|\tau_z Dp_t^h - Dp_t^h\|_{p'} \le C_p \min\{(t+h^2)^{-1/2-2/p}, |z|(t+h^2)^{-1-2/p}\}.$$

The first bound follows from the triangle inequality and eq. 3.dccclxxiii; the second telescopes one further difference along a coordinate path. Distinct grid points have $|z| \ge h$. Split its time integral at $t = |z|^2$. The small-time contribution is at most $C_p|z|^{1-4/p}$, since $1/2 + 2/p < 1$. The large-time contribution has the same bound by direct integration. The fixed-time term $DP_1 u$ has increment at most $C_p|z|\|u\|_p$, which is bounded by $C_p|z|^{1-4/p}\|u\|_p$ for $|z| \le 1$. This proves the seminorm. Cutoffs again use only the displayed first and second difference commutators. □

For example, a bounded physical H^1 solution with a locally L^2 Laplacian first has gradient in L^3 and itself in every fixed finite L^q. A subsequent L^3 forcing bound gives a bounded solution and gradient in L^8. An L^8 forcing bound then gives bounded gradient. Once the equation supplies an L^p Laplacian bound at any chosen finite $p > 4/(1-\alpha)$, the same estimate gives a gradient Hölder exponent at least α. All these implications use strict inequalities in Prop. 3.81; none uses an endpoint singular-integral estimate.

3.24.5. *All finite-p derivatives in an admitted Coulomb gauge.* We finish with the coefficient estimate needed in the vector bootstrap. Suppose the real connection on a fine box has an admitted logarithmic Coulomb representative $U = e^{ihA}$ with

$$\|A\|_\infty \le C\kappa/R, \qquad D^\sharp A = 0, \qquad \|F_U\|_\infty \le \kappa/R^2,$$

on a box of size comparable to R, with the fixed larger collars of the current-free local gauge construction. The existence of that representative was proved in § 3.16; its initial construction does not use a current bound.

Corollary 3.83. For every finite $1 < p < \infty$, on a fixed smaller box,

$$\|DA\|_p \le C_p \kappa R^{4/p-2}. \tag{3.dccclxxxiv}$$

There is no derivative of curvature or physical current in this assertion. ■□

Proof. The exact four-link logarithm gives

$$F_U = \mathrm{d}A + E_h(A), \qquad \|E_h(A)\|_\infty \le C\|A\|_\infty^2.$$

Every nonlinear term has at least two factors hA before the factor h^{-2} is removed. This bound therefore requires no derivative of A. Insert this curl identity and $D^\sharp A = 0$ into eq. 3.dccclxxx, using an intermediate cutoff box. Its three terms are bounded by

$$C_p \left\{ \frac{\kappa}{R^2} R^{4/p} + \frac{\kappa^2}{R^2} R^{4/p} + R^{-1} \frac{\kappa}{R} R^{4/p} \right\}.$$

The fixed small curvature ceiling bounds κ^2 by a constant times κ. This proves the claim. In a complex C^1 tube about this real representative, the added potential and its first derivative have the same finite-p scale bounds by their stated supremum norms. This last observation changes coefficients only; it does not assert unitarity of the complex connection. □

3.25. **Strong responses on actual determining regions.** The proper-region energy inverse controls a local physical potential and its gradient. We upgrade it to pointwise and Hölder control for bounded forces. The proof uses finite L^p estimates in current-free Coulomb frames. Curvature is never differentiated. The actual Wilson stencil, the smoothed site projection and the nonlinear constraint Hessian enter the argument in different ways.

Keep the actual determining regions, outward rows and physical pairings of Prop. 3.70. Increase their fixed separation and interior collar constants once as specified below. All constants may depend on the fixed L, and Hölder constants may depend on their exponent. They are independent of depth, mesh, compatible volume and the shapes of the separated regions. The frozen geometry and positive row weights are used throughout.

3.25.1. *The forces and the local strong norm.* Let B_y be an assigned pillar of side ξ_y. At a nonbare pillar choose concentric interior boxes of radii fixed multiples of ξ_y. The largest multiple R_* is fixed after the actual carrier constant C_L, with enough room for four successive cutoffs and four complete carrier enlargements. Take ρ larger than their fixed geometric margin. These boxes meet at most two adjacent assigned levels; all their scales are comparable within a fixed L factor. Their fixed enlargements meet only a bounded number of assigned pillars. A nonbare such box lies inside the inner-plaquette region. The bare case has $\xi_y = \eta$ and will be estimated directly.

For finite $4 < p < \infty$ define

$$\mathcal{F}_p(f) = \sup_y \xi_y^{3-4/p} \|f\|_{p,B_y}, \qquad \mathcal{F}_\infty(f) = \sup_b \mathsf{L}(b)^3 |f(b)|. \tag{3.dccclxxxv}$$

Replacing B_y by any of the fixed boxes changes this norm by a constant. In particular $\mathcal{F}_p(f) \le C_p \mathcal{F}_\infty(f)$. The cell energy amplitude is

$$\mathcal{E}_{\text{cell}}(v) = \sup_y \{\xi_y^{-1} \|v\|_{2,B_y} + \|\nabla_U v\|_{2,B_y^+}\}. \tag{3.dccclxxxvi}$$

One fine-step collars are included in B_y^+.

The local gradient Hölder seminorm below is covariant: two values based at x, x' are compared after adjoint transport along a fixed coordinate-order path inside the same interior box. Denote it by $[\nabla_U v]^U_{\alpha,y}$. At bare cells it is the corresponding finite one-step collar seminorm on present stencils, with the zero-extension convention of X. No regularity across a rough exterior boundary or between disconnected components is asserted. Set

$$\|v\|_{\text{str},\alpha} = \sup_y \{\xi_y \|v\|_{\infty,B_y} + \xi_y^2 \|\nabla_U v\|_{\infty,B_y} + \xi_y^{2+\alpha} [\nabla_U v]^U_{\alpha,y}\}. \tag{3.dccclxxxvii}$$

This definition uses actual short transports and is unchanged by real site gauges. For complex connections in the tube considered below, the short transports and their inverses have uniformly bounded norms.

3.25.2. *Scalar finite-p regularity without a current bound.* On a nonbare box use the current-free local Coulomb construction. In its frame, with $r = \xi_y$,

$$U_\mu = e^{i\eta a_\mu}, \qquad \|a\|_\infty \le C\kappa r^{-1}, \qquad \|Da\|_q \le C_q \kappa r^{4/q-2} \quad (1 < q < \infty). \tag{3.dccclxxxviii}$$

These are the curvature-only conclusions of Cor. 3.83, not the additional current-dependent L^∞ derivative estimate. The largest box still has small scaled curvature after one fixed reduction of the curvature ceiling.

For site fields the exact covariant Laplacian is

$$(\Delta_U u)(x) = \eta^{-2} \sum_\mu \{2u(x) - \operatorname{Ad} U_\mu(x) u(x+\eta e_\mu) - \operatorname{Ad} U_\mu(x-\eta e_\mu)^{-1} u(x-\eta e_\mu)\}. \tag{3.dccclxxxix}$$

Rescale the box by r, putting $h = \eta/r$. In this frame it can be written exactly as

$$\Delta_U = L_h + \sum_\mu a_\mu^{(1)} D_\mu + b^{(0)}, \qquad \|a^{(1)}\|_\infty \le C\kappa, \qquad \|b^{(0)}\|_q \le C_q(\kappa + \kappa^2). \tag{3.dcccxc}$$

Forward and backward shifted terms may both occur in this notation. To verify it, put $E_+(x) = (\operatorname{Ad} e^{iha(x)} - 1)/h$ and define E_- with the inverse exponential. The difference from L_h is a first difference of u with coefficients $E_\pm = O(a)$, and a zeroth coefficient $-[E_+(x) + E_-(x - he_\mu)]/h$. Since $E_- = -E_+ + O(ha^2)$, that coefficient is bounded by first differences of a and Ca^2. This proves eq. 3.dcccxc with no second derivative of the connection.

Lemma 3.84 (Two local bootstraps)**.** In the rescaled fixed boxes the following estimates are uniform in h.

If $\Delta_U u = g$, $g \in L^p$, $4 < p < \infty$, and the outer H^1 norm of u is at most B, then, for $0 < \alpha < 1 - 4/p$,

$$\|u\|_\infty + \|Du\|_\infty + [Du]_\alpha \le C_{p,\alpha}(B + \|g\|_p). \tag{3.dcccxci}$$

The same conclusion holds if additional zeroth-order operators with complete carrier radius C_L have bounded local L^q-operator norms for every finite q, using the successive carrier enlargements.

If $\Delta_U u = D_U^\sharp F + g_0$, the same outer energy is at most B, $F \in L^p$, and g_0 is bounded by B in all the finite norms used, then

$$\|u\|_p + \|Du\|_p \le C_p(B + \|F\|_p). \tag{3.dcccxcii}$$

This is a finite-p divergence-source estimate. It includes no $p = \infty$ derivative assertion. ∎

Proof. All cutoffs have fixed physical derivative bounds. The energy heat embedding first gives $u \in L^3$. For example insert $u = P_1 u + \int_0^1 P_t D^\sharp Du\, dt$; the derivative heat bound is integrable from L^2 to L^3. Thus $b^{(0)}u \in L^2$, using $b^{(0)} \in L^6$. The other lower term is in L^2. The interior estimate Cor. 3.80 and the strict heat embeddings Prop. 3.81 give $D^2u \in L^2$, $Du \in L^3$, and $u \in L^{12}$ on a smaller box. Now $b^{(0)}u \in L^3$, using its L^4 bound. A second cutoff gives $D^2u \in L^3$, then $u \in L^\infty$ and $Du \in L^q$ for every $q < 12$. If $4 < p \le 8$, take $q = p$. If $p > 8$, first take $q = 8$ and use another cutoff to obtain $D^2u \in L^8$ and $Du \in L^\infty$. The final L^p equation and Prop. 3.82 prove eq. 3.dcccxci. The extra zeroth-order operator reads the already controlled outer L^q field at each step. The reserved complete carrier collars give exactly these larger input boxes. All Sobolev gains just used are strict.

For the divergence source, apply $D(L_h + 1)^{-1}$ to the cutoff equation. Its divergence term is $D(L_h + 1)^{-1}D^\sharp(\chi F)$, bounded on each finite L^q by Prop. 3.79. Its other terms have the order-minus-one heat bound. Starting with the outer energy, these terms are in L^2; the derivative output is in L^3, since $1/2 + 2(1/2 - 1/3) < 1$. The field output is also in L^{12}. The next lower terms are in L^3, giving derivatives in every $q < 12$, in particular $q = \min\{8, p\}$. The field becomes bounded. If $p > 8$, the order-minus-one terms from L^8 are bounded, while the divergence term is estimated in the requested finite L^p. This proves eq. 3.dcccxcii. Covariant $D_U^\sharp F$ differs from the flat divergence by the bounded product aF. Cutoff commutators add only F, Du, u on the outer boxes. No difference of F is estimated in an L^p norm. □

First-order Morrey, obtained from the same order-minus-one translation kernels, gives $\|a\|_{C^\beta} \le C_q(\|a\|_q + \|Da\|_q)$ for $q > 4$, $\beta = 1 - 4/q$. Thus the ordinary derivative estimate in eq. 3.dcccxci also controls the covariant derivative and its transported Hölder seminorm. The short transport differs from the identity by $C\kappa|x - x'|$ in these rescaled boxes.

3.25.3. *Strong columns of the actual site smoothing.* Let $F = G_s q^\sharp \Xi^{-2}$, $M = F^\sharp F$, $P = 1 - R = FM^{-1}F^\sharp$, with all the actual site definitions. A column input supported at top z is measured in its physical top Hilbert norm. Its unit vector has value $\xi_z^{-2}e$, not value e.

Proposition 3.85 (Strong normalized site columns)**.** For every $0 < \alpha < 1$, a fixed $m > 0$ can be chosen such that

$$\begin{aligned}\xi_y^2\|F1_z b\|_{\infty,B_y} + \xi_y^3\|D_U F1_z b\|_{\infty,B_y} \\ + \xi_y^{3+\alpha}[D_U F1_z b]^U_{\alpha,y} \le C_\alpha e^{-md(y,z)}\|1_z b\|_{\mathrm{top}}.\end{aligned} \tag{3.dcccxciii}$$

No current premise or differentiated curvature is used. ■

Proof. The weighted balanced site form and normalized Gram estimates give the column energy bounds

$$\|u\|_{2,\mathcal{D}_y} + \xi_y\|D_U u\|_{2,\mathcal{D}_y} \le Ce^{-m_0 d(y,z)}\|1_z b\|_{\mathrm{top}}, \qquad u = F1_z b,$$

on each fixed enlarged box. Its equation is

$$\Delta_U u = q^\sharp \Xi^{-2} 1_z b - q^\sharp a_s q u.$$

The actual adjoint $q^\sharp$ extends a top colour as its transported density on its own pillar. Its pointwise coefficient has norm one for real fields; there is no fine factor η^{-4}. Also $|qu(t)| \le C\xi_t^{-2}\|u\|_{2,B_t}$. Consequently the right side on $\mathcal{D}_y$ is bounded by $C\xi_y^{-4}e^{-m_0 d(y,z)}\|1_z b\|_{\mathrm{top}}$. The direct source vanishes unless the box meets the source pillar, where its normalized amplitude has this same bound. Scale u as $u' = \xi_y^2 u$. Its outer H^1 norm and bounded forcing have the same exponential bound. Apply Lem. 3.84 with a finite $p > 4/(1 - \alpha)$ and scale back.

At a bare cell the physical atomic inequality $|u(x)| \le \eta^{-2}\|u\|_{2,B_x}$ and its one-step neighbours prove the result directly, including the finite collar seminorm. This gives eq. 3.dcccxciii, after one fixed decrease of the exponential rate. □

Lemma 3.86 (The smoothed gauge term is a pointwise force)**.** If $\mathcal{E}_{\mathrm{cell}}(v) \le B$, then

$$\|D_U P D_U^\sharp v\|_{\infty,B_y} + \xi_y^\alpha [D_U P D_U^\sharp v]^U_{\alpha,y} \le C_\alpha \xi_y^{-3} B. \tag{3.dcccxciv}$$

The actual field row mass also satisfies

$$\|Q^\sharp a_f Q v\|_{\infty,B_y} \le C\xi_y^{-3} B, \qquad \|Q^\sharp \mu\|_{\infty,B_y} \le C\xi_y^{-3} \sup_c \xi_c^3 |\mu(c)|. \tag{3.dcccxcv}$$

■

Proof. Use physical orthonormal top columns F_z. Their derivative L^2 norm on B_y is at most $C\xi_y^{-1} e^{-md(y,z)}$. Thus

$$|(D_U F)^\sharp v(z)|_{\mathrm{ON}} \le \sum_y C\xi_y^{-1} e^{-md(y,z)} \|v\|_{2,B_y} \le CB.$$

The normalized Gram inverse has exponential orthonormal entries and bounded row sums. Its output coefficients are therefore $O(B)$. Sum the pointwise and Hölder derivative columns eq. 3.dcccxciii to obtain eq. 3.dcccxciv. The metric growth rate is chosen below half the retained exponential rate.

For an actual field row, $|Qv(c)| \le C\xi_c^{-2}\|v\|_{2,\mathrm{car}\, c} \le C\xi_c^{-1} B$. Its coefficient at a fixed fine bond is at most $C(\eta/\xi_c)^4$. The physical adjoint multiplies this by $\eta^{-4}\xi_c^4$; these factors cancel. Only a bounded number of rows with comparable scales meet that bond. Since $a_f(c) = O(\xi_c^{-2})$, both assertions in eq. 3.dcccxcv follow. This argument uses the full outward carrier, not an individual endpoint value. □

3.25.4. *The exact Wilson stencil in Feynman form.*

Lemma 3.87 (A bounded curvature kernel)**.** On every interior full stencil,

$$D^2 A_{\Omega_0}(U) + D_U D_U^\sharp = \Delta_U^{\mathrm{comp}} + \mathcal{Z}_U, \tag{3.dcccxcvi}$$

where Δ_U^{comp} is the site covariant Laplacian acting on each vector component. The operator $\mathcal{Z}_U$ reads at most a fixed two-fine-step collar and has row and column coefficient sums at most $C\kappa\xi_y^{-2}$ on a scale-ξ_y box. In particular it is a local bounded L^p zeroth-order operator, uniformly for $1 \le p \le \infty$. ■

Proof. Use the exact plaquette insertion eq. 3.dlxiii. After division by the physical fine measure, its remainder is a matrix on four plaquette edges with each coefficient bounded by $C|P_p - 1|\eta^{-2}$. Hence this part is a bounded finite-shift kernel of size $C|F_p|$.

Let $\mathfrak{d}_U = \mathrm{d}_U + E$, with the actual curl convention in eq. 3.dlxvi. Each coefficient of E is bounded by $C|P_p - 1|/\eta \le C\eta|F_p|$; each coefficient of d_U is $O(\eta^{-1})$. Expand

$$\mathfrak{d}_U^\sharp \mathfrak{d}_U - \mathrm{d}_U^\sharp \mathrm{d}_U = \mathrm{d}_U^\sharp E + E^\sharp \mathrm{d}_U + E^\sharp E.$$

Multiply these stencil coefficients directly. The first two products have coefficients $O(|F|)$ at a bounded number of shifted sites; the last is $O(\eta^2|F|^2)$. Taking a finite difference of F is unnecessary. This also proves the absolute column bounds, since each product has a bounded number of incoming as well as outgoing stencil entries.

Finally set $T_\mu = \mathrm{Ad}\, U_\mu\, \tau_\mu$. The off-diagonal entries of the exact covariant curl-divergence sum are

$$\eta^{-2}(T_\mu T_\nu^{-1} - T_\nu^{-1} T_\mu).$$

The two paths differ by an elementary plaquette. Their difference is a two-step shift times a conjugate of $\mathrm{Ad}\, P - 1$, with bounded transport coefficients. It has size $C|F|$. The diagonal entries equal $\sum_\nu \eta^{-2}(2 - T_\nu - T_\nu^{-1})$. Combining these three finite-stencil calculations proves eq. 3.dcccxcvi. All identities hold bilinearly on the complex continuation as well. □

The actual constraint Hessian $B_\omega = \Delta^{(2)}[\omega]$ has a different carrier, of radius $C_L\xi_y$. The two-leg moment eq. 3.dcii and its symmetric counterpart give

$$\|B_\omega v\|_{p,\mathcal{D}_y} \le C_L\gamma_\omega\xi_y^{-2}\|v\|_{p,\mathcal{D}_y^{+C_L}}, \qquad 1 \le p \le \infty. \tag{3.dcccxcvii}$$

Indeed its physical fine operator is $\eta^{-4}\sum_c \xi_c^4\omega(c)D^2q_c$. For a fixed fine leg the absolute other-leg sum is at most $C\gamma_\omega\xi_y^{-2}$; symmetry gives the column bound. Weighted Schur or Jensen gives eq. 3.dcccxcvii. Scales on a complete carrier are comparable. This proves an L^p-to-L^p estimate, not an energy-to-pointwise assertion.

3.25.5. *The penalized and full row-constrained strong inverses.* Write the actual displayed precision as

$$K_{U,\omega} = D^2A_{\Omega_0}(U) - B_\omega + D_URD_U^\sharp + Q^\sharp a_f Q. \tag{3.dcccxcviii}$$

The multiplier is small in $\gamma_\omega = \sup_c \xi_c^3|\omega(c)|$. This is the local constraint Hessian, with no independently named current completion.

Proposition 3.88 (The proper strong inverse)**.** For the real backgrounds of Prop. 3.70, and finite $4 < p < \infty$, $0 < \alpha < 1 - 4/p$,

$$\|K_{U,\omega}^{-1}f\|_{\mathrm{str},\alpha} \le C_{p,\alpha}\mathcal{F}_p(f). \tag{3.dcccxcix}$$

In particular bounded physical forces give this estimate for every $\alpha < 1$. For the full row saddle

$$K_{U,\omega}v - Q^\sharp\mu = f, \qquad Qv = b,$$

one has

$$\|v\|_{\mathrm{str},\alpha} + \sup_c \xi_c^3|\mu(c)| \le C_{p,\alpha}\{\mathcal{F}_p(f) + \sup_c \xi_c|b(c)|\}. \tag{3.cm}$$

Removing the row mass from the saddle adjusts its multiplier by $-a_f b$ and preserves this bound. ■

Proof. The exponential energy inverse gives $\mathcal{E}_{\mathrm{cell}}(v) \le C\mathcal{F}_p(f)$; on a pillar the dual forcing norm is $\xi_y\|f\|_2 \le C\mathcal{F}_p(f)$. Use $R = 1 - P$ and eq. 3.dcccxcvi to write its interior equation as

$$\Delta_U^{\mathrm{comp}}v = f + D_UPD_U^\sharp v - Q^\sharp a_f Qv + B_\omega v - \mathcal{Z}_U v. \tag{3.cmi}$$

The first two nonlocal smoothing and row terms have bounded pointwise amplitude $C\xi_y^{-3}\mathcal{E}_{\mathrm{cell}}(v)$. The remaining two operators have the local L^q bounds just proved. Set $v' = \xi_y v$, $f' = \xi_y^3 f$. Its outer H^1 bound is the cell energy amplitude and its scalar component equation is precisely the one in Lem. 3.84. The four nested boxes retain every constraint carrier at each step. That lemma proves the required local bound. Ordinary and covariant derivative seminorms are equivalent by eq. 3.dccclxxxviii and first-order Morrey. Bare cells follow directly from their physical atomic energy bounds; only a fixed number of neighbouring fine values is read there.

For the row saddle, the normalized Schur construction of Prop. 3.72 applies also to this precision: its proof uses its energy inverse, exact row lift and weighted coefficients, which eq. 3.dcccxcviii has. The array kernel of its unnormalized inverse is bounded by $C\xi_c^{-3}\xi_d e^{-md(c,d)}$. Thus its action on b has ξ^3 amplitude at most $C\sup_d \xi_d|b(d)|$. The other multiplier contribution is the transpose minimizing lift applied to f. Its energy column proof eq. 3.dcccxlviii requires only $\sup_y \xi_y\|f\|_{2,B_y} \le C\mathcal{F}_p(f)$; it gives the same pointwise multiplier bound. The row-lift columns and energy inverse give the corresponding cell energy estimate for v. Finally eq. 3.dcccxcv bounds $Q^\sharp\mu$ as an additional point force. Apply the same local bootstrap to obtain eq. 3.cm. □

3.25.6. *Finite-p restoration of a force.* The adjoint restoration is not bounded on fine L^∞ in general. The finite-p substitute is sufficient.

Proposition 3.89. For every finite $4 < p < \infty$,

$$\mathcal{F}_p(S^\sharp f) \le C_p \mathcal{F}_p(f). \tag{3.cmii}$$

In particular a bounded physical force has a restored force with the correct local amplitude in every finite L^p. ■

Proof. Put $u_s = G_s D_U^\sharp f$. The weighted site energy form gives the four cell bounds for G_s, $D_U G_s$, $G_s D_U^\sharp$ and $D_U G_s D_U^\sharp$, with scale factors $\xi_y\xi_z, \xi_z, \xi_y, 1$, respectively, times $Ce^{-md(y,z)}$. This is the same weighted form and distance argument as for the field energy inverse. The site gap supplies its mass term. Choose the fixed separation so the metric growth and one scale-ratio cost ξ_y/ξ_z together are less than half the retained decay rate. Since $\|f\|_{2,B_z} \le C\xi_z^{-1}\mathcal{F}_p(f)$, summing these columns gives

$$\|u_s\|_{2,\mathcal{D}_y} + \xi_y \|D_U u_s\|_{2,\mathcal{D}_y} \le C\mathcal{F}_p(f).$$

Its local equation is $\Delta_U u_s = D_U^\sharp f - q^\sharp a_s q u_s$. The average term is a bounded point forcing of amplitude $C\xi_y^{-4}\mathcal{F}_p(f)$. Rescale $u_s' = \xi_y^2 u_s$, $f' = \xi_y^3 f$, and apply the divergence-source estimate eq. 3.dcccxcii. It follows that

$$\xi_y^{3-4/p} \|D_U u_s\|_{p,\mathcal{D}_y} \le C_p \mathcal{F}_p(f).$$

Exactly $S^\sharp f = f - D_U R u_s$. Write $Ru_s = u_s - FM^{-1}F^\sharp u_s$. The just proved L^2 cell amplitude of u_s, the exponential F columns and the normalized Gram inverse bound its last derivative pointwise by $C\xi_y^{-3}\mathcal{F}_p(f)$. The displayed finite-$p$ derivative bound controls the other term. This proves eq. 3.cmii. The proof used the divergence-source Riesz estimate only at finite exponents. □

3.25.7. *Physical critical pairs and the actual Landau saddle.* Let $H_L = D^2 A_{\Omega_0}(U) - B_\omega$. At a physical critical pair full stationarity is $j_U = Q^\sharp \omega$. Let $\mathfrak{q}_U(a)$ be the actual nonlinear field-mean coordinate, with $D\mathfrak{q}_U(0) = Q$. Its actual gauge cocycle gives

$$D\mathfrak{q}_U(a)\Gamma_a\lambda = \mathrm{d}(a)\tau_a\lambda, \qquad \tau_0 = q, \quad \mathrm{d}(0) = \bar{D}_{\mathrm{ext}}.$$

The extended outward endpoint values are part of this identity. Fine gauge invariance and onto q give $\bar{D}_{\mathrm{ext}}^\sharp \omega = 0$. For $q\lambda = 0$, differentiate the displayed identity in an arbitrary field direction. Its $\mathrm{d}'(a)\tau_0\lambda$ term vanishes, and its $\mathrm{d}(0)\tau_0'\lambda$ term pairs to zero with ω. Differentiating the action Ward identity produces the same gauge-generator acceleration; full stationarity cancels it against the constraint term. Therefore

$$H_L D_U \lambda = 0 \qquad (q\lambda = 0). \tag{3.cmiii}$$

This proves the full bilinear null identity, not only its restriction to the constraint kernel.

Since $qG_sR = 0$, it follows that $K_{U,\omega} D_U G_s R = D_U R$. Its inverse and row lift have the physical horizontality identities used in § 3.22. For a force represented by f on the actual Landau slice, use the extension $S^\sharp f$; it agrees there with f. The full row saddle with this source is horizontal, by the Ward identity and $SD_U G_s R = 0$. It is consequently the actual physical Landau saddle after removal of the row mass. Prop. 3.89 and eq. 3.cm give

$$\|v\|_{\mathrm{str},\alpha} + \sup_c \xi_c^3 |\mu(c)| \le C_{p,\alpha}\{\mathcal{F}_p(f) + \sup_c \xi_c |b(c)|\}. \tag{3.cmiv}$$

There is no fine L^∞ assertion for $S^\sharp f$ in this argument.

3.25.8. *Complex tubes, small volumes and scope.* The same full penalized and full row-saddle strong estimates hold in a sufficiently small weighted C^1 tube eq. 3.dcccliv about a real reference. Here is the required weighted energy justification. Repeat the balanced site form with a spatial exponential weight on both the source and the output. Its normalized perturbation is $O(\varepsilon_*+|s|)$. The normalized F, Gram and R therefore have the same weighted bounds by Neumann series from the real reference. The full penalized field form changes by $C(\varepsilon_* + \gamma_\omega + |s|)$. Its real reference gap gives the complex weighted inverse and all cell energy estimates used above. This argument concerns the full penalized form; it does not assert a new spatial exponential theorem for an arbitrary moving-slice saddle.

Use the real reference's Coulomb frame on each interior box. The complex perturbation has bounded potential and first derivative in that frame by the C^1 tube. The logarithm of its product with the real reference links therefore has $\|a\|_\infty \le C(\kappa+\varepsilon_*)/\xi$ and $\|Da\|_q \le C_q(\kappa+\varepsilon_*)\xi^{4/q-2}$. All scalar and stencil estimates continue with these bounds. Their proofs use bilinear algebra and absolute estimates, not positivity at a complex background. The strong conclusions follow unchanged. For actual complex physical critical pairs the analytic Ward identity eq. 3.cmiii also proves eq. 3.cmiv. At an arbitrary noncritical complex pair only the full penalized and full row-constrained strong conclusions have been established here.

If a local box does not embed in a small torus, lift all actual rows, data and backgrounds to a finite periodic cover with periods exceeding $8R_*\max\xi$. Site and Gram inverses preserve the deck-invariant subspace by uniqueness; so do the full field and saddle inverses. The cover has a bounded number of sheets because the original periods contain at least two largest blocks. Apply the local estimates on the cover and descend. For a single column sum its finitely many deck images; each distance is at least the original torus distance, and one fixed decrease of the rate absorbs the bounded multiplicity.

We have proved bounded-force pointwise and local gradient Hölder responses on the actual multiscale determining regions. The estimates include the physical critical Landau saddle and small complex C^1 continuations in the ranges explicitly stated. They do not infer a pointwise singular Green kernel from a bounded-force bound. No nonlinear proper-region critical background or independently named current completion has been constructed by these linear estimates.

3.26. **An explicit current completion of the projected Hessian.** The invariant physical Hessian is determined by its Landau projection. Its continuation to an independent current requires an additional convention. We fix that convention by the second jet of an explicit finite gauge chain. This identifies the current correction with the symmetric form already estimated, fixes the order of its two propagator variants, and gives their bounded-force regularity on the actual determining geometry.

Throughout this section the action is the sum of inner Wilson plaquettes in Ω_0. Its physical current is j_U, its ambient Hessian is $\mathscr{D}_U$, and transposes use the physical bilinear pairings. All means are re-centered at U. The field row Q is the derivative per unit row length of the actual straightened mean; it is not the derivative of the plain mean. The site map q is its actual own-pillar gauge average, with the full extension at outward endpoints. Increase the fixed complete-carrier collars and separation once for the finitely many scalar stages below, independently of depth.

3.26.1. *The physical projection and its normalization.* Write

$$\begin{aligned} G_s &= (D^\sharp D + q^\sharp a_s q)^{-1}, \quad F = G_s q^\sharp \Xi^{-2}, \quad M = F^\sharp F, \\ R &= 1 - FM^{-1}F^\sharp, \qquad \Lambda = G_s R D^\sharp, \qquad S = 1 - D\Lambda. \end{aligned} \tag{3.cmv}$$

The site-top scale Ξ differs from the field-row length multiplication m. The intrinsic projection in this formula is precisely

$$R = 1 - G_s q^\sharp (q G_s^2 q^\sharp)^{-1} q G_s.$$

Indeed the two factors Ξ^{-2} in M cancel with its inverse in their indicated order. This is an algebraic normalization, not a different projection.

The exact identities are

$$\begin{gathered} qG_sR = 0, \qquad D^\sharp DG_sR = R, \qquad RD^\sharp S = 0, \qquad S^2 = S, \\ QD = \bar{D}_{\mathrm{ext}} q, \qquad QS = Q, \qquad SDG_sR = 0. \end{gathered} \tag{3.cmvi}$$

Thus $\lambda = \Lambda A$ is the unique zero-average parameter for which $RD^\sharp(A - D\lambda) = 0$. For uniqueness, $D^\sharp D$ maps $\ker q$ onto $\operatorname{ran} R$, with inverse G_sR. The site gap makes its kernel zero. These statements hold on the actual proper graph, including all outward rows and bare collars.

The physically projected Hessian is

$$\Delta^{\mathrm{phys}}_{\pi,U} = S^\sharp \mathscr{D}_U S. \tag{3.cmvii}$$

This determines the correction at $J = j_U$. It alone does not determine a linear map at every independent J: the physical current graph is not an open subset of the field-current product domain. We use the following finite-gauge convention to make that continuation explicit.

3.26.2. *A finite gauge chain fixes the independent-current map.* For a fine vector A put $\lambda_A = \Lambda A$. At a bond b, let $\ell_A = \lambda_A(b_-)$ and $r_A = \operatorname{Ad} U_b\, \lambda_A(b_+)$. Define the germ

$$\Pi_U(A)(b) = \frac{1}{i\eta} \log\left(e^{-i\ell_A} e^{i\eta A(b)} e^{ir_A}\right). \tag{3.cmviii}$$

It is the relative potential of the actual finite gauge transform by $e^{-i\lambda_A}$. Only its second jet at zero is used. Its first derivative is S. No nonlinear Landau-slice assertion about $\Pi_U(A)$ is needed or made.

Set $T_U[u,v] = D^2\Pi_U(0)[u,v]$, and define the independent-current completion by

$$\langle u, \Delta'_{\pi,U}[J]v\rangle := \langle J, T_U[u,v]\rangle. \tag{3.cmix}$$

This is our explicit convention for the named independent-current operator. It retains the physical projection eq. 3.cmvii. It does not assert uniqueness among all possible current-linear extensions with that physical value.

Proposition 3.90 (The explicit gauge-chain jet)**.** The completion eq. 3.cmix equals exactly $\mathcal{B}_U[J]$ of eq. 3.cdlxvii, for every independent real or complex current. More explicitly,

$$\begin{aligned} W_U[J]\lambda(b) &= \frac{i}{2}[\lambda(b_-) + \operatorname{Ad} U_b \lambda(b_+), J(b)], \\ \Delta'_{\pi,U}[J] &= W_U[J]\Lambda + \Lambda^\sharp W_U[J]^\sharp \\ &\quad - \tfrac{1}{2}\Lambda^\sharp(D^\sharp W_U[J] + W_U[J]^\sharp D)\Lambda. \end{aligned} \tag{3.cmx}$$

In particular it is symmetric and linear in J. The identity does not assume $D^\sharp J = 0$. ∎

Proof. The second-order logarithm of the three exponentials in eq. 3.cmviii has the quadratic part

$$\frac{i}{2}[A, \ell_A + r_A] - \frac{i}{2\eta}[\ell_A, r_A].$$

Polarizing gives

$$\begin{aligned} T_U[u,v](b) = \frac{i}{2}\{&[u(b), \ell_v + r_v] + [v(b), \ell_u + r_u]\} \\ &- \frac{i}{2\eta}\{[\ell_u, r_v] + [\ell_v, r_u]\}. \end{aligned} \tag{3.cmxi}$$

The apparent inverse spacing in the second term does not produce an inverse-spacing norm loss. Since $D\lambda = (\ell - r)/\eta$, cyclicity of the colour trace rewrites its pairing as

$$\begin{aligned}\langle J, T_U[u,v]\rangle &= \langle u, W_U[J]\Lambda v\rangle + \langle W_U[J]\Lambda u, v\rangle \\ &\quad - \tfrac{1}{2}\langle D\Lambda u, W_U[J]\Lambda v\rangle - \tfrac{1}{2}\langle W_U[J]\Lambda u, D\Lambda v\rangle.\end{aligned} \tag{3.cmxii}$$

For example $[\ell_u - r_u, \ell_v + r_v] + [\ell_v - r_v, \ell_u + r_u] = 2([\ell_u, r_v] + [\ell_v, r_u])$. This verifies both the factor one half and the physical power of η. Taking bilinear transposes in eq. 3.cmxii proves eq. 3.cmx. No divergence identity for the independent current was inserted. □

Gauge invariance gives $A_{\Omega_0}(e^{i\eta A}U) = A_{\Omega_0}(e^{i\eta\Pi_U(A)}U)$. The second chain rule at zero therefore proves

$$\mathscr{D}_U - \Delta'_{\pi,U}[j_U] = S^\sharp \mathscr{D}_U S. \tag{3.cmxiii}$$

This is an exact physical identity even when U is not constrained critical. It also follows from $\mathscr{D}_U D = W_U[j_U]$. The bilinear chain calculation extends holomorphically in the complex field. After taking its jet, the coefficient formula defines the form on all finite fine vectors; an arbitrary Gaussian vector need not lie in a nonlinear gauge chart.

The current dependence is now fully specified: $D_J\Delta'_{\pi,U}[J]\dot{J} = \Delta'_{\pi,U}[\dot{J}]$, and higher current derivatives vanish. A definition using a nonlinear gauge parameter with the same first jet could add a term pairing $D^\sharp J$ with its second gauge jet. Such a term is invisible on physical currents. Formula eq. 3.cmix fixes this freedom before using the physical current identity.

3.26.3. *The two named variants in their actual order.* Let $C_U^{(2)}$ be the quadratic part per unit length of the re-centered straightened field mean. Thus its group-angle logarithm has expansion $\mathsf{m}(QA + C_U^{(2)}(A) + \cdots)$. Define

$$\langle A, \Delta_U^{(2)}[\omega]A\rangle = 2\langle \omega, C_U^{(2)}(A)\rangle. \tag{3.cmxiv}$$

In particular this is the quadratic part of the straightened mean. With the row pairing held fixed, multiplication by m converts a multiplier for the group angle to a per-length multiplier. The conversion to the counting pairing is given below. All transposes below include the physical fine and row volumes.

The precise order is

$$\begin{aligned} G_0^{-1} &= \mathscr{D}_U + DRD^\sharp + Q^\sharp a_f Q, \\ G^{-1} &= G_0^{-1} - \Delta'_{\pi,U}[J], \\ H &= GQ^\sharp(QGQ^\sharp)^{-1}, \qquad \omega_* = H^\sharp J, \\ G_1^{-1} &= G^{-1} - S^\sharp \Delta_U^{(2)}[\omega_*]S, \\ H_1 &= G_1 Q^\sharp (QG_1Q^\sharp)^{-1}. \end{aligned} \tag{3.cmxv}$$

3.26.3.1. The same completion in the propagator convention. There is a sign change between the covariant forward difference used for the propagator construction and the infinitesimal gauge generator of eq. 3.cdlx. In per-length units the forward difference at a bond is $(r - \ell)/\eta$, while the gauge generator is $(\ell - r)/\eta$. The site inverse and R are unchanged by this change of sign when the site average and mass are the same. Hence the site parameter in the forward-difference formula for the projection is $v = -\lambda_A$. In that convention the current term is the pairing of J with

$$i[v_-, A] - i[A, v_+] - i[v_-, D_{\mathrm{forw}}v].$$

Here v_- and v_+ are its values at the initial and transported terminal endpoints and $D_{\mathrm{forw}}v = (v_+ - v_-)/\eta$. Substitution gives

$$i[A, \ell_A + r_A] - \frac{i}{\eta}[\ell_A, r_A],$$

which is $T_U[A,A]$ from eq. 3.cmxi. The fine pairing in both formulas is the trace pairing with the bare cell volume. By polarization the two current completions agree also for independent complex J on the common graph with the same site average. For the separate correction from the second derivative of the mean, let $C^{(2)}$ be the quadratic term in the per-length row coordinates of the same mean. The raw quadratic term is $\mathsf{m}C^{(2)}$. The raw lift is $\mathsf{H}\mathsf{m}^{-1}$, with counting-row transpose $\mathsf{m}^3\mathsf{H}^*$, where the star uses row volumes m^4. Therefore its contraction with the current is

$$(\mathsf{m}C^{(2)}(A), \mathsf{m}^3\mathsf{H}^*J)_{\mathrm{count}} = (C^{(2)}(A), \mathsf{H}^*J)_{\mathrm{vol}}.$$

The two corrections thus have the same readouts when the site maps, row maps, and local domains have been identified. The calculation is unchanged on the projected field with A replaced by SA.

The additional quadratic form is exactly

$$-2\langle J, HC_U^{(2)}(SA)\rangle = -\langle A, S^\sharp \Delta_U^{(2)}[H^\sharp J]SA\rangle.$$

Thus it is precisely the second explicit variant. The H inside the second subtraction is formed from the first G, and is not H_1. Nor does $C_U^{(2)}(SA)$ mean the second derivative of the nonlinear composite mean with $\Pi_U(A)$.

With the convention eq. 3.cmix, all operators in eq. 3.cmxv are the already constructed explicit operators. In particular Prop. 3.73 proves

$$\sup_c \xi_c^3 |\omega_*(c)| \le C\gamma_J, \qquad \gamma_J = \sup_b \mathsf{L}(b)^3 |J(b)|. \tag{3.cmxvi}$$

At a small full-current radius this already admits the second subtraction. The support refinement below requires only a small current on bonds touching Ω_1 for the propagators, while retaining the full γ_J in this all-row amplitude estimate.

3.26.4. *Gauge defects and the meaning of on shell.* Put $\delta J = J - j_U$. Equations eq. 3.cmvi and eq. 3.cmxiii give

$$\begin{aligned} G^{-1}DG_sR &= DR - \Delta'_{\pi,U}[\delta J]DG_sR, \\ G_{(1)}DR &= DG_sR + G_{(1)}\Delta'_{\pi,U}[\delta J]DG_sR. \end{aligned} \tag{3.cmxvii}$$

The parenthesized index permits either variant. The second subtraction vanishes on DG_sR because $SDG_sR = 0$. Transposition gives its corresponding row-lift slice defect. On shell that defect is zero; no independent current is declared divergence free.

Only bonds touching Ω_1 matter for the first current correction. Write J^{t} for its restriction to those bonds and $J^{\mathrm{b}} = J - J^{\mathrm{t}}$. Set

$$\gamma_{\mathrm{t}} = \sup_{b:\, b \text{ touches } \Omega_1} \mathsf{L}(b)^3 |J(b)|. \tag{3.cmxviii}$$

The supremum is zero if that set is empty. Indeed $\Lambda A \in \ker q$, so it vanishes at all bare sites. Both $W_U[\delta J]\Lambda A$ and $D\Lambda A$ therefore vanish on bonds with neither endpoint in Ω_1. Consequently equality $J = j_U$ on bonds touching Ω_1 already implies $\Delta'_{\pi,U}[J] = \Delta'_{\pi,U}[j_U]$. In particular $\Delta'_{\pi,U}[J] = \Delta'_{\pi,U}[J^{\mathrm{t}}]$.

The same support statement suffices for the second variant. Let P_0 restrict row data to the bare rows. The exact identity is $Q_0 H = P_0$. Thus a datum supported on a nonbare row lifts to a vector which must vanish on bare bonds. Under the touching-bond on-shell condition, $H^\sharp(J - j_U)$ has only bare row components. More precisely, because the physical fine and bare-row measures are both η^4, that same restriction identity gives

$$\omega_*[J] = \omega_*[J^{\mathrm{t}}] + \iota_0 J^{\mathrm{b}}, \tag{3.cmxix}$$

where ι_0 identifies a bare bond with its level-zero row. The actual bare mean is linear, so its quadratic part is zero. These components do not contribute to $\Delta_U^{(2)}[\omega_*]$. This retains the on-shell

condition on bonds touching Ω_1; it does not strengthen it to a condition on every bare bond. Applying eq. 3.cmxvi to J^{t} gives

$$\sup_{c\ \text{nonbare}} \xi_c^3 |\omega_*(c)| \le C\gamma_{\mathrm{t}}. \tag{3.cmxx}$$

Thus G, H, G_1, H_1 are independent of J^{b}. Their admission and strong bounds use only a small γ_{t}. Their all-row induced current still has the full γ_J bound eq. 3.cmxvi; arbitrary bare currents are not thereby bounded.

If U is an actual physical critical point with $j_U = Q^\sharp \omega_{\mathrm{phys}}$, then, for the full physical current, $H^\sharp j_U = \omega_{\mathrm{phys}}$. The physical Lagrangian Ward identity eq. 3.cmiii gives

$$S^\sharp(\mathscr{D}_U - \Delta_U^{(2)}[\omega_{\mathrm{phys}}])S = \mathscr{D}_U - \Delta_U^{(2)}[\omega_{\mathrm{phys}}].$$

Therefore the named second precision is exactly

$$G_1^{-1} = \mathscr{D}_U - \Delta_U^{(2)}[\omega_{\mathrm{phys}}] + DRD^\sharp + Q^\sharp a_f Q. \tag{3.cmxxi}$$

The same conclusion holds under the on-shell condition just described, since the remaining induced-current change is bare-only. This identifies the actual physical second variant with the local Lagrangian precision, not merely their restrictions to horizontal vectors.

3.26.5. *Regularity at independent currents.* The current form eq. 3.cmxii and weighted restoration give

$$|\langle u, \Delta'_{\pi,U}[J]v\rangle| \le C\gamma_{\mathrm{t}} \|u\|_X \|v\|_X.$$

Its conjugated version has that same bound. The first and second variants therefore have the energy and exponential cell estimates already proved, for a fixed ceiling on γ_{t}. Only the nonbare part of ω_* enters the second subtraction. For real pairs their forms are positive. On a small complex C^1 tube the inverses are bounded analytic perturbations of the real references. No physical-current identification is used for this admission.

We next justify the pointwise and gradient Hölder bounds for these independent-current variants. Keeping the apparent derivative of J out of this proof is essential. Use the normalized $\mathcal{F}_p$ and cell energy amplitudes of § 3.25. All exponents p in the following argument are finite.

Lemma 3.91 (Current terms from cell energy)**.** Suppose $\mathcal{E}_{\mathrm{cell}}(v) \le B$. Then

$$\mathcal{F}_8(\Delta'_{\pi,U}[J]v) \le C\gamma_{\mathrm{t}} B. \tag{3.cmxxii}$$

For a row current with small $\gamma_{\omega,\mathrm{nb}} = \sup_{c\ \text{nonbare}} \xi_c^3 |\omega(c)|$, the second form initially has the bound

$$\mathcal{F}_3(S^\sharp \Delta_U^{(2)}[\omega] S v) \le C\gamma_{\omega,\mathrm{nb}} B. \tag{3.cmxxiii}$$

Here $\mathcal{F}_3$ means the same local physical formula as eq. 3.dccclxxxv at exponent 3. If in addition the normalized local $W^{2,3}$ norm of v is bounded by B_1, both current terms belong to every finite $\mathcal{F}_p$, $p > 4$, with bound $C_p(\gamma_{\mathrm{t}} + \gamma_{\omega,\mathrm{nb}})(B + B_1)$. ∎

Proof. By the exact support identities, replace J by J^{t} and discard bare row components of ω. Set $\lambda = \Lambda v$. The local divergence has site L^2 amplitude of grade two bounded by B. Its P part has the pointwise grade-two bound: use $F^\sharp D^\sharp v = (DF)^\sharp v$, whose normalized top coefficients are $O(B)$, and sum the strong site columns. Thus $RD^\sharp v$ has the same local L^2 amplitude. Site energy columns, with one scale-ratio reserve, give

$$\xi_y^{-2} \|\lambda\|_{2,\mathcal{D}_y} + \xi_y^{-1} \|D\lambda\|_{2,\mathcal{D}_y} \le CB.$$

Since $\Delta_U \lambda = RD^\sharp v$, the first scalar L^2 cutoff step gives normalized $W^{2,2}$ bounds. The strict heat embeddings imply that λ lies in every finite local L^q and $D\lambda$ lies in local L^3, with the physical dimensions 1 and ξ^{-1}. The same L^3 bound holds for v.

Group the exact correction as

$$\Delta'_{\pi,U}[J]v = W_U[J]\lambda + DRG_s\{W_U[J]^\sharp(v - \tfrac{1}{2}D\lambda) - \tfrac{1}{2}D^\sharp W_U[J]\lambda\}. \tag{3.cmxxiv}$$

The site force $a = W_U[J]^\sharp(v - D\lambda/2)$ has local L^3 grade-four amplitude at most $C\gamma_{\mathrm{t}}B$. The site energy estimate for $G_s a$ and the scalar cutoff bootstrap through L^3 give a derivative in L^8 of grade three. Subtracting its P part costs a bounded pointwise derivative, by the site columns and the Gram inverse. Hence $DRG_s a \in \mathcal{F}_8$. The other force $h = W_U[J]\lambda$ is in every finite $\mathcal{F}_q$, because λ is in every finite local L^q. Exactly

$$DRG_s D^\sharp h = h - S^\sharp h.$$

The finite-q restoration bound eq. 3.cmii, at $q = 8$, controls this term and the direct h term. This proves eq. 3.cmxxii.

For the second form, $Sv = v - D\lambda$ has its normalized L^3 bound. The actual two-leg Schur estimate eq. 3.dcccxcvii gives $\Delta_U^{(2)}[\omega]Sv \in \mathcal{F}_3$. The force-restoration proof at this one exponent uses just its first divergence-source step: the local energy of $G_s D^\sharp h$ and $h \in L^3$ give $DG_s D^\sharp h$ in L^3 by finite-3 Riesz, while the remaining point source in L^2 has derivative in L^3. Its P part is bounded pointwise. This proves the finite-3 version of restoration and eq. 3.cmxxiii. No endpoint statement is needed.

Finally a local $W^{2,3}$ bound gives $v \in L^\infty$ and $Dv \in L^8$. Then $RD^\sharp v \in L^8$ at grade two, since its P part remains pointwise bounded. The scalar bootstrap for λ gives both λ and $D\lambda$ bounded at their physical grades. Thus h and a in eq. 3.cmxxiv are bounded. A bounded site force of grade four has $DRG_s a$ pointwise bounded at grade three, by the scalar point bootstrap and its smoothed P part. The divergence-source term is controlled in every finite $\mathcal{F}_p$ by force restoration. Also Sv is bounded, so the constraint term is bounded before the final finite-p restoration. This proves the last assertion. Every derivative has fallen on a resolvent or the unknown field, not on the independent current. □

Proposition 3.92 (Strong propagators under the explicit convention)**.** For $G_\bullet \in \{G, G_1\}$, finite $4 < p < \infty$ and $0 < \alpha < 1 - 4/p$,

$$\|G_\bullet f\|_{\mathrm{str},\alpha} \le C_{p,\alpha}\mathcal{F}_p(f). \tag{3.cmxxv}$$

Their full row saddles have the same strong bound with $\sup_c \xi_c|b(c)|$ added, and their multiplier has bounded ξ^3 amplitude. The ceiling on γ_{t} can be fixed independently of α. The result holds on real regular pairs and their small complex C^1 tubes. ■

Proof. The energy estimate supplies $\mathcal{E}_{\mathrm{cell}}(v) \le C\mathcal{F}_p(f)$ for either variant. Relative to G_0^{-1}, their equations have the first correction in $\mathcal{F}_8$ and, for the second variant, the second correction in $\mathcal{F}_3$, with $\gamma_{\omega_*,\mathrm{nb}} \le C\gamma_{\mathrm{t}}$ by eq. 3.cmxx. The local scalar vector proof of Prop. 3.88, stopped after its L^3 equation, therefore gives normalized $W^{2,3}$ control. All carrier enlargements are retained. The last part of Lem. 3.91 now puts both corrections in the requested finite $\mathcal{F}_p$. Applying the full G_0 strong estimate proves eq. 3.cmxxv. This is a bootstrap, not an α-dependent absorption of a singular-integral constant into the current radius.

For the full row saddle the already proved coarse Schur kernels bound its multiplier by the normalized force and row datum amplitudes. Its $Q^\sharp\mu$ is a bounded point force by eq. 3.dcccxcv. The same two stages prove its strong field estimate. Complex coefficients have the same absolute bounds in the real reference's local Coulomb frames, and the energy inverse there was obtained by Neumann series. The proof does not use Hermitian positivity at a complex pair. □

The argument can retain a small spatial exponential weight at every step. Its local oscillation on complete carriers is bounded, and the site, Gram and row sums retain a strict metric growth reserve. This gives the corresponding cell-to-cell strong response estimates. For a bounded source supported in B_z, the normalized output in eq. 3.dccclxxxvii on B_y is at most $C_\alpha e^{-md(y,z)}\xi_z^3\|f\|_{\infty,B_z}$. If desired

the factor $(\xi_z/\xi_y)^3$ is absorbed by one further fixed scale-ratio reserve to express the potential bound as $C\xi_y^2 e^{-m'd(y,z)}\|f\|_\infty$.

These bounded-force conclusions do not assert an L^∞ bound for $\Delta_U G$ or $\Delta_U G_1$. The divergence term containing $W_U[J]\lambda$ was controlled only in finite L^p, as required when no derivative of J is prescribed. Nor does a weighted cell estimate alone construct a background-local walk expansion. The canonical continuation eq. 3.cmix has been made explicit; identifying another independently prescribed off-current convention would still require its own formula comparison.

3.27. **Finite-carrier equations for the actual current inverse.** The projected gauge and current terms conceal global site inverses. We display an equivalent system whose coefficients are actual local rows and covariant differences. We prove its inverse on every source component, including divergence sources. This also identifies the cutoff estimates needed for a subsequent local parametrix. No compression of an indefinite system is presumed invertible.

Use the actual proper geometry, physical bilinear transposes and comparison length ℓ of §§ 3.19 and 3.26. The field is real and has the curvature ceiling of Prop. 3.70. Put

$$A_s = D^\sharp D + q^\sharp a_s q, \quad G_s = A_s^{-1}, \quad F = G_s q^\sharp \Xi^{-2}, \quad M = F^\sharp F, \quad P = FM^{-1}F^\sharp, \quad R = 1 - P. \tag{3.cmxxvi}$$

All site rows, field rows and constraint derivatives are the actual re-centered ones, including complete outward carriers. As permitted by the exact support identities in § 3.26, replace J by its restriction to bonds touching Ω_1, and discard bare components of the constraint multiplier. These changes leave both named field operators unchanged. They avoid putting irrelevant, possibly unbounded bare currents into auxiliary coefficients.

Write $W = W_U[J]$ for the actual local current map, and $C_\omega = \Delta_U^{(2)}[\omega]$ for the unprojected constraint Hessian. In the second named variant $\omega = H^\sharp J$ uses the first lift. The following arguments also allow an independent nonbare ω within the same small ceiling. Define

$$K_F = H_U^{\mathrm{W}} + DD^\sharp + Q^\sharp a_f Q, \qquad \Lambda = G_s R D^\sharp, \qquad S = 1 - D\Lambda. \tag{3.cmxxvii}$$

Here H_U^{W} is the actual inner Wilson Hessian. The two field operators are

$$K^{(0)} = K_F - DPD^\sharp - B_U[J], \qquad K^{(1)} = K^{(0)} - S^\sharp C_\omega S. \tag{3.cmxxviii}$$

They are respectively the first and second canonical named precisions. Their energy inverses follow from § 3.26; the retained current ceilings are sufficiently small fixed constants.

3.27.1. *Site source spaces with their physical weights.* Let X be the actual field energy space. Introduce the site norms

$$\begin{aligned} \|u\|_Y^2 &= \|u\|_2^2 + \|\ell Du\|_2^2, \\ \|\lambda\|_Z &= \|\ell^{-2}\lambda\|_2 + \|\ell^{-1}D\lambda\|_2 + \|\nabla_U D\lambda\|_2, \\ \|h\|_{Y^\flat} &= \sup_{u\neq 0} \frac{|\langle h, \ell^2 u\rangle|}{\|u\|_Y}, \qquad \|c\|_{T_{-2}} = \|\Xi^{-2}c\|_{\mathrm{top}}. \end{aligned} \tag{3.cmxxix}$$

The second differences and the bare collar have the convention of eq. 3.dcclxxxiv. In particular this is a norm on the actual finite site space, with the atomic convention at bare sites. $Y^\flat$ uses the displayed weighted pairing; it is not the unweighted dual norm of Y. If $h = h_0 + D^\sharp h_1$, the product rule gives

$$\|h\|_{Y^\flat} \le C\{\|\ell^2 h_0\|_2 + \|\ell h_1\|_2\}. \tag{3.cmxxx}$$

Thus a divergence source need not have a pointwise derivative. The constants below are uniform in the depth and compatible volume, and in all separated proper shapes under consideration.

Lemma 3.93 (A second-difference site lift)**.** There is a real linear right inverse E of q such that

$$qE = 1, \qquad \|Ec\|_Z \le C\|c\|_{T_{-2}}. \tag{3.cmxxxi}$$

Only the small curvature and the actual pillar geometry are required; no physical-current bound is used. ■

Proof. Use the compact interior bump construction of Lem. 3.58, with its exact transported normalization on each pillar. On the fixed surrounding cube of length $C_L\xi_y$, a current-free Coulomb frame has

$$\|a\|_\infty \le C_L\kappa\xi_y^{-1}, \qquad \|Da\|_2 \le C_L\kappa.$$

The second bound is the finite exponent $p = 2$ case of Cor. 3.83; using a smaller cube keeps its collar inside the nonbare determining region. For one profile of amplitude c_y, two covariant differences contain $D^2\phi$, $aD\phi$, $Da\,\phi$ and $a^2\phi$. Their L^2 sum is at most $C_L|c_y|$. The mass and first-gradient terms with weights ℓ^{-2}, ℓ^{-1} have that same bound. The normalization matrix is constant within that pillar, so differentiating the profile does not differentiate this matrix.

For the finitely coarse meshes use its center seed; its weighted second differences cost a fixed constant depending on L. At a bare top this is the one-site seed, and every difference cost is paid by its scale η. The complete derivative collars have bounded overlap. Summing the squared estimates gives $\sum_y |c_y|^2 = \|\Xi^{-2}c\|^2_{\mathrm{top}}$. If the surrounding frame cube does not embed, construct on a finite periodic cover and average the operator over simultaneous fine and top deck shifts. The right-inverse identity and these Hilbert norms descend, with the same sheet factor on both sides. □

Lemma 3.94 (Two actual site blocks)**.** The following systems have unique solutions:

$$A_s\lambda + v = f, \qquad A_s v - q^\sharp \Xi^{-2}\beta = h, \qquad q\lambda = c, \tag{3.cmxxxii}$$

$$A_s t + q^\sharp \Xi^{-2}\beta' = h', \qquad A_s\kappa - t = r, \qquad q\kappa = d. \tag{3.cmxxxiii}$$

Their respective estimates are

$$\begin{aligned} \|\lambda\|_Z + \|v\|_Y + \|\beta\|_{\mathrm{top}} &\le C\{\|f\|_2 + \|h\|_{Y^\flat} + \|c\|_{T_{-2}}\}, \\ \|\kappa\|_Z + \|t\|_Y + \|\beta'\|_{\mathrm{top}} &\le C\{\|r\|_2 + \|h'\|_{Y^\flat} + \|d\|_{T_{-2}}\}. \end{aligned} \tag{3.cmxxxiv}$$

■

Proof. The balanced test in eq. 3.dcclxxviii, with the same small Lipschitz constant for ℓ, proves

$$\|G_s h\|_Y \le C\|h\|_{Y^\flat}. \tag{3.cmxxxv}$$

Indeed its real left side controls $\|\ell Du\|_2^2 + \|qu\|^2_{\mathrm{top}}$, and the actual block Poincare estimate controls $\|u\|_2^2$. This argument applies to every source h, not only to a site-row column.

For the first block put $w = G_s h$. Its exact solution is

$$\begin{aligned} \beta &= M^{-1}\{F^\sharp(f - w) - \Xi^{-2}c\}, \\ v &= w + F\beta, \qquad \lambda = G_s(f - v). \end{aligned} \tag{3.cmxxxvi}$$

The identity $qG_sF = \Xi^2 M$ proves $q\lambda = c$. The normalized Gram gap and the balanced column estimate for F bound β, v. For the Z bound set $\lambda_0 = \lambda - Ec$. It has zero q average and

$$\Delta_U\lambda_0 = f - v - q^\sharp a_s c - \Delta_U Ec.$$

The right side has L^2 norm at most the first displayed source bound: $q^\sharp$ is the actual coisometric transported extension, $a_s \asymp \Xi^{-2}$, and Lem. 3.93 controls $\Delta_U Ec$. Apply eq. 3.dcclxxxiv and then add Ec.

For the second block put $w' = G_s h'$. The formulas are

$$\begin{aligned} \beta' &= M^{-1}\{F^\sharp(w'+r) - \Xi^{-2}d\}, \\ t &= w' - F\beta', \qquad \kappa = G_s(t+r). \end{aligned} \tag{3.cmxxxvii}$$

The same argument, with $\kappa - Ed$, proves its bound. These formulas prove existence and uniqueness as well. All transposes and weights are the physical ones; replacing the top transpose by a counting-array transpose would change the displayed normalizations. □

3.27.2. *The complete finite-carrier system.* Use $\epsilon = 0$ or 1 to select a variant, and set

$$\delta = \epsilon C_\omega(A - D\lambda), \qquad h_J(A,\lambda) = W^\sharp A - \tfrac{1}{2}\{D^\sharp W\lambda + W^\sharp D\lambda\} - D^\sharp\delta. \tag{3.cmxxxviii}$$

The unknowns are $A, \lambda, v, \beta, t, \kappa, \beta'$. With arbitrary sources they satisfy

$$\begin{aligned} K_F A - Dv - W\lambda - \delta - Dt &= f_0, \\ A_s\lambda + v - D^\sharp A &= g, \\ A_s v - q^\sharp\Xi^{-2}\beta &= h, \qquad q\lambda = c, \\ A_s t + q^\sharp\Xi^{-2}\beta' - h_J(A,\lambda) &= h', \\ A_s\kappa - t &= r, \qquad q\kappa = d. \end{aligned} \tag{3.cmxxxix}$$

In particular every coefficient is a covariant difference, an actual site or field row, a local current multiplication or an actual two-leg constraint coefficient. No inverse, projector or induced multiplier is hidden in this matrix. For the second variant its prescribed coefficient ω must still be constructed from the first lift.

Proposition 3.95 (Unfolding with all auxiliary sources)**.** For the actual real curvature-small pairs and current ceilings above, eq. 3.cmxxxix is invertible and

$$\begin{aligned} &\|A\|_X + \|\lambda\|_Z + \|\kappa\|_Z + \|v\|_Y + \|t\|_Y + \|\beta\|_{\mathrm{top}} + \|\beta'\|_{\mathrm{top}} \\ &\quad \le C\{\|f_0\|_{X^*} + \|g\|_2 + \|r\|_2 + \|h\|_{Y^\flat} + \|h'\|_{Y^\flat} + \|c\|_{T_{-2}} + \|d\|_{T_{-2}}\}. \end{aligned} \tag{3.cmxl}$$

At zero auxiliary sources its field block is precisely $(K^{(\epsilon)})^{-1}$. Appending $-Q^\sharp\mu$ to the field equation and $QA = b$ gives the full actual row saddle, with the additional bound $\|a_f^{-1/2}\mu\|_{\mathrm{rows}}$ on the left and $\|a_f^{1/2}b\|_{\mathrm{rows}}$ on the right. ■

Proof. At zero auxiliary sources, the primal block gives

$$v = PD^\sharp A, \qquad \lambda = \Lambda A.$$

The transpose block gives $t = RG_s h_J(A,\lambda)$. Since $\Lambda^\sharp = DRG_s$, the exact symmetric current formula in eq. 3.cmxxiv shows

$$W\lambda + DRG_s\{W^\sharp A - (D^\sharp W\lambda + W^\sharp D\lambda)/2\} = B_U[J]A.$$

The remaining two terms are $-\delta + DRG_s D^\sharp\delta = -S^\sharp\delta$. Thus the field equation is exactly eq. 3.cmxxviii, with the stated sign and order.

Here are the bounds needed for nonzero auxiliary sources. The actual undifferentiated current and two-leg coefficient estimates give

$$\begin{aligned} \|\ell W\lambda\|_2 &\le C\gamma_J\|\lambda\|_Z, \\ \|W^\sharp A\|_{Y^\flat} + \|W^\sharp D\lambda\|_{Y^\flat} + \|D^\sharp W\lambda\|_{Y^\flat} &\le C\gamma_J(\|A\|_X + \|\lambda\|_Z), \\ \|\ell C_\omega u\|_2 &\le C\gamma_\omega\|\ell^{-1}u\|_2. \end{aligned} \tag{3.cmxli}$$

The last line is a two-leg Schur estimate, not an L^2-to-supremum estimate. A fixed-leg row has physical density $(\eta/\xi)^4$; the transpose cancels it with $\eta^{-4}\xi^4$. Both absolute sums are bounded and all lengths on the carrier are comparable. This proves that line also for an arbitrary field u. The

middle line uses eq. 3.cmxxx for the term $D^\sharp W\lambda$, and differentiates no current. Also Dv and Dt have X^* norms at most $C\|v\|_2, C\|t\|_2$, by the full physical adjoint.

Solve the primal block for a given A. Subtract its zero-source solution to obtain remainders λ_e, v_e bounded by $\|g\|_2 + \|h\|_{Y^\flat} + \|c\|_{T_{-2}}$. Solve the transpose block next. Its part depending on A is exactly the one just eliminated. Its remaining source is bounded by the auxiliary source norms, using eq. 3.cmxli. The field equation therefore reduces to $K^{(\epsilon)}A = f_0 + f_e$, where $\|f_e\|_{X^*}$ has that same bound. The actual canonical energy inverse bounds A. The site-block estimates then bound every remaining variable. For the row saddle use its actual energy inverse instead; the right inverse of Q and its dual row norm give the displayed multiplier estimate. No stationarity or physical-current identity is used in this argument. □

Corollary 3.96 (Bilinear complex continuation)**.** The full augmented inverse and the appended row saddle continue holomorphically, with the same source and solution spaces, to a common smaller weighted C^1 tube about a real reference. The independent touching current and nonbare multiplier stay within their indicated complex ceilings. ■□

Proof. Use the fixed real physical norms. In the local coefficients, the weighted C^1 tube controls $A_s : Z \to L^2$ and $A_s : Y \to Y^\flat$; it controls $K_F : X \to X^*$ by its weak plaquette form. Actual transported row differences have both normalized sums bounded by $C\varepsilon$. The same holds for the actual two-leg coefficient by its analytic row bound. The current terms obey eq. 3.cmxli without a current derivative. Thus the augmented operator is a small holomorphic perturbation, between exactly the displayed spaces, of its real reference operator. A Neumann inverse proves the assertion. Complex transposes are bilinear throughout; no orthogonal positivity at a complex pair is used. □

3.27.3. *Slow cutoffs and the bare boundary.* Let χ be a real scalar cutoff on the actual sites. Use its endpoint average on fine bonds and its center or midpoint value on tops and rows. Suppose

$$|\chi| \le 1, \qquad |\ell D\chi| \le C/m, \qquad |\ell^2 \Delta_{\mathrm{graph}}\chi| \le C/m.$$

The last operator is the scalar Laplacian on the actual site graph. At an action boundary its first-difference boundary term satisfies this bound because $\ell \asymp \eta$ there. Inside a smooth patch a second-difference cutoff bound $C/(m^2\ell^2)$ is sufficient. Every complete row carrier must have χ oscillation at most C_L/m. Cutoffs on patches of radius $m\ell$ have this property when m Lip(ℓ) is sufficiently small.

Proposition 3.97 (The actual unfolded commutator)**.** Let $\mathbb{K}^{(\epsilon)}$ be eq. 3.cmxxxix, and multiply each component by the corresponding scalar cutoff. In the source and solution norms of eq. 3.cmxl,

$$\|[\mathbb{K}^{(\epsilon)}, \chi]\Psi\|_{\mathrm{source}} \le Cm^{-1}\|\Psi\|_{\mathrm{solution}}. \tag{3.cmxlii}$$

The same assertion holds with the actual row saddle appended. ■

Proof. The product rules and the complete row oscillation give

$$\begin{aligned}
\|[A_s, \chi]\lambda\|_2 &\le Cm^{-1}\|\lambda\|_Z,\\
\|[A_s, \chi]v\|_{Y^\flat} &\le Cm^{-1}\|v\|_Y,\\
\|[q, \chi]\lambda\|_{T_{-2}} &\le Cm^{-1}\|\lambda\|_Z,\\
\|[q^\sharp\Xi^{-2}, \chi]\beta\|_{Y^\flat} &\le Cm^{-1}\|\beta\|_{\mathrm{top}}.
\end{aligned}$$

For the first line the Laplacian product contains $D\chi\, D\lambda$ and $\Delta_{\mathrm{graph}}\chi\,\lambda$. For the second line use the weak gradient form and test against $\ell^2 u$; only $D\chi$ is required. For the two row lines use the actual positive absolute averaging weights and the displayed carrier oscillation. The site mass commutator satisfies the first two bounds by these same two row estimates.

The field form K_F has $\|[K_F, \chi]A\|_{X^*} \le Cm^{-1}\|A\|_X$. This follows in its actual weak plaquette and full-divergence forms, together with the two field-row sums. It uses no derivative of curvature. The

commutators of $D, D^\sharp$ cost $|D\chi|$, with exactly the powers of ℓ in the displayed spaces. In the current terms insert the same carrier oscillation in eq. 3.cmxli. For the constraint term, $\|\ell[C_\omega,\chi]u\|_2 \le C\gamma_\omega m^{-1}\|\ell^{-1}u\|_2$. The extra expression from $A - D\lambda$ is $-[D,\chi]\lambda$, whose weighted mass norm is at most $Cm^{-1}\|\lambda\|_Z$. Finally treat every $D^\sharp\delta$ as a divergence source using eq. 3.cmxxx. These bounds cover each row of the system.

At a rough action boundary use the actual full adjoints and retain every incident inner plaquette. The preceding weak product identities still hold. The atomic scale $\ell \asymp \eta$ pays every one-edge boundary difference. No continuation of a Coulomb frame across a missing plaquette is part of this estimate. □

3.27.4. *A positive factorization for the projected gauge.* The following alternative separates the actual nonlocal Landau gauge into local positive operators and a positive coarse inverse.

Proposition 3.98 (The actual gauge Schur matrix)**.** At a real curvature-small background put $G_F = K_F^{-1}$ and

$$\Theta = M - (DF)^\sharp G_F (DF). \tag{3.cmxliii}$$

There is a uniform $0 < \delta < 1$ such that

$$\delta M \le \Theta \le M. \tag{3.cmxliv}$$

For the zero-current Landau inverse one has exactly

$$G_0 = G_F + G_F DF\, \Theta^{-1} (DF)^\sharp G_F. \tag{3.cmxlv}$$

All quantities admit bounded holomorphic continuation to a common smaller weighted C^1 tube. ■

Proof. The actual zero-current precision is $K_0 = K_F - DFM^{-1}(DF)^\sharp$. It controls $c\|A\|_X^2$ by Prop. 3.70, while the local form K_F is at most $C\|A\|_X^2$. Thus $K_0 \ge \delta K_F$. For $T = G_F^{1/2} DF M^{-1/2}$ this says $1 - TT^\sharp \ge \delta$, hence $1 - T^\sharp T \ge \delta$. Conjugating by $M^{1/2}$ proves eq. 3.cmxliv. The normalized Gram gap makes it a genuine depth-uniform coarse gap. The resolvent multiplication identity for $K_F - DFM^{-1}(DF)^\sharp$ now gives eq. 3.cmxlv. Every transpose here uses the physical fine or top measure.

In a weighted C^1 tube the operators between the displayed fixed physical spaces are small holomorphic perturbations of their real reference values. This is the site/Gram continuation of § 3.23 and the actual current continuation. In particular the gaps supply bounded inverse maps there, and the algebraic identity continues by multiplication. Positivity is used only at the real reference. □

For a set of sites or bonds, the Dirichlet compression of A_s or K_F is obtained by zero extension into the actual form. Retain the full coefficient of every crossing row. Each positive compression inherits the corresponding global coercivity in its zero-extension energy norm. Its entries depend only on the complete carriers of rows meeting that set, together with the incident inner plaquettes. Thus its geometry-decision collar is finite. In contrast, deleting the exterior part of a row and asking for a new row right inverse can destroy its inf-sup constant; and an indefinite compression of eq. 3.cmxxxix is not asserted to satisfy eq. 3.cmxl.

The positive local walk construction in Prop. 3.102 supplies the local parametrix step with these crossing coefficients and a deterministic finite-decision cover. Coarse inverse carriers for M, Θ, the small current corrections and the first-lift readout must then be assembled in their actual physical normalizations. The present equations, estimates and factorization do not by themselves produce the enlarged independent cube-parameter family or identify a clean conditional history law.

3.28. **Local walks for the positive finite-carrier inverses.** An exponentially decreasing inverse need not have coefficients determined by local background data. We now construct such coefficients for the two positive finite-carrier operators that enter the projected precision. The local inverse in the construction is a genuine Dirichlet compression. No global inverse with a locally changed background is declared to be a local coefficient.

The geometry, physical measures and true outer boundary are those of § 3.19. All coarse rows retain their complete carriers. For a real regular connection set

$$\mathcal{A}_s = D_U^\sharp D_U + q^\sharp a_s q, \qquad \mathcal{A}_F = \mathscr{D}_U + D_U D_U^\sharp + Q^\sharp a_f Q. \tag{3.cmxlvi}$$

Here $\mathscr{D}_U$ is the actual inner Wilson Hessian. The second operator in eq. 3.cmxlvi is the full Feynman operator, before a site-projection subtraction or an independent-current correction. The result of this subsection does not assert locality of those nonlocal subtractions.

3.28.1. *The positive forms and the cell norms.* For site or vector fields write

$$\|u\|_{\mathcal{E}}^2 = \|D_U u\|_2^2 + \|\xi^{-1} u\|_2^2,$$

using the componentwise covariant gradient in the vector case. Its local version $\mathcal{E}_y$ uses B_y and one fine-step collar. For an L^2 source supported in B_z, put

$$\|f\|_{\mathcal{F}_z} = \xi_z \|f\|_{2,B_z}.$$

Thus $|\langle f, u\rangle| \le \|f\|_{\mathcal{F}_z} \|u\|_{\mathcal{E}_z}$. Cutoffs and collars have bounded overlap, so the squared global energy is equivalent to the sum of the squared cell energies. No pointwise Green-kernel norm is implicit in this notation.

There are uniform constants $c, C > 0$ with

$$c\|u\|_{\mathcal{E}}^2 \le \langle u, \mathcal{A}_\bullet u\rangle \le C\|u\|_{\mathcal{E}}^2, \qquad \bullet = s, F. \tag{3.cmxlvii}$$

For the site operator this is the actual block inequality eq. 3.dcclxxiii and the transported-average upper bound. For the vector operator,

$$\mathcal{A}_F = K_{U,0} + D_U P D_U^\sharp, \qquad P = 1 - R.$$

The real projection satisfies $0 \le P \le 1$. The lower bound follows from eq. 3.dcccxxviii, and the additional term is at most $\|D_U^\sharp u\|_2^2$, bounded by the component gradient and bare mass energy. The latter pays any one-edge term at a rough true boundary, where $\xi = \eta$. This proves the upper bound too. In particular this argument does not require the connection to be stationary.

Let E_D inject fields supported on any chosen fine set D, extending them by zero in the original field space. Define the compressed operator

$$\mathcal{A}_{\bullet,D} = E_D^\sharp \mathcal{A}_\bullet E_D. \tag{3.cmxlviii}$$

Its norm is the energy of that zero extension, including the artificial boundary gradients. Inequality eq. 3.cmxlvii holds on this space with exactly the same constants. For an averaging row crossing the boundary of D, its contribution is its full row evaluated on the zero extension. It is not replaced by a renormalized partial average. There is consequently no new partial-row inf-sup assertion.

The matrix eq. 3.cmxlviii depends only on the fine coefficients on D, their finite difference collar and the complete rows meeting that collar. It also retains which original inner plaquettes are present. These observations apply at the actual outer boundary as well as at an artificial interior boundary.

3.28.2. *A locally determined slow partition.* We give an explicit weighted cover so its choice does not depend on a globally ordered greedy selection. Fix a large integer m, and then choose the comparison-length slope $\delta > 0$ so $m\delta$ is sufficiently small. Increase the separation so $\rho\delta \geq C_L$. The comparison length ℓ is eq. 3.dcclxx. Put

$$r_x = m\ell(x)$$

at every ambient fine site x, including the geometric exterior. Initially suppose the periods are large enough that the balls below embed. The periodic case is handled after the construction.

Choose a fixed nonnegative smooth bump φ, equal to one on the ball of radius $1/4$ and supported in the ball of radius $1/2$. Define

$$\begin{aligned} \omega_x &= \eta^4 r_x^{-4}, \\ N(y) &= \sum_x \omega_x \varphi((y-x)/r_x)^2, \\ \chi_x(y) &= N(y)^{-1/2}\varphi((y-x)/r_x). \end{aligned} \tag{3.cmxlix}$$

The sums are ambient fine-site sums. The radius and weight at a centre are fixed while y varies.

Lemma 3.99 (Weighted slow partition)**.** Uniformly in mesh and depth,

$$\sum_x \omega_x \chi_x(y)^2 = 1, \qquad c \leq N(y) \leq C, \qquad |D^a \chi_x(y)| \leq C_a r_x^{-a} \quad (a = 0, 1, 2). \tag{3.cml}$$

Only centres with $|x - y| \leq C r_y$ contribute at y, and

$$\sum_{x:\, y \in B(x, 2r_x)} \omega_x \leq C. \tag{3.cmli}$$

The same holds with any fixed enlargement of those balls, after reducing $m\delta$. All assigned scales in an enlarged ball are comparable within a fixed L factor. ■

Proof. If $|x - y| \leq a r_x$ for a fixed enlargement factor a, then

$$|r_x - r_y| \leq m\delta |x - y| \leq am\delta r_x.$$

Thus r_x and r_y are comparable, and all such centres lie in a fixed multiple of the radius-r_y ball. Conversely, in a sufficiently small fixed multiple of that ball, the bump is bounded below. Since $\ell \geq \eta$, $r_y \geq m\eta$. Fine lattice counting in these balls therefore gives

$$\sum_{|x-y| \leq c r_y} \eta^4 r_x^{-4} \geq c, \qquad \sum_{|x-y| \leq C r_y} \eta^4 r_x^{-4} \leq C.$$

This proves the bounds for N and the weighted overlap. In particular the large number of fine centres has been canceled by their physical weights, rather than estimated by an unweighted count.

Differentiate N in y. Only the bump is differentiated; each derivative costs r_x^{-1}. The preceding comparisons give $|D^a N(y)| \leq C_a r_y^{-a}$ for $a \leq 2$. The product rule and its positive lower bound prove the cutoff estimates. The partition identity is its definition. Finally $\ell \leq \xi \leq L\ell$; the same Lipschitz comparison makes all assigned scales in these balls comparable. The separation excludes nonadjacent layers on the fixed enlargements used here. □

The partition is local in the geometry. Here is the point needed for exact carrier dependence. If x is assigned level j, a candidate in the infimum defining $\ell(x)$ at level at most $j - 2$ has distance at least $\rho\xi_{j-1}$. For $\rho\delta > 2L$, its distance term alone exceeds $2\xi_j$, so it cannot attain an infimum at most ξ_j. A candidate at level at least j cannot improve the zero-distance candidate x. Only the adjacent lower level need be examined, at distance at most ξ_j/δ. Consequently all radii and cutoff normalizations used near x are decided by the layer labels in

$$B(x, C_L \ell(x)/\delta). \tag{3.cmlii}$$

Increase $\rho\delta$ so this collar meets only the fixed adjacent levels. This may be a larger collar than the support of χ_x; it is included in the carrier. It cannot be omitted on the ground that ℓ is merely comparable to the assigned scale.

3.28.3. *Local inverse columns and the commutator.* Let D_x contain the fine variables in $B(x, 2r_x)$, intersected with the original field space. Its finite carrier collar is fixed large enough for the complete rows. Write

$$I_x = E_{D_x} \mathcal{A}_{\bullet, D_x}^{-1} E_{D_x}^{\sharp}.$$

The two outside injections specify zero extension; I_x is not an inverse on a newly defined determining region. In particular the original outward rows and bare boundary are still used in its compression.

Lemma 3.100 (Uniform local columns)**.** For some $s_0 > 0$,

$$\|1_y I_x 1_z\|_{\mathcal{F}_z \to \mathcal{E}_y} \le C e^{-s_0 d(y,z)}. \tag{3.cmliii}$$

The constants are independent of the patch radius, mesh and depth. The same conclusion holds for the small complex C^1 tubes of the actual regular real coefficients. ■

Proof. The unweighted energy estimate is eq. 3.cmxlvii restricted to the zero-extension subspace. For a spatial exponential weight whose logarithm changes by at most $s\eta/\xi$ on a fine step, the covariant product rule changes the principal form by at most $Cs\|u\|_{\mathcal{E}}^2$. The oscillation of that weight on one complete q or Q carrier is $O(s)$, so the same estimate holds for their positive row forms. The Wilson plaquette form has this bound by its exact finite insertion formula. Taking s small compared with c preserves coercivity. Multiplication by the weight preserves zero extension, so this argument is unchanged by the artificial Dirichlet boundary. Choose the logarithm to be the truncated distance from B_z in the actual comparison metric. The weighted energy bound gives eq. 3.cmliii.

For a complex tube, the local operator coefficients are analytic. The relative form estimates used in the complex inverse construction apply to the two local parts of eq. 3.cmxlvi. Restricting their inputs by zero extension cannot enlarge those relative bounds. A fixed sufficiently small tube is therefore a Neumann perturbation of every weighted real compression, with the same constants. No Hermitian positivity at the complex coefficient is asserted. □

Lemma 3.101 (Slow commutator)**.** The local columns also satisfy

$$\|1_y [\mathcal{A}_\bullet, \chi_x] I_x \chi_x 1_z\|_{\mathcal{F}_z \to \mathcal{F}_y} \le \frac{C}{m} e^{-s_1 d(y,z)} \tag{3.cmliv}$$

for a fixed $s_1 > 0$, whenever the indicated supports meet. Its output and input lie in fixed enlargements of the patch. Its coefficients depend only on the data there and in eq. 3.cmlii. ■

Proof. In a covariant second difference, the exact scalar product rule expresses the commutator as first differences of χ_x times first covariant differences of the unknown, and second differences of χ_x times the unknown. There is no derivative of a connection coefficient in this identity. The same rule for the curl-divergence principal form of the vector operator has these two types of terms. The remaining plaquette kernel has bounded finite-shift coefficients by Lem. 3.87; its commutator is smaller. After multiplying the output L^2 norm by ξ_y, these bounds are

$$\frac{C}{m} \{ \|D_U u\|_{2, \mathcal{D}_y} + \xi_y^{-1} \|u\|_{2, \mathcal{D}_y} \}.$$

Here $\mathcal{D}_y$ is a fixed cell enlargement, with comparable assigned scales.

For the averaging terms introduce the scalar cutoff value at the row's top. The row commutators are $q\chi_x - \chi_{x,\mathrm{top}} q$ and $Q\chi_x - \chi_{x,\mathrm{row}} Q$. Every difference of cutoff values on their complete carrier is at most C/m. Their normalized row and column bounds therefore give that same factor in the physical L^2 mass norm. The physical transpose is essential here; no fine row count remains. Use Lem. 3.100 and sum the finitely many neighbouring cells. This proves the displayed exponential

bound with a slightly smaller rate. The local matrices, cutoffs and complete row carriers give its stated exact dependence.

At a true boundary, the full interior curl-divergence identity need not hold. Every such stencil is in the bare layer. There $\xi = \eta$; each present matrix entry is $O(\eta^{-2})$, its cutoff difference is $O(1/m)$, and it reads only finitely many neighbours. Thus its force norm is bounded by C/m times the bare mass energy directly. This also covers a missing neighbour in the scalar graph Laplacian. No second-difference cancellation across an absent stencil is required. □

This proof works next to a rough outer boundary. The identity is the commutator of the original finite matrices and their diagonal cutoffs. Missing exterior plaquettes are not filled in, and no local Coulomb gauge across that boundary has been assumed.

3.28.4. *An exact local parametrix.* Define

$$\mathcal{M} = \sum_x \omega_x \chi_x I_x \chi_x. \tag{3.cmlv}$$

All sums are finite on a finite torus. The preceding bounds make them uniformly bounded between cell source and energy norms. Because χ_x has support strictly inside D_x, compression and extension give the exact identity

$$\mathcal{A}_\bullet \mathcal{M} = 1 + \mathcal{T}, \qquad \mathcal{T} = \sum_x \omega_x [\mathcal{A}_\bullet, \chi_x] I_x \chi_x. \tag{3.cmlvi}$$

To verify its main term, multiply by χ_x on the output of the compressed equation:

$$\chi_x \mathcal{A}_\bullet I_x \chi_x = \chi_x^2.$$

The weighted sum of these squares is one by eq. 3.cml. Thus there is no residual background-replacement term in eq. 3.cmlvi. The operator is exactly the same local operator inside each compression.

For a block operator $\mathcal{B}$ put

$$\|\mathcal{B}\|_{\mathrm{Sch,s}} = \max\left\{ \sup_y \sum_z e^{sd(y,z)} \|\mathcal{B}_{yz}\|, \sup_z \sum_y e^{sd(y,z)} \|\mathcal{B}_{yz}\| \right\},$$

using $\mathcal{F} \to \mathcal{F}$ for $\mathcal{T}$ and $\mathcal{F} \to \mathcal{E}$ for $\mathcal{M}$. The metric growth reserve is chosen below the column decay. Equations eq. 3.cmli and eq. 3.cmliv give

$$\|\mathcal{T}\|_{\mathrm{Sch,s}} \le C/m, \qquad \|\mathcal{M}\|_{\mathrm{Sch,s}} \le C. \tag{3.cmlvii}$$

Indeed for fixed output cell, all contributing centres have radius comparable to $m\xi_y$; their physical weights have bounded sum. Sum the remaining exponential input-cell kernel. The column calculation is the same with the two cells reversed. The local column estimate, rather than the total energy norm of a whole patch, prevents a spurious factor m^2.

3.28.5. *Carriers and absolute walk sums.* Choose a tagged mixed-scale carrier for each centre as follows. Include its inverse patch, the complete row collars and the geometric decision collar eq. 3.cmlii. Cover that set by the ambient $M_{\mathrm{c}}\xi_j$ cubes at its adjacent assigned levels. Choose the fixed carrier cube integer M_{c} large enough compared with C_L/δ, and then enlarge ρ once more compared with LM_{c}. Only a bounded number B_L of tagged cubes is needed. Connect intersecting or neighbouring cubes at the same or adjacent level. Their connected carrier has length at most B_L. This records geometry dependence as well as matrix endpoints. Include also the canonical tagged M_{c}-cube of each input and output assigned cell. Any short joining paths cost a fixed number of tags, absorbed into B_L. For multiplication use the shifted length $\sigma_c(X) = b_L + d_c(X)$, where $b_L \ge 1$ exceeds the fixed cost of joining two carriers at a common intermediate cell. Then

$$\sigma_c(X \vee Y) \le \sigma_c(X) + \sigma_c(Y).$$

Here $X \vee Y$ includes that short join if the original tagged vertex sets were disjoint despite meeting physically. This convention is equivalent, up to one fixed factor in the norm, to the usual connected tree length. Enlarge B_L once to bound σ_c for every local carrier.

Fix any desired finite carrier rate $\kappa_c > 0$. The parameters are chosen in this order: first κ_c and the operator gap constants, then m sufficiently large, then δ, M_{c}, and ρ as above. The bound on the number of carrier cubes is independent of their physical radius after this choice of M_{c}. Thus m can be chosen so

$$(C/m)e^{\kappa_c B_L} < 1/2. \tag{3.cmlviii}$$

The global curvature and complex tube ceilings are reduced only after these finitely many fixed parameters. None depends on depth or volume. The carrier cube size M_{c} is distinct from a prescribed history cube size. A statement giving only one history cube of separation must verify that its physical width meets the present ρ bound. That history-admission comparison is not part of the local inverse theorem.

Group local terms with the same carrier. For an operator-valued family $\mathbf{B} = (B_X)$, use the weighted Schur norm with the additional sum over X and factor $e^{\kappa_c \sigma_c(X)}$. The two estimates eq. 3.cmlvii then become

$$\|\mathbf{T}\|_{\mathrm{Sch,s},\kappa_{\mathrm{c}}} < 1/2, \qquad \|\mathbf{M}\|_{\mathrm{Sch,s},\kappa_{\mathrm{c}}} \le C_{\kappa_c}.$$

These are sums of norms of actual coefficients. No cancellation between distinct carriers was used to make the first estimate small.

Proposition 3.102 (Positive inverse walks on the determining geometry)**.** For $\bullet = s, F$, the actual inverse has the exact absolutely convergent walk representation

$$\mathcal{A}_\bullet^{-1} = \mathcal{M} \sum_{n \ge 0} (-\mathcal{T})^n. \tag{3.cmlix}$$

Its carrier coefficients are holomorphic functions of the local background data and the declared local determining geometry. They have a uniform weighted cell-to-cell energy norm with the carrier rate just fixed. This holds on the real regular domain and its specified small complex C^1 tubes. ■

Proof. The Schur family norm is submultiplicative. In a product, the intermediate cell joins the two contributing carriers. Use their recorded short join and the subadditive shifted length. Its carrier weight is at most the product of the two weights, and the output-input distance obeys the triangle inequality. Thus the absolute sum of walks of length n is at most $C_{\kappa_c} 2^{-n}$. This proves convergence in the stated family norm. Multiply eq. 3.cmlix by $\mathcal{A}_\bullet$ and use eq. 3.cmlvi. The product is the identity. The positive operator is invertible by eq. 3.cmxlvii, so the series is its inverse.

Each local factor is a finite matrix inverse of eq. 3.cmxlviii, multiplied by local cutoff and stencil coefficients. Its matrix entries, original row list and original plaquette list are determined inside its recorded carrier. Agreement of two determining geometries and backgrounds there therefore gives exactly the same coefficient. This is stronger than a shielding estimate. The local inverse is analytic on its uniformly admitted complex tube. Products are analytic on the union carrier, and the normally convergent walk sum is analytic there. □

3.28.6. *Small periods and the scope of the locality statement.* If the physical balls wrap around a small compatible torus, first lift the local coefficients and geometry to a finite periodic cover whose periods exceed the fixed patch and decision diameters. A bounded number of copies suffices, since the original periods contain the largest assigned blocks. The lifted positive form has the same uniform gap. Its inverse preserves the deck-invariant subspace by uniqueness. On that subspace it is exactly the original inverse.

There is no multiplicity loss in the Schur contraction. Before projecting a filed family, average it over the finite deck group, translating its carrier tags as well. This step is needed if the auxiliary carrier grid itself is not deck invariant. The total inverse is unchanged by uniqueness, and the

absolute family norm does not increase. The averaged family is now deck covariant. For a base source cell, its lift is the sum of its deck images. The projected kernel is the sum of the corresponding cover kernel columns. A base row sum is consequently bounded by the cover row sum; the column statement follows by deck covariance. Projection of a connected carrier cannot increase its length. The same absolute walk estimates descend with the same contraction constant. This argument concerns classical linear inverses; it does not identify a quantum partition function with the partition function on a larger cover.

The result constructs local walks for $\mathcal{A}_s^{-1}$ and the full Feynman inverse. The exact compositions with the site projection, coarse inverses and independent current are supplied by Prop. 3.112. Their strong output and cube-parameter versions are Prop. 3.171 and Lem. 3.172. The carriers retain their tagged mixed-scale determining geometry. Equality with a separately prescribed signed or absolute-contour precision requires that precision's gauge comparison.

3.29. **Local carrier expansions for the positive coarse inverses.** We invert the actual positive coarse matrices while retaining the full background carriers of their coefficients. The short part is cut by its recorded carrier, and its matrix powers are combined before taking absolute values. This permits the real Hilbert-space gap to control the absolute walk expansion. The local positive inverses used as inputs are those of Prop. 3.102; no compression of an indefinite projected operator is inverted here.

The initial carrier tile size is M_0. The final size M_c will be chosen larger after a finite short-power construction. Both are aligned powers of L. Neither is silently identified with a prescribed history size M_h. The result requires the separation specified below. Admission of a separately fixed history geometry remains a comparison to be checked.

3.29.1. *The actual matrices and their physical normalization.* Retain the physical site and field pairings. Put

$$\begin{aligned} G_s &= \mathcal{A}_s^{-1}, \qquad F = G_s q^\sharp \Xi^{-2}, \qquad M = F^\sharp F, \\ G_F &= \mathcal{A}_F^{-1}, \qquad \Theta = M - (D_U F)^\sharp G_F (D_U F). \end{aligned} \tag{3.cmlx}$$

Here $\mathcal{A}_s, \mathcal{A}_F$ are the positive local operators in eq. 3.cmxlvi. The coarse Hilbert norm is $\sum_y \xi_y^4 |b(y)|^2$. Thus

$$(Jb)(y) = \xi_y^2 b(y), \qquad \widehat{M} = JMJ^{-1}, \qquad \widehat{\Theta} = J\Theta J^{-1} \tag{3.cmlxi}$$

is the unitary passage to counting ℓ^2. All matrix families and ordinary transposes below refer to this normalization. Physical transposes have not been replaced by unweighted transposes in eq. 3.cmlx.

Both normalized real matrices have fixed positive gaps. The Gram bound is eq. 3.dcclxxvi. To check the second one define

$$K_L = \mathscr{D}_U + D_U R D_U^\sharp + Q^\sharp a_f Q.$$

The real lower bound in eq. 3.dcccxxviii and the upper energy bound for $\mathcal{A}_F$ give $K_L \geq \delta \mathcal{A}_F$ for one $\delta > 0$. Since

$$K_L = \mathcal{A}_F - (D_U F) M^{-1} (D_U F)^\sharp,$$

the operator $C = G_F^{1/2} (D_U F) M^{-1/2}$ obeys $I - CC^\sharp \geq \delta I$. Hence $\|C\|^2 \leq 1 - \delta$ and $I - C^\sharp C \geq \delta I$. Conjugating gives

$$\delta M \leq \Theta \leq M. \tag{3.cmlxii}$$

Consequently, for $A \in \{\widehat{M}, \widehat{\Theta}\}$,

$$aI \leq A \leq bI \tag{3.cmlxiii}$$

with $a, b > 0$ independent of depth, compatible volume and the sufficiently separated geometry. This is a real positivity argument; complex continuation will use a perturbation of these real matrices.

3.29.2. *Actual coefficient families before coarse inversion.* A tag is a complete ambient $M_0\xi_j$ cube with its level, row weights and determining-geometry data retained. A carrier X records a finite connected collection of tags and its fixed short joins. Its endpoints include the canonical assigned-level tags of the matrix input and output cells. Use the guarded length

$$\sigma_0(X) = b_L + d_{c,0}(X)$$

from the positive-walk construction, with b_L paying the fixed cost of joining two carriers at a common cell. In particular $\sigma_0(X \vee Y) \le \sigma_0(X) + \sigma_0(Y)$. The length is that of the recorded full carrier, not a shorter connection through unrecorded geometry. Each tag covers assigned cells of its declared level, or is one of the fixed short joining tags. This is the covering used for the positive-walk coefficients.

For a counting-normalized matrix family $\mathbf{A}$ write $A_{yz} = \sum_X A_{yz}[X]$ and set

$$\|\mathbf{A}\|_{s,\kappa,0} = \max\left\{ \sup_y \sum_{z,X} e^{sd(y,z)+\kappa\sigma_0(X)} \|A_{yz}[X]\|, \sup_z \sum_{y,X} e^{sd(y,z)+\kappa\sigma_0(X)} \|A_{yz}[X]\| \right\}. \quad \text{(3.cmlxiv)}$$

Joining full carriers in a matrix product and using the triangle inequality for d makes this an algebra norm. The identity has its canonical one-cell carrier and a bounded norm. Transpose preserves the norm. Replacing a family by half its sum with its transpose makes each coefficient symmetric under endpoint reversal without changing a symmetric total matrix or increasing the norm.

For every fixed finite κ_0, the actual matrices in eq. 3.cmlxi have families with

$$\|\mathbf{A}\|_{s_0,\kappa_0,0} \le K_{\kappa_0}, \qquad s_0 > 0. \quad \text{(3.cmlxv)}$$

Here M_0 and the primitive parameters are first chosen as in the positive-walk theorem. The constants are uniform above their separation threshold. We verify the physical scaling in this assertion, because an unweighted fine entry sum would not prove it.

A unit counting top datum is $b_z = \xi_z^{-2} e_z$ in physical coordinates. The source $q^\sharp \Xi^{-2} b_z$ has cell L^2 norm at most $C\xi_z^{-2}$, and thus source norm $C\xi_z^{-1}$ in the notation of Lem. 3.100. The actual site walk gives

$$\|1_y F b_z\|_2 \le C(\xi_y/\xi_z) e^{-sd(y,z)}, \qquad \|1_y D_U F b_z\|_2 \le C\xi_z^{-1} e^{-sd(y,z)}. \quad \text{(3.cmlxvi)}$$

These inequalities also hold as sums over the recorded walk carriers, at the prescribed rate. Applying a fine derivative uses the energy output of that walk and its already included one-step collar. Similarly the field walk gives

$$\|1_w G_F 1_v\|_{2\to 2} \le C\xi_w\xi_v e^{-sd(w,v)}. \quad \text{(3.cmlxvii)}$$

The local q injection and all complete row carriers are retained in these coefficients.

For $\widehat{M}_{yz}$, Cauchy–Schwarz inside each physical fine cell leaves the factor $\xi_w^2/(\xi_y\xi_z)$. For the subtracted term in $\widehat{\Theta}_{yz}$ it leaves $\xi_w\xi_v/(\xi_y\xi_z)$ on the chain y, w, v, z. The level barrier eq. 3.cdliii bounds each scale ratio by a fixed L factor times $\exp\{(\log L)d/\rho\}$. Reserve that small rate before summing the exponentially decreasing cell chains with eq. 3.cdlvi. This proves eq. 3.cmlxv, including its absolute row and column sums. No fine lattice count or power of η^{-1} is inserted. Carrier unions are the actual unions of the site, field and injection carriers; the shared fine cell and the guarded join preserve locality.

The positive-walk coefficients are uniformly holomorphic on their common small complex C^1 tubes. Their normally convergent family sums and the preceding bounded compositions give the same assertion for eq. 3.cmlxv. On a smaller tube, Cauchy's estimate gives a Lipschitz bound in that family norm. This supplies the complex perturbation used below; it supplies no independent enlarged physical cube domains.

3.29.3. *Short connected carriers and the actual local counting.* Fix finite integers m, R for the moment. On the final separation threshold, every old connected carrier of length at most R has metric diameter at most $C_L M_0(R+1)$. A chain of m of them is contained in a ball of radius

$$B = C_L M_0 m(R+1). \tag{3.cmlxviii}$$

Choose the final separation much larger than LB. A metric ball of radius $4B + C_L$ then meets at most two adjacent levels. Otherwise a path between its extreme levels would cross a complete intervening layer at cost at least ρ, contradicting the bound on the ball diameter. Its reached scales are comparable within L, and its physical extent is $C_L(B+1)\xi_y$. Counting their two grids proves

$$\#\{z : d(y,z) \le 2B + C_L\} \le C_L(1+B)^4. \tag{3.cmlxix}$$

This is a local consequence of separation. The global growth bound remains eq. 3.cdlvi.

The same observation proves the diameter assertion for the short carriers: neighboring complete old tiles have metric span $C_L M_0$, and fewer than $m(R+1)$ such steps cannot cross two separated interfaces. All tag eligibility, row lists and geometry decisions are read in the resulting ball, since those data were included in each old carrier. Cutoff by endpoint distance alone would not have this property.

Now choose a final aligned carrier tile size M_c, an L-power multiple of M_0, with

$$M_c \ge C_L(B+1), \qquad \rho \ge C_L L M_c. \tag{3.cmlxx}$$

The union of two radius-B balls with centers at distance at most B has a connected covering with at most B_L final tags, including its endpoint tags and short joins. The constant B_L depends on L and the fixed collar conventions, not on m, R. Write σ_c for the same guarded length on these final tags. Reblocking an old carrier into its aligned parents preserves its connections and satisfies $\sigma_c(\pi X) \le \sigma_0(X)$. Thus an old strong carrier weight pays the final one.

3.29.4. *Combine a short power before taking absolute values.* Fix the desired finite final carrier rate $\kappa > 0$ and use eq. 3.cmlxv at a stronger rate $\kappa_0 > \kappa + 1$. Choose $\beta \ge 2b$ and put

$$H = I - A/\beta, \qquad S = H_{\le R}, \qquad E = H_{>R}, \qquad H_{\le R} = \sum_{\sigma_0(X)\le R} H[X]. \tag{3.cmlxxi}$$

The families are first transpose symmetrized. This cutoff consequently preserves the real symmetry of S. Let $K_H \ge 2$ bound the old family norms of H, S, including the identity carrier. The tail obeys

$$\|\mathbf{E}\|_{s,\kappa,c} \le K_H e^{-(\kappa_0-\kappa)R} \quad (0 \le s \le s_0). \tag{3.cmlxxii}$$

Here and below the old coefficients are reblocked into final tags when the subscript c is used. This estimate cuts by the full old carrier; a long dependency with nearby matrix endpoints remains in the tail.

For R above a fixed threshold the unweighted tail operator norm is at most $a/(2\beta)$. Since $I/2 \le H \le (1 - a/\beta)I$ on the real domain,

$$0 \le S \le qI, \qquad q = 1 - a/(2\beta) < 1. \tag{3.cmlxxiii}$$

The real spectral estimate is used only at this point. The short matrix has propagation at most B/m. Therefore its mth power has range B, and eq. 3.cmlxix and the Hilbert row estimate give

$$\|S^m\|_{\mathrm{Sch}} \le C_L(1+B)^2 q^m. \tag{3.cmlxxiv}$$

Indeed the squared Hilbert–Schmidt norms of the blocks in one row sum to at most $r_0\|S^m\|_{2\to 2}^2$, where r_0 bounds the colour block dimension. Cauchy–Schwarz costs the square root of the number of reached cells. The same holds for columns. This estimate concerns the already combined matrix entries of S^m, not the absolute values of its individual paths.

Assign that combined entry $(S^m)_{yz}$ the symmetric full carrier covering the two radius-B balls of y, z. It includes every short path and its full coefficient dependencies. This is a local function:

agreement of backgrounds and recorded geometry on that carrier leaves all contributing short factors and their eligibility unchanged. Its final length is at most B_L. Denote the resulting family by $\mathbf{N}_m$. At any $0 < s \le s_0$ it has bound

$$\|\mathbf{N}_m\|_{s,\kappa,c} \le C_L e^{sB+\kappa B_L}(1+B)^2 q^m. \tag{3.cmlxxv}$$

In particular the cancellation used in eq. 3.cmlxxiv takes place inside a specified local coefficient before filing it.

Keep the remaining part as an actual word family:

$$\begin{aligned} E_j &= H^j - S^j = \sum_{i=0}^{j-1} S^i E H^{j-1-i}, \\ \|\mathbf{E}_j\|_{s,\kappa,c} &\le j K_H^j e^{-(\kappa_0-\kappa)R}. \end{aligned} \tag{3.cmlxxvi}$$

The family products file into their full joined carriers. Transpose symmetrization preserves the bound and the total operator E_j, since both H^j and S^j are symmetric. Define

$$\mathbf{T} = \mathbf{N}_m + \mathbf{E}_m. \tag{3.cmlxxvii}$$

Its total operator is exactly H^m.

Here is a noncircular choice of all parameters. First fix the real gaps and $\kappa_0 > \kappa + 1$, using the earlier fixed energy estimates. The comparison length slope and the carrier grids are auxiliary; changing them for the walks does not change the actual coarse matrices or their already proved gaps. Next construct the positive-walk inputs and their initial M_0, K_H, s_0. Choose a positive integer D so that $(\kappa_0-\kappa)D > 2\log K_H + 2$ and $R = Dm$ already meets the spectral-tail threshold for $m \ge 1$. Then choose m large. The quantity

$$\Gamma_m = 2C_L e^{\kappa B_L}(1 + C_L M_0 m(Dm+1))^2 q^m + m K_H^m e^{-(\kappa_0-\kappa)Dm} \longrightarrow 0. \tag{3.cmlxxviii}$$

Choose m with $\Gamma_m < 1/4$, put $R = Dm$, and choose M_c as in eq. 3.cmlxx. Set

$$s_* \le \min\{s_0/2, \log 2/(B+1)\}. \tag{3.cmlxxix}$$

Only then require

$$\rho \ge \max\{\rho_0, C_L L M_c, 64(\log L)/s_*\}. \tag{3.cmlxxx}$$

The last reserve allows later scale conversions and global cell sums at a smaller spatial rate. All gap and input-family bounds used to choose m are uniform above their initial separation threshold ρ_0. Thus no constant used earlier is being determined by the final geometry. The resulting family satisfies

$$\|\mathbf{T}\|_{s_*,\kappa,c} < 1/4 \quad \text{at real inputs.} \tag{3.cmlxxxi}$$

This retains the prescribed finite carrier rate κ through the enlarged carrier tile M_c. It does not retain a prescribed spatial rate: the positive s_* has been decreased explicitly.

3.29.5. *The exact coarse inverse and complex continuation.*

Proposition 3.103 (Carrier inverses of the actual positive coarse matrices)**.** For every prescribed finite carrier rate κ, choose the parameters and require the separation in eq. 3.cmlxxx. Then both M^{-1} and Θ^{-1} have exact local carrier families. In counting normalization these satisfy

$$\|\widehat{\mathbf{M}^{-1}}\|_{s_*,\kappa,c} + \|\widehat{\mathbf{\Theta}^{-1}}\|_{s_*,\kappa,c} \le C_\kappa. \tag{3.cmlxxxii}$$

The constants are uniform in depth, compatible volume and admitted geometry. The families are holomorphic on a common sufficiently small complex C^1 tube about the real regular domain and retain exact dependence on their recorded background and geometry. The physical inverses are obtained by $J^{-1}(\cdot)J$. ∎

Proof. For either normalized A, let $\star$ denote the joined-carrier product. The explicit inverse family is

$$\mathbf{B} = \beta^{-1} \left(\sum_{j=0}^{m-1} \mathbf{H}^{\star j} \right) \star \sum_{v \geq 0} \mathbf{T}^{\star v}. \tag{3.cmlxxxiii}$$

Its norm is at most $\beta^{-1} \sum_{j<m} K_H^j / (1 - \|\mathbf{T}\|)$. Every factor is an actual local coefficient and every product carries its full joined union. The sum is absolutely convergent in the family norm. At complete coefficients its operator is

$$\beta^{-1} \left(\sum_{j<m} H^j \right) (I - H^m)^{-1} = A^{-1}.$$

This follows from $(I - H) \sum_{j<m} H^j = I - H^m$; all factors are polynomials or convergent functions of H. The real positive matrix is invertible by eq. 3.cmlxiii. Final transpose symmetrization of the family preserves this inverse, its locality and its two-sided norm.

For complex continuation keep the same geometry, cutoff, powers and filing balls. Suppose

$$\|\mathbf{A}(z) - \mathbf{A}(z_0)\|_{s_0,\kappa_0,0} < \varepsilon, \tag{3.cmlxxxiv}$$

where z_0 is real. Tail projection is bounded in the input family norm. Each finite product is Lipschitz with bound $j(K_H + 1)^{j-1}$ times the perturbation. For the combined near entry, the same finite matrix identity bounds $S(z)^m - S(z_0)^m$ in unweighted Schur norm; its single local ball carrier costs at most $e^{s_* B + \kappa B_L}$. Thus $\|\mathbf{T}(z) - \mathbf{T}(z_0)\|_{s_*,\kappa,c} \leq C_{m,R,\kappa} \varepsilon$. Choose ε so this is below $1/4$. The actual input-family analyticity proved above then provides a common physical C^1 tube on which $\|\mathbf{T}(z)\| < 1/2$.

Series eq. 3.cmlxxxiii is normally convergent there. Its polynomial identity still makes it the inverse of the actual complex matrix. No Hermitian inequality is asserted at a complex input. Each filed coefficient is analytic in the data on its union carrier; the absolutely convergent sum over words with that recorded carrier preserves this local dependence. Banach Cauchy estimates give local derivative families on a smaller tube. Equivalently the actual first derivative has the local representation $-A^{-1}(DA)A^{-1}$, and higher derivatives are the finite ordered resolvent products. Their joined carriers retain every marked input. This proves the proposition. □

Corollary 3.104 (Positive row Schur inverses)**.** The same construction applies to an actual coarse matrix with a bounded number of row types per assigned cell, after its physical counting-unitary normalization, whenever its real gap and its actual input family satisfy eq. 3.cmlxiii and eq. 3.cmlxv. Its inverse then has the bound in eq. 3.cmlxxxii, with the corresponding finite constants and carrier tiles. In particular it applies to

$$\begin{aligned} T_0^{\mathrm{n}} &= \Xi_\Gamma^2 a_f^{1/2} Q G_0 Q^\sharp a_f^{1/2} \Xi_\Gamma^{-2}, \\ G_0 &= G_F + G_F (D_U F) \Theta^{-1} (D_U F)^\sharp G_F. \end{aligned} \tag{3.cmlxxxv}$$

There are at most eight rows per assigned top, as in eq. 3.dcccxxxviii. Small symmetric actual family-norm perturbations of this matrix have the same inverse construction through eq. 3.cmlxxxiv. ■□

Proof. Bundle the actual row species at each top; their colour block dimension is at most twenty-four. The counting proof and Hilbert row estimate use only this uniform bound. The row metric locations and their complete carriers differ from their incident tops by a fixed distance, so the same local and global geometry estimates apply.

For eq. 3.cmlxxxv, multiplication by $K_L = \mathcal{A}_F - (D_U F) M^{-1} (D_U F)^\sharp$ verifies the displayed Woodbury expression for $G_0 = K_L^{-1}$, using $\Theta = M - (D_U F)^\sharp G_F (D_U F)$. It is an exact composition of the local families already constructed. More explicitly, eq. 3.cmlxvi and eq. 3.cmlxvii give

$\|1_y G_F D_U F J^{-1} e_z\|_{\mathcal{E}_y} \le C e^{-s' d(y,z)}$. The only intermediate scale ratio is ξ_w/ξ_z, absorbed by the retained separation reserve. Thus G_0 has the same source-to-energy family grade as G_F. The normalized trace $\mathcal{Q}_n = \Xi_\Gamma^2 a_f^{1/2} Q$ is bounded from field energy to counting row space and has the actual finite complete carriers. Its counting-to-physical transpose is $\mathcal{Q}_n^\sharp = Q^\sharp a_f^{1/2} \Xi_\Gamma^{-2}$. The actual row density gives the stronger source bound

$$|(\mathcal{Q}_n^\sharp e_c)(b)| \le C \xi_c^{-3} \mathbf{1}_{\mathrm{carrier}(c)}(b), \qquad \xi_y \|1_y \mathcal{Q}_n^\sharp e_c\|_2 \le C. \tag{3.cmlxxxvi}$$

On its complete carrier ξ_y/ξ_c is bounded by a fixed L factor, and physical cell volume is ξ_y^4. Thus the injection belongs to the force-cell space already admitted by the positive walks. Composing these local injections with G_0 gives the actual input family of T_0^{n} in the proved norms. The real lower bound is the smooth-row-seed argument in eq. 3.dcccxl; the upper bound follows from the same trace and energy inverse bounds.

Choose the Gram and Θ inverse families at a stronger intermediate carrier rate first. Their finite compositions then meet the stronger input rate needed for this second application. This adds only finitely many parameter choices: the final carrier tile and separation are increased after both constructions. The proof does not identify that tile with M_h. Finally the perturbation assertion is precisely the common-tube argument above, once the stated actual family difference has been bounded. □

3.29.6. *Periods and the admission retained by the result.* For small periods choose one finite periodic cover large enough for all primitive and coarse patches and both aligned tile grids. Construct the primitive positive-walk families, their coarse compositions and the short-power inversion on that same cover, before any family projection. Thus the aligned M_0 to M_c parent relation is used before projected translated tag phases appear. The positive operators and actual coarse matrices descend on the deck-invariant subspace. If the auxiliary tile grid is not itself invariant under deck shifts, first average the final filed inverse family over the deck group, translating its carrier tags as well. Its total inverse is unchanged by uniqueness, and its family norm does not increase. The average is now covariant as a family.

Project its carriers with their level and periodic identification data retained. A base row sum is bounded by the cover row sum over all source lifts. By deck covariance the base column sum is bounded by the cover column sum over all output lifts. Connected projection cannot increase carrier length, and base distances cannot increase. Thus there is no sheet-count loss. Projected translated-cover tags are part of the recorded geometry; agreement with an independently prescribed history tiling is not assumed.

The result supplies actual local coefficients for the positive Gram and coarse Schur inverses on the admitted proper row graph. All complex bounds concern the common physical tube just proved. Independent enlarged cube input domains, separately prescribed indicator fillings, and hereditary tower comparisons require their own admission arguments. In particular a source history with only its stated M_h separation is not declared to satisfy eq. 3.cmlxxx by renaming M_h as the carrier size M_c.

3.30. **Local carriers for the named current propagators.** We assemble the actual site projection, gauge restoration and two current inverses in their prescribed order. The local positive walks are those of Prop. 3.102. All coefficients retain the actual complete rows, outward endpoints and inner plaquette set. The carrier cube size is M_{c}; it is independent of a prescribed history cube size M_{h}. Start with the actual real curvature-small reference and determining geometry of that positive-walk theorem. The final separation requirements of the finitely many coarse-inversion stages are retained. Complex coefficients range over their common weighted C^1 tube about this real reference. The independent current is specified below. The fixed positive site and field row weights are included in the declared local coefficient data.

Use the shifted connected carrier length σ_c, canonical endpoint tags and short joins of that construction. For a family $\mathbf{T} = (T_C)$ between normalized cell spaces, write

$$\|\mathbf{T}\|_{s,\kappa} = \max\Big\{ \sup_y \sum_{z,C} e^{sd(y,z)+\kappa\sigma_c(C)} \|1_y T_C 1_z\|, \\ \sup_z \sum_{y,C} e^{sd(y,z)+\kappa\sigma_c(C)} \|1_y T_C 1_z\| \Big\}. \tag{3.cmlxxxvii}$$

Only families whose carriers contain their matrix endpoints are used. Products retain the indicated short join at each intermediate cell. The carrier inequality and triangle inequality make this norm submultiplicative whenever the intermediate normalized spaces agree.

Site L^2 uses the physical fine measure. The field energy is X, its dual is X^*, and Z is the actual site second-difference space in eq. 3.cmxxix. Their local norms use the assigned cells and fixed derivative collars. Energy spaces and their duals are localized by a smooth square partition on fixed enlargements of the disjoint pillars. Each profile has first difference at most C_L/ξ_y, and their overlaps are bounded. Such a partition is obtained by normalizing squared smooth bumps on the pillar cubes; overlapping scales are comparable within L. Multiplication is bounded in the physical energy and dual norms by the product rule and the mass term. Inserting this square partition in a product proves the Schur multiplication estimate, with one fixed localization constant. Absorb that constant in the algebra norm used in eq. 3.cmlxxxvii. This avoids a sharp characteristic-function cutoff in a Sobolev space. Pure L^2 blocks may use disjoint cell ownership. All localization collars are retained in the carriers. Coarse spaces will always specify their physical-to-counting unitary. No unweighted array transpose is substituted for a physical transpose.

Fix a finite carrier rate $\kappa > 0$, and leave a strict reserve in the positive-walk spatial rate. Separation can be increased so that, for some sufficiently small ε_g,

$$\max\{\xi_y/\xi_z, \xi_z/\xi_y\} \le C_L e^{\varepsilon_g d(y,z)}. \tag{3.cmlxxxviii}$$

Indeed crossing one nonadjacent layer costs a fixed multiple of ρ in the layer distance, while its scale changes by a factor L; adjacent-cell ratios cost only C_L. The same choice leaves the cell-count reserve used below. All geometric constants, tile choices and rate reserves are fixed before the depth or volume.

3.30.1. *The output site factor has two differences.* The positive site parametrix uses the local output factor

$$L_x = \chi_x E_{D_x} A_{s,D_x}^{-1} E_{D_x}^{\sharp} \chi_x.$$

Its artificial Dirichlet boundary lies outside the support of χ_x, with room for every complete row and derivative collar. Let Z_y denote the local Z norm.

Lemma 3.105 (A current-free second-difference output)**.** For a source in the assigned cell B_z,

$$\|1_y L_x 1_z f\|_{Z_y} \le C \frac{\xi_z}{\xi_y} e^{-s_1 d(y,z)} \|f\|_{2,B_z} \tag{3.cmlxxxix}$$

whenever this local factor is present. The constants are uniform in the patch radius, mesh and depth. The coefficient retains the positive-walk carrier, enlarged only by its fixed derivative collar. No physical-current bound is a premise. ∎

Proof. Put $v = E_{D_x} A_{s,D_x}^{-1} E_{D_x}^{\sharp} \chi_x 1_z f$ and $u = \chi_x v$. The local positive column bound gives

$$\|v\|_{\mathcal{E}_y} \le C \xi_z e^{-s_0 d(y,z)} \|f\|_{2,B_z}.$$

Multiplication by χ_x preserves that bound on fixed cell enlargements. Consequently the mass and first-gradient parts of Z_y have the stated additional factor ξ_y^{-1}.

For the second differences the exact compressed equation, multiplied by the interior cutoff, gives in the original site space

$$\Delta_U u = \chi_x^2 1_z f + [A_s, \chi_x]v - q^\sharp a_s q u. \tag{3.cmxc}$$

There is no artificial boundary source on the support of this equation: its cutoff is separated from the compression boundary by more than the row range. The slow-commutator estimate bounds its middle term locally by $C\xi_y^{-1}\|v\|_{\mathcal{E}_{\mathcal{D}_y}}$. For the last term the actual transported row bound gives

$$\|q^\sharp a_s q u\|_{2,B_y} \le C\xi_y^{-2}\|u\|_{2,\mathcal{D}_y} \le C\xi_y^{-1}\|u\|_{\mathcal{E}_{\mathcal{D}_y}}.$$

The enlargement $\mathcal{D}_y$ has bounded metric radius and bounded cell count, with comparable scales. This uses the complete average; it is not a point evaluation of u.

At a nonbare cell take a cutoff on a fixed surrounding cube, equal to one on the derivative collar of B_y. That cube is inside the actual action region by separation. The unitary discrete Hodge calculation applied to its compactly supported scalar field gives

$$\|\nabla_U D_U u\|_{2,B_y} \le C\{\|\Delta_U u\|_{2,\mathcal{D}_y} + \xi_y^{-1}\|D_U u\|_{2,\mathcal{D}_y} + \xi_y^{-2}\|u\|_{2,\mathcal{D}_y}\}. \tag{3.cmxci}$$

In that calculation the curl of $D_U u$ is a finite curvature multiplication and shift of u, and the covariant Hodge commutator is curvature times $D_U u$. Thus it uses no derivative of curvature or of the current. It is the local compact-support version of the calculation in eq. 3.dcclxxxviii.

Insert eq. 3.cmxc and the column bound. The direct source term is present only on a bounded enlargement of B_z, where its scale ratio and distance are bounded. All other terms are at most $C(\xi_z/\xi_y)e^{-s_1 d(y,z)}\|f\|_2$, with a fixed smaller rate.

At a true outer boundary the assigned scale is η. Each first or second difference has finitely many neighbours and costs η^{-1} or η^{-2}. The atomic mass and gradient parts of the local energy therefore bound the same Z_y norm by $C\eta^{-1}\|v\|_{\mathcal{E}_{\mathcal{D}_y}}$. This proves the result without applying an interior Hodge identity across a missing plaquette. □

Proposition 3.106 (A local site inverse in the actual source norm)**.** The actual site inverse has an exact carrier family with

$$\|\mathbf{G}_s\|_{L^2\to Z;s,\kappa} \le C_\kappa, \qquad \|D\mathbf{G}_s\|_{L^2\to X;s,\kappa} \le C_\kappa \tag{3.cmxcii}$$

for a fixed $s > 0$. It is holomorphic on a common smaller complex C^1 tube about each actual real reference, in the fixed real physical norms. ■

Proof. In the positive-walk series replace only its leftmost output factor by eq. 3.cmlxxxix. An error factor between source cells, expressed in unweighted L^2 norms, carries the ratio $\xi_{\text{input}}/\xi_{\text{output}}$, since the positive source norm is $\xi\|f\|_2$. The output upgrade has exactly that same endpoint ratio. In every product these ratios telescope. The whole walk therefore pays ξ_z/ξ_y once, not once at every step. Use eq. 3.cmlxxxviii to absorb it by the fixed spatial-rate reserve. The positive error-family contraction and the shifted carrier weight are unchanged. Its absolute geometric sum proves the first bound. The local map $D : Z \to X$ proves the second.

For complex coefficients, use the real reference Hodge estimate. The weighted C^1 tube gives locally

$$\|(\Delta_U - \Delta_{U_0})u\|_2 \le C\varepsilon\{\xi_y^{-1}\|D_{U_0}u\|_2 + \xi_y^{-2}\|u\|_2\}.$$

This is the actual first-difference coefficient expansion used in the complex site comparison; it needs only the tube's first covariant difference. The local inverse column bound is already uniform on that tube. The preceding proof and the equivalence of its fixed norms therefore apply unchanged. Each factor is a local finite matrix inverse and a local differentiated cutoff, so it is holomorphic; normal convergence gives the claimed carrier-family holomorphy. □

Corollary 3.107 (A divergence source without its derivative)**.** The same family gives

$$\|\,\mathbf{G}_s D^\sharp\,\|_{X^*\to L^2;s,\kappa} \le C_\kappa. \tag{3.cmxciii}$$

This is the physical transpose of $D\mathbf{G}_s : L^2 \to X$. The source $D^\sharp f$ is interpreted by its variational pairing. The assertion requires no fine pointwise value of that divergence. ■□

3.30.2. *Variational sources and balanced site fields.* Let $\mathfrak{F}$ be the fine force space with local norm $\|f\|_{\mathfrak{F}_y} = \xi_y \|f\|_{2,B_y}$. It embeds in X^*, with a uniform constant. Use the site spaces $Y, Y^\flat$ of eq. 3.cmxxix.

Lemma 3.108 (Local positive factors accept variational sources)**.** The positive inverse families also have the bounds

$$\|\mathbf{G}_F\|_{X^*\to X;s,\kappa} + \|\mathbf{G}_s\|_{Y^\flat\to Y;s,\kappa} \le C_\kappa. \tag{3.cmxciv}$$

The site divergence $D^\sharp f$ can be used as a $Y^\flat$ source whenever $\|\ell f\|_2$ is finite. All these statements use physical variational pairings. ■

Proof. The local weighted energy proof in Lem. 3.100 applies to a functional supported on a cell, with its local energy-dual norm: testing the compressed equation and its exponential conjugate uses only that norm. Multiplying the functional by the smooth input cutoff is bounded by the same product rule. Thus the local inverse has energy-dual to energy columns with the same decay.

The commutator in Lem. 3.101 maps that energy output into the L^2 force space $\mathfrak{F}$. Consequently the rightmost error factor in a nonempty positive walk maps an energy-dual source to $\mathfrak{F}$; all subsequent error factors act in the already controlled $\mathfrak{F}$ space. The zero-error term is the local variational inverse itself. The same absolute geometric sum therefore proves the energy-dual inverse family. For the vector operator its energy space is X.

For the scalar operator the local unbalanced energy is $\mathcal{E}_y \simeq \xi_y^{-1} Y_y$. Its local dual, when used as a source in the unweighted equation, has norm $\xi_y^{-1} Y_y^\flat$, because $Y^\flat$ uses the pairing with $\ell^2 u$. Thus the scalar column picks up the ratio ξ_y/ξ_z. Absorb this once by eq. 3.cmlxxxviii, as in the preceding proof. This gives the second bound in eq. 3.cmxciv. Finally

$$|\langle D^\sharp f, \ell^2 u\rangle| = |\langle f, D(\ell^2 u)\rangle| \le C\|\ell f\|_2 \|u\|_Y.$$

No derivative of f, and hence no derivative of an independent current, is taken. □

3.30.3. *Physical top units, projection and restoration.* Write $J_s = \Xi^2$ for the unitary from the physical top space to counting ℓ^2, and define

$$\widehat{F} = F J_s^{-1} = G_s q^\sharp \Xi^{-4}, \qquad \widehat{M} = J_s M J_s^{-1} = \widehat{F}^\sharp \widehat{F}. \tag{3.cmxcv}$$

The transpose in the last equality is between counting top space and the physical fine site space. In particular $\widehat{F}^\sharp = J_s F^\sharp$; this formula keeps the physical top measure.

The actual injection $q^\sharp \Xi^{-4}$ maps a unit counting top datum to density $C\xi_z^{-4}$ on its pillar. Its local $Y^\flat$ norm is bounded, since that norm supplies ξ_z^2 and the physical L^2 norm supplies another ξ_z^2. Consequently eq. 3.cmxciv proves

$$\|\widehat{\mathbf{F}}\|_{\ell^2_{\mathrm{top}}\to Y;s,\kappa} + \|\widehat{\mathbf{F}}\|_{\ell^2_{\mathrm{top}}\to L^2;s,\kappa} + \|D\widehat{\mathbf{F}}\|_{\ell^2_{\mathrm{top}}\to \mathfrak{F};s,\kappa} \le C_\kappa. \tag{3.cmxcvi}$$

Equivalently its unabsorbed local L^2 column has factor ξ_y/ξ_z, as in eq. 3.cmlxvi. No fine-coordinate dimension appears in this normalization.

Choose the positive coarse inverse families of Prop. 3.103 at a stronger intermediate carrier rate $\kappa_1 > \kappa + 1$. Their input positive families are first obtained at another fixed rate $\kappa_2 > \kappa_1 + 1$. All ensuing finite reblockings use aligned parents and the recorded joins. Work on a common final periodic cover when needed, so the canonical tags for all products agree before descent. Until the row-Schur inversion, the following compositions are made at κ_1; their displayed weaker bounds at κ follow by decreasing the carrier weight.

Proposition 3.109 (Local projection and gauge restoration)**.** The actual maps

$$P = \widehat{F}\widehat{M}^{-1}\widehat{F}^{\sharp}, \quad R = 1 - P, \quad \Lambda = G_s R D^{\sharp}, \quad S = 1 - D\Lambda \tag{3.cmxcvii}$$

have exact local carrier families, with bounds

$$\begin{aligned} \|\mathbf{P}\|_{L^2\to Y;s,\kappa} + \|\mathbf{R}\|_{L^2\to L^2;s,\kappa} + \|\mathbf{R}\|_{Y\to Y;s,\kappa} &\le C_\kappa, \\ \|\mathbf{\Lambda}\|_{X\to Z;s,\kappa} + \|D\mathbf{\Lambda}\|_{X\to X;s,\kappa} + \|\mathbf{S}\|_{X\to X;s,\kappa} + \|\mathbf{S}^{\sharp}\|_{\mathfrak{F}\to\mathfrak{F};s,\kappa} &\le C_\kappa. \end{aligned} \tag{3.cmxcviii}$$

■

Proof. Compose eq. 3.cmxcvi with the actual normalized Gram inverse. Its transpose has $\widehat{F}^{\sharp} : L^2 \to \ell^2_{\mathrm{top}}$. This proves $P : L^2 \to Y$, hence the two bounds for R. The full physical divergence maps X locally into site L^2. Near a true boundary its one-edge term is paid by the bare mass. Composing it with R and eq. 3.cmxcii proves the bounds for $\Lambda, D\Lambda, S$.

For the last bound use the exact transpose

$$S^{\sharp} = 1 - DRG_sD^{\sharp}.$$

Here $D^{\sharp} : \mathfrak{F} \to Y^{\flat}$ is a variational divergence, $G_s : Y^{\flat} \to Y$, $R : Y \to Y$, and $D : Y \to \mathfrak{F}$. Every factor has the claimed local family. This is a weighted L^2 force assertion; it is not an L^∞ Riesz assertion. □

3.30.4. *The zero-current Landau inverse.* Put $\widehat{B} = D\widehat{F}$ and $\widehat{\Theta} = J_s\Theta J_s^{-1}$. The exact positive factorization is

$$G_0 = G_F + G_F\widehat{B}\widehat{\Theta}^{-1}\widehat{B}^{\sharp}G_F. \tag{3.cmxcix}$$

It is the physical identity eq. 3.cmxlv in counting top units. The injection $\widehat{B} : \ell^2_{\mathrm{top}} \to \mathfrak{F}$ is eq. 3.cmxcvi; its transpose acts from field energy into counting top space. Thus the positive coarse families and the positive field families prove

$$\|\mathbf{G}_0\|_{X^*\to X;s,\kappa_1} + \|\mathbf{G}_0\|_{\mathfrak{F}\to X;s,\kappa_1} \le C_{\kappa_1}. \tag{3.m}$$

There is no replacement of the actual projected precision by a periodic model in this argument. The inverse $\widehat{\Theta}^{-1}$ contains its complete geometry carrier.

3.30.5. *The first current precision and its lift.* Restrict J to bonds touching Ω_1, as allowed by the exact identities in § 3.26, and put

$$\gamma_{\mathrm{t}} = \sup_{b \text{ touches } \Omega_1} \mathsf{L}(b)^3|J(b)|.$$

We make this restriction before forming the coefficient families. It is a global exact identity for the field operator; an individual inverse coefficient need not vanish on bare bonds.

Lemma 3.110 (The actual current family is small)**.** The canonical symmetric correction has an exact carrier family with

$$\|\mathbf{B}_U[J]\|_{X\to\mathfrak{F};s,\kappa_1} + \|\mathbf{B}_U[J]\|_{X\to X^*;s,\kappa_1} \le C_{\kappa_1}\gamma_{\mathrm{t}}. \tag{3.mi}$$

No derivative of J is used. ■

Proof. For $\lambda = \Lambda v$, the exact grouped formula is

$$B_U[J]v = W[J]\lambda + DRG_sh_J, \qquad h_J = W[J]^{\sharp}v - \tfrac{1}{2}\{D^{\sharp}W[J]\lambda + W[J]^{\sharp}D\lambda\}. \tag{3.mii}$$

The actual endpoint current bounds in eq. 3.cmxli show that $W[J]\lambda$ is in $\mathfrak{F}$, with norm $C\gamma_{\mathrm{t}}\|\lambda\|_Z$, while h_J is in $Y^{\flat}$, with norm $C\gamma_{\mathrm{t}}(\|v\|_X + \|\lambda\|_Z)$. These bounds hold as carrier bounds: $W[J]$ reads one bond and its two endpoint values, and $D^{\sharp}W[J]\lambda$ is kept as a divergence. Compose with the families $G_s : Y^{\flat} \to Y$, $R : Y \to Y$ and $D : Y \to \mathfrak{F}$. Every union keeps the actual input current bond and both matrix endpoints. The two Schur sums give eq. 3.mi. □

The first named inverse is now defined without an implicit change of completion:

$$\begin{aligned}\mathbf{G} &= \mathbf{G}_0 \star \sum_{n\ge 0} (\mathbf{B}_U[J] \star \mathbf{G}_0)^{\star n},\\ \sum_C G_C = G &= (G_0^{-1} - B_U[J])^{-1}.\end{aligned} \tag{3.miii}$$

The right side denotes its joined-carrier family; at complete coefficients it is the displayed matrix inverse. Choose the touching-current ceiling so the $\mathfrak{F} \to \mathfrak{F}$ error norm is less than $1/4$. For a general X^* source only the rightmost current factor uses $B_U[J]G_0 : X^* \to \mathfrak{F}$; all subsequent loops use $\mathfrak{F} \to \mathfrak{F}$. This proves exact normally convergent families for

$$G : X^* \to X, \qquad G : \mathfrak{F} \to X,$$

and the same family norm for $G - G_0$ is $C_{\kappa_1}\gamma_{\mathrm{t}}$.

Let the physical field-row measure be ξ_c^4 and put

$$J_\Gamma = \Xi_\Gamma^2, \qquad \mathcal{Q}_n = J_\Gamma a_f^{1/2} Q, \qquad \mathcal{Q}_n^\sharp = Q^\sharp a_f^{1/2} J_\Gamma^{-1}. \tag{3.miv}$$

This trace maps X to counting row space; its transpose maps counting rows into $\mathfrak{F}$. The latter is the actual density computation in eq. 3.cmlxxxvi. Define

$$\mathcal{T}_0 = \mathcal{Q}_n G_0 \mathcal{Q}_n^\sharp, \qquad \mathcal{T}_J = \mathcal{Q}_n G \mathcal{Q}_n^\sharp. \tag{3.mv}$$

The real $\mathcal{T}_0$ has the actual SCR lower and upper gap. Apply Cor. 3.104 to its actual family, using the intermediate rate κ_1. It gives a family for $\mathcal{T}_0^{-1}$ at the final rate κ, with a final aligned tile size M_{c} and a positive final spatial rate. Reblock all preceding families into those parents and reduce their spatial rates to a common positive value. The actual difference satisfies

$$\|\mathcal{T}_{\mathbf{J}} - \mathcal{T}_{\mathbf{0}}\|_{s,\kappa} \le C_\kappa \gamma_{\mathrm{t}}.$$

A second fixed decrease of the current ceiling therefore gives the exact inverse family

$$\mathcal{T}_{\mathbf{J}}^{-\mathbf{1}} = \mathcal{T}_{\mathbf{0}}^{-\mathbf{1}} \star \sum_{n\ge 0} [-(\mathcal{T}_{\mathbf{J}} - \mathcal{T}_{\mathbf{0}}) \star \mathcal{T}_{\mathbf{0}}^{-\mathbf{1}}]^{\star n}. \tag{3.mvi}$$

At a complex background the same argument is centered at the real reference matrix and includes its small actual physical-tube family perturbation.

Write $\mathcal{S}_J = QGQ^\sharp$. The normalized first lift and the physical lift are

$$\mathcal{H}_J = G\mathcal{Q}_n^\sharp \mathcal{T}_J^{-1}, \qquad H = \mathcal{H}_J J_\Gamma a_f^{1/2} = GQ^\sharp \mathcal{S}_J^{-1}. \tag{3.mvii}$$

Thus $\mathcal{H}_J$ has a local carrier family from counting rows into X, and H has one from the physical datum norm $\|a_f^{1/2} b\|_{\mathrm{rows}}$. In particular $QH = 1$ as an exact identity of the sums. No termwise row or gauge identity has been assumed.

3.30.6. *The first-lift induced multiplier retains its root.* Let J_{full} be the original current and $J = J_{\mathrm{full}}^{\mathrm{t}}$ the restriction used above. Define

$$\omega^{\mathrm{t}} = H^\sharp J.$$

For a carrier coefficient H_C, retain the coefficient $\omega_{c,C}^{\mathrm{t}} = ((H_C)^\sharp J)(c)$. The carrier contains the row c, every paired fine current bond, and the background data read by H_C.

Proposition 3.111 (An absolutely rooted multiplier family)**.** The first-lift readout satisfies

$$\sup_c \sum_C e^{\kappa\sigma_c(C)} \xi_c^3 |\omega_{c,C}^{\mathrm{t}}| \le C_\kappa \gamma_{\mathrm{t}}. \tag{3.mviii}$$

The actual multiplier for the unrestricted bare current is

$$\omega_* = H^\sharp J_{\mathrm{full}} = \omega^{\mathrm{t}} + \iota_0 J_{\mathrm{full}}^{\mathrm{b}}. \tag{3.mix}$$

In particular its nonbare family obeys eq. 3.mviii. An all-row bound retains the full current radius $\gamma_{\mathrm{full}} = \sup_b \mathsf{L}(b)^3 |J_{\mathrm{full}}(b)|$. ■

Proof. Fix a unit colour e at row c and use $b^{(c)} = \xi_c^{-1} e_c$. Its physical datum energy is bounded above and below by constants. The exact physical transpose gives

$$\xi_c^3 \langle \omega^{\mathrm{t}}_{c,C}, e\rangle = \langle H_C b^{(c)}, J\rangle_{\mathrm{fine}}. \tag{3.mx}$$

Split the fine pairing by disjoint bond ownership cells. On such a cell $\|\xi J\|_2 \le C_L \gamma_{\mathrm{t}}$, while the mass part of X_y bounds $\|\xi^{-1} H_C b^{(c)}\|_2$. Therefore the left side of eq. 3.mviii is at most

$$C\gamma_{\mathrm{t}} \sum_{y,C} e^{\kappa \sigma_c(C)} \|1_y H_C b^{(c)}\|_{X_y} \le C_\kappa \gamma_{\mathrm{t}}.$$

This is the actual family column sum; no whole-volume energy norm is charged to J.

For the bare split use the exact identities $Q_0 H = P_0$ and equality of the physical fine and level-zero row measures, both η^4. They give $H^\sharp J^{\mathrm{b}}_{\mathrm{full}} = \iota_0 J^{\mathrm{b}}_{\mathrm{full}}$, as in eq. 3.cmxix. This is an identity of the complete sums. It does not assert that a nonbare column of each H_C vanishes at every bare bond. We used the touching restriction before forming these families for precisely this reason. The extra bare family is local and has amplitude bounded by the full γ_{full}, rather than by γ_{t}. □

3.30.7. *Only then form the second precision.* The actual bare re-centered mean is linear, so its second derivative is zero. Thus $\Delta^{(2)}_U[\omega_*] = \Delta^{(2)}_U[\omega^{\mathrm{t}}]$. Form the constraint family by joining each rooted coefficient $\omega^{\mathrm{t}}_{c,C}$ to the complete two-leg carrier of its actual row c. The physical two-leg bound then gives

$$\|\mathbf{C}_{\omega_*}\|_{X\to\mathfrak{F};s,\kappa} \le C_\kappa \gamma_{\mathrm{t}}, \qquad \mathbf{C}_{\omega_*} = \boldsymbol{\Delta}^{(\mathbf{2})}_{\mathbf{U}}[\omega_*]. \tag{3.mxi}$$

To check this normalization, the row coefficient has fixed-leg density $C_L \xi_c (\eta/\xi_c)^4$. Its physical transpose has factor $\eta^{-4}\xi_c^4$. Inserting $|\omega(c)| \le C\gamma_{\mathrm{t}} \xi_c^{-3}$ and the field mass norm gives $\|\ell C_{\omega_*} v\|_2 \le C\gamma_{\mathrm{t}} \|\ell^{-1} v\|_2$. Both leg sums are retained. There are only a bounded number of incident rows and neighbouring assigned cells. For a coefficient family, use the absolute sum eq. 3.mviii in place of the single multiplier bound. The row star changes the carrier length by a fixed constant and its input-output metric radius is bounded. This proves eq. 3.mxi as a family estimate.

By eq. 3.cmxcviii,

$$\mathbf{V}_* = \mathbf{S}^\sharp \star \mathbf{C}_{\omega_*} \star \mathbf{S}, \qquad \|\mathbf{V}_*\|_{X\to\mathfrak{F};s,\kappa} \le C_\kappa \gamma_{\mathrm{t}}. \tag{3.mxii}$$

The exact second inverse is consequently

$$\begin{aligned} \mathbf{G}_1 &= \mathbf{G} \star \sum_{n\ge 0} (\mathbf{V}_* \star \mathbf{G})^{\star n}, \\ \sum_C (G_1)_C = G_1 &= (G^{-1} - S^\sharp \Delta^{(2)}_U[\omega_*] S)^{-1}. \end{aligned} \tag{3.mxiii}$$

Decrease the same fixed touching-current ceiling so the force-space error has family norm less than $1/4$. As for the first inverse, a general X^* source is used only at the rightmost factor; subsequent loops take place in $\mathfrak{F}$. This proves carrier bounds for $G_1 : X^* \to X$ and $G_1 : \mathfrak{F} \to X$, and for $G_1 - G_0$ with the additional factor γ_{t}. The lift inside ω_* throughout this construction is H, not the following H_1.

Put

$$\mathcal{T}_1 = \mathcal{Q}_n G_1 \mathcal{Q}_n^\sharp, \qquad \mathcal{H}_1 = G_1 \mathcal{Q}_n^\sharp \mathcal{T}_1^{-1}, \qquad H_1 = \mathcal{H}_1 J_\Gamma a_f^{1/2}. \tag{3.mxiv}$$

The difference $\mathcal{T}_1 - \mathcal{T}_0$ has family norm $C_\kappa \gamma_{\mathrm{t}}$. Use the already constructed $\mathcal{T}_0^{-1}$ in the same Neumann formula as eq. 3.mvi. This constructs the exact $\mathcal{T}_1^{-1}$ and H_1 families without a new positivity assumption at an independent current. At complete coefficients,

$$H_1 = G_1 Q^\sharp (Q G_1 Q^\sharp)^{-1}, \qquad Q H_1 = 1.$$

3.30.8. *The assembled range and its limits.*

Proposition 3.112 (Named current carriers in physical norms)**.** Fix a finite carrier rate κ. Choose the two positive coarse-inversion stages, their carrier tiles, separation reserves and common complex C^1 tube as above. There is a fixed touching-current ceiling $\gamma_* > 0$ such that for $\gamma_{\mathrm{t}} < \gamma_*$ the actual canonical operators have exact, normally convergent local carrier families in the following spaces:

$$\begin{aligned} &G_s : L^2 \to Z, \quad R : L^2 \to L^2, \quad \Lambda : X \to Z, \quad S : X \to X, \\ &G_0, G, G_1 : X^* \to X, \qquad G_0, G, G_1 : \mathfrak{F} \to X, \\ &\mathcal{H}_J, \mathcal{H}_1 : \ell^2_{\mathrm{rows}} \to X, \qquad \mathcal{T}_J^{-1}, \mathcal{T}_1^{-1} : \ell^2_{\mathrm{rows}} \to \ell^2_{\mathrm{rows}}. \end{aligned} \tag{3.mxv}$$

Their family norms are bounded by fixed C_κ. The nonbare first-lift readout has the rooted bound eq. 3.mviii. The physical Schur inverses and lifts are obtained by the displayed row unitaries and weights, not by changing transposes.

Every coefficient is holomorphic in the actual local background and touching-current data on the stated tubes, with its complete recorded determining geometry. Agreement of these data on its carrier gives the same coefficient. The constants are independent of depth, compatible volume and admitted region shape. The current ceiling depends on the fixed carrier constants and has no Hölder-exponent dependence. ■

Proof. The successive constructions prove each assertion in the order $R, \Lambda, G_0, G, H, \omega_*, G_1, H_1$. All operations are finite local coefficients, positive coarse inverse families or normally convergent small-current series in the same joined-carrier algebra. Each product retains its endpoint tags and fixed short joins. The cutoff-source and scale-ratio reserves were paid before these compositions.

Only finitely many positive inversion and reblocking stages are used. Choose the intermediate carrier rates first, then their finite short-power parameters, the final aligned M_{c}, and the common separation threshold. Finally choose the common physical tube and the current ceiling smaller than the finitely many displayed Neumann bounds. None of these steps uses a Hölder exponent or a current derivative. The H^2 output argument uses only the L^2 unitary Hodge estimate.

For small periods carry out this entire finite construction on one sufficiently large compatible periodic cover with common tag grids. Average the final families over simultaneous deck shifts and project their recorded tags. The row and column absolute sums descend as in the positive and coarse walk proofs. Their shifted joins and physical unitaries are retained. Thus no sheet-count factor enters the bound or the current ceiling. □

For clarity, write $G_J = G$. The physical row Schur inverse is

$$(QG_iQ^\sharp)^{-1} = a_f^{1/2} J_\Gamma^{-1} \mathcal{T}_i^{-1} J_\Gamma a_f^{1/2}, \qquad i = J, 1.$$

In the physical angle and dual-current units $\beta = \Xi_\Gamma b$, $\nu = \Xi_\Gamma^3 \mu$, put $c_a = \Xi_\Gamma a_f^{1/2}$. The mass-removed coarse operator therefore has the exact normalized family

$$\Xi_\Gamma^3 \{(QG_iQ^\sharp)^{-1} - a_f\} \Xi_\Gamma^{-1} = c_a(\mathcal{T}_i^{-1} - 1)c_a. \tag{3.mxvi}$$

This identity retains the artificial mass subtraction. The separate lower bound on the actual outer plain-constraint fibre is proved in Prop. 5.45, with the full outer constraint curvature and the specified relative contour quadratic form. Its physical absolute-contour identification holds in an averaged-contour axial representative.

The result gives the canonical completion selected in § 3.26. The first-order output families on the same C^1 domain and their enlarged cube-parameter discs are constructed in Prop. 3.171 and Lem. 3.172. All prescribed histories must use the common separation and filing constants of these constructions. The positive clean conditional measure and its normalizer require their own measure and gauge identifications.

3.31. **Second derivatives in a discrete Hölder norm.** The bounded-force estimates give a first derivative in every fixed Hölder class below exponent one. For the nonlinear gauge slice, a site gauge requires two derivatives in the same Hölder class. This needs cancellation of the second-resolvent kernel, in addition to its finite-p bounds. We prove that estimate and then apply it to the actual site inverse.

Fix $0 < \alpha < 1$. On $h\mathbb{Z}^4$ write

$$\|f\|_{C_h^\alpha} = \|f\|_\infty + \sup_{0<|x-x'|\le 1} \frac{|f(x) - f(x')|}{|x - x'|^\alpha}.$$

Only distinct lattice points occur in the seminorm. First and second difference norms use all forward or backward component differences. On a fixed interior box the same notation restricts to present stencils. All statements concern the physical lattice measure of § 3.24.

3.31.1. *Cancellation of a truncated second kernel.* Let $k_h = D_i^\sigma D_j^\tau (L_h + 1)^{-1}$ denote its physical convolution kernel. In addition to Lem. 3.78, it obeys

$$|k_h(x)| + |Dk_h(x)| \le C_N |x|^{-N}, \qquad |x| \ge 1, \tag{3.mxvii}$$

for any fixed sufficiently large N. Indeed insert the heat representation and use eq. 3.dccclxxii with spatial power N, retaining the factor e^{-t}. For a derivative of order $a = 2, 3$, its integral is bounded by

$$C_N |x|^{-N} \int_0^\infty e^{-t} (t + h^2)^{(N-4-a)/2}\, dt.$$

Choose $N > 4 + a$. The integral is uniformly bounded for $h \le 1$. No exponential off-diagonal assertion is needed here.

Lemma 3.113 (Uniform truncated cancellation)**.** The kernel has total physical sum zero and

$$\left| h^4 \sum_{|x|\le r} k_h(x) \right| \le C, \qquad r \ge h. \tag{3.mxviii}$$

The constant is independent of the mesh and of the truncation radius. ■

Proof. For fixed h the massive kernel is absolutely summable by the heat L^1 estimate in Prop. 3.79. Each differentiated heat kernel has sum zero, so its time integral has sum zero as well. For the truncated sum split the time integral at r^2.

For $0 < t < r^2$, replace the sum over the ball by the negative sum over its complement. The differentiated heat tail bound eq. 3.dclxxxiv, in its infinite-lattice version used in § 3.24, gives

$$\left| h^4 \sum_{|x|\le r} D_i^\sigma D_j^\tau p_t^h(x) \right| \le C_N (t + h^2)^{-1} (1 + r/\sqrt{t + h^2})^{-N}.$$

Its integral is bounded uniformly: put $v = t + h^2$, use $h \le r$, and bound it by $C_N r^{-N} \int_0^{2r^2} v^{N/2-1}\, dv$. For $t \ge r^2$, use the physical volume Cr^4 of the lattice ball and the pointwise derivative bound Ct^{-3}. The integral is at most $Cr^4 \int_{r^2}^\infty t^{-3}\, dt = C$. The mass factor only improves both bounds. □

The same bound holds for a ball whose centre is displaced from the kernel centre by at most one quarter of its radius. Compare concentric inner and outer balls of comparable radii; their difference is an annulus on which the absolute kernel bound has total mass at most C. This observation will control the constant part of a nearby Hölder increment.

3.31.2. *The scalar Hölder multiplier.*

Proposition 3.114 (Uniform discrete Schauder multiplier)**.** For every $0 < \alpha < 1$,

$$\|D_i^\sigma D_j^\tau (L_h + 1)^{-1} f\|_{C_h^\alpha} \le C_\alpha \|f\|_{C_h^\alpha}. \tag{3.mxix}$$

The same constant holds on every compatible periodic torus. At fixed mesh the convolution is the ordinary absolutely summable massive kernel; no principal value is left undefined. ■

Proof. Write $Tf = k_h * f$. Cancellation gives

$$Tf(x) = h^4 \sum_w k_h(x - w)[f(w) - f(x)].$$

For $|w - x| \le 1$, use the Hölder increment and $|k_h(z)| \le C(|z| + h)^{-4}$. The sum over dyadic annuli is at most $C_\alpha [f]_\alpha$, including its last atomic annulus. For larger distances, eq. 3.mxvii gives $C\|f\|_\infty$. This proves the supremum bound.

For the seminorm let $\delta = |x - x'|$, $h \le \delta \le 1/16$. Since each translate of the kernel has sum zero,

$$Tf(x) - Tf(x') = h^4 \sum_w [k_h(x - w) - k_h(x' - w)][f(w) - f(x)].$$

Split the sum into $|w - x| \le 4\delta$ and its complement. In the near part, the first kernel is multiplied by a Hölder increment at its own centre, so its absolute sum is $C_\alpha [f]_\alpha \delta^\alpha$. For the second kernel write

$$f(w) - f(x) = [f(w) - f(x')] + [f(x') - f(x)].$$

The first term has the same bound. The constant second term is multiplied by the kernel sum over a ball of radius 4δ centred a distance δ from its kernel centre. Lem. 3.113 and the following annulus comparison bound that sum by C. Its contribution is therefore also at most $C[f]_\alpha \delta^\alpha$.

In the far part, telescope a coordinate path from x to x'. The derivative bound of Lem. 3.78 gives

$$|k_h(x - w) - k_h(x' - w)| \le C\delta |x - w|^{-5} \quad (4\delta < |x - w| \le 1).$$

Multiplication by $[f]_\alpha |x - w|^\alpha$ and dyadic summation gives

$$C_\alpha [f]_\alpha \delta \sum_{\delta \le r \le 1,\ \text{dyadic}} r^{\alpha - 1} \le C_\alpha [f]_\alpha \delta^\alpha.$$

At distance at least one, the differentiated far bound eq. 3.mxvii gives $C\delta\|f\|_\infty$, which is bounded by $C\delta^\alpha \|f\|_\infty$. For $1/16 < \delta \le 1$, the already proved supremum bound suffices. If the mesh exceeds $1/16$, this last case covers every distinct pair.

A periodic input extends to the infinite lattice with the same supremum norm and no larger local Hölder seminorm: the periodic distance is at most the distance of any chosen lifts. Convolution by the absolutely summable kernel is its periodic massive multiplier. Applying the estimate to that extension proves the periodic claim, independently of the periods. □

3.31.3. *Interior flat and covariant second derivatives.*

Corollary 3.115 (Interior second-derivative estimate)**.** Let $Q_r \subset Q_R$ be fixed nested physical boxes with room for the difference stencils. For their sampled smooth cutoffs,

$$\|D^2 u\|_{C^\alpha(Q_r)} \le C_{\alpha,r,R} \{\|L_h u\|_{C^\alpha(Q_R)} + \|u\|_{C^{1,\alpha}(Q_R)}\}. \tag{3.mxx}$$

The constant is uniform in the fine mesh. Here $\|u\|_{C^{1,\alpha}}$ means $\|u\|_\infty + \|Du\|_\infty + [Du]_\alpha$. ■□

Proof. Take a cutoff $\chi = 1$ on Q_r, with support a fixed distance inside Q_R. Extend $v = \chi u$ by zero. Then

$$D^2 v = D^2 (L_h + 1)^{-1} (L_h + 1) v.$$

The discrete product rule writes its source as $\chi L_h u$, χu, and finitely many shifted products of $D\chi, Du$ or $D^2\chi, u$. Their global C^α norms have the displayed bound. All neighbours lie in the indicated outer box, including at the support boundary. Apply Prop. 3.114. □

Suppose now that $U_0 = e^{iha_0}$ in a local real Coulomb frame and that

$$\|a_0\|_{C^{1,\alpha}} \le C_0. \tag{3.mxxi}$$

This is available at an actual small-curvature, small-current reference from eq. 3.dclxxvii; the current is used here, in contrast with the curvature-only estimates in § 3.25. The exact scalar decomposition eq. 3.dcccxc has first and zeroth coefficients bounded in C^α by a constant depending only on C_0. For the zeroth coefficient this uses one difference of a_0, not two: the divided difference of $(\operatorname{Ad} e^{iha_0} - 1)/h$ is an analytic bounded coefficient times a first difference of a_0.

Consequently a site solution $\Delta_{U_0} u = g$ satisfies

$$\|D^2_{U_0} u\|_{C^\alpha(Q_r)} \le C_{\alpha,C_0,r,R}\{\|g\|_{C^\alpha(Q_R)} + \|u\|_{C^{1,\alpha}(Q_R)}\}. \tag{3.mxxii}$$

Indeed its flat Laplacian is g minus the lower-order terms in that decomposition. Products preserve C^α, so Cor. 3.115 applies. Covariant second differences differ from ordinary second differences by terms containing $a_0 Du$, $Da_0 u$ and bounded quadratic coefficients in a_0. Their C^α norms have the same bound. All comparisons are in this fixed local frame; transported seminorms give the gauge-covariant statement.

3.31.4. *The proper site gauge inverse.* Fix the real proper reference and its actual q_0, G_s, F, M, R_0, with their physical site and top pairings. Assume the actual local curvature and current bounds needed for eq. 3.mxxi on the same complete interior collars. Let

$$\|\rho\|_{\alpha,2} = \sup_y \{\xi_y^2 \|\rho\|_{\infty,B_y} + \xi_y^{2+\alpha}[\rho]^{U_0}_{\alpha,y}\}. \tag{3.mxxiii}$$

At bare cells the finite collar convention of § 3.25 is used. The seminorm compares pairs across adjoining pillar faces on the same complete interior boxes used there. Taking it separately inside each pillar would admit discontinuous piecewise-constant sources and is not the norm in this statement. This same complete-box convention is used for the derivatives below. For a site gauge parameter define

$$\begin{aligned}\|\lambda\|_{Y^{2,\alpha}} = \sup_y \{&\|\lambda\|_{\infty,B_y} + \xi_y \|D_{U_0}\lambda\|_{\infty,B_y} \\ &+ \xi_y^2 \|D^2_{U_0}\lambda\|_{\infty,B_y} + \xi_y^{2+\alpha}[D^2_{U_0}\lambda]^{U_0}_{\alpha,y}\}.\end{aligned} \tag{3.mxxiv}$$

The short coordinate transports are those already fixed in the strong norm. A fixed increase of the separation absorbs the scale-ratio factors in the following sums.

Proposition 3.116 (Strong inverse of the proper site gauge block)**.** The actual projection and inverse satisfy

$$\|R_0\rho\|_{\alpha,2} \le C_\alpha \|\rho\|_{\alpha,2}, \tag{3.mxxv}$$

and

$$\|G_s R_0 \rho\|_{Y^{2,\alpha}} \le C_\alpha \|\rho\|_{\alpha,2}. \tag{3.mxxvi}$$

In particular, for $\rho \in \operatorname{ran} R_0$, $\lambda = G_s\rho$ is the unique site solution of

$$q_0\lambda = 0, \qquad R_0 \Delta_{U_0}\lambda = \rho. \tag{3.mxxvii}$$

The true bare-site zero condition is retained. ■

Proof. Use physical orthonormal top columns F_z. Prop. 3.85 gives their pointwise size $C\xi_y^{-2} e^{-md(y,z)}$ and their local Hölder size $C_\alpha \xi_y^{-2-\alpha} e^{-md(y,z)}$. A source with unit $\|\cdot\|_{\alpha,2}$ norm has L^2 norm at most C on each pillar. Thus its pairing with F_z is bounded by the uniformly summable exponential cell sum. The normalized Gram inverse preserves that coefficient bound. Summing the output columns

proves eq. 3.mxxv for $R_0 = 1 - FM^{-1}F^\sharp$. For the Hölder bound use the column increment before summing; no derivative of the input is taken.

Set $u = G_s R_0 \rho$. The exact site identity $q_0 G_s R_0 = 0$ gives

$$q_0 u = 0, \qquad \Delta_{U_0} u = R_0 \rho.$$

The second identity follows from $G_s^{-1} = \Delta_{U_0} + q_0^\sharp a_s q_0$. Its exponential energy columns give

$$\xi_y^{-2} \|u\|_{2,B_y} + \xi_y^{-1} \|D_{U_0} u\|_{2,B_y^+} \le C \|\rho\|_{\alpha,2}.$$

For example the G_s block carries $\xi_y \xi_z e^{-md(y,z)}$, while the source L^2 cell norm is bounded. The ratio ξ_z/ξ_y is absorbed by the retained metric rate. The derivative block is treated in the same way. The projection R_0 has already been included in the source bound.

Rescale a nonbare box by ξ_y. The bounded-force site bootstrap Lem. 3.84 gives its $C^{1,\alpha}$ norm, by choosing a finite $p > 4/(1-\alpha)$. Its source has the rescaled C^α bound from eq. 3.mxxv. The local reference potential has the fixed $C^{1,\alpha}$ bound eq. 3.mxxi. Apply eq. 3.mxxii on one further nested box. Rescaling back gives every power in eq. 3.mxxvi. At a bare cell the physical atomic energy inequality and a fixed two-step collar prove those same weighted bounds directly. In particular $q_0 u = 0$ forces the bare site values to be zero.

For uniqueness in eq. 3.mxxvii, suppose $q_0 \lambda = 0$ and $R_0 \Delta_{U_0} \lambda = 0$. Then $\Delta_{U_0} \lambda$ belongs to $\operatorname{ran} F$, say $\Delta_{U_0} \lambda = Fa$. Since $q_0 \lambda = 0$, $\lambda = G_s F a$. Applying q_0 gives $q_0 G_s F a = 0$. But

$$q_0 G_s F = \Xi^2 M$$

by $F = G_s q_0^\sharp \Xi^{-2}$ and $M = F^\sharp F$. The normalized Gram is invertible, so $a = 0$, then $\lambda = 0$. This proves uniqueness with the same actual boundary convention. □

The second-derivative site estimate uses the physical current of the reference to obtain its $C^{1,\alpha}$ local potential. It does not upgrade an arbitrary curvature-only connection to that class. Its purpose is the gauge restoration near an actual regular critical reference, while the curvature-only bounded-force field estimates remain as stated in § 3.25.

3.32. **Nonlinear continuation of an actual proper critical reference.** We construct a nearby constrained-critical orbit on the actual determining region, starting from a given real physical critical reference. The region, its outward rows and its bare boundary are kept. The reference is not inferred from small curvature of a datum. The input is an actual solution, and the conclusions are a uniform analytic continuation, full stationarity, literal constraint and local orbit uniqueness.

Use the proper geometry and norms of § 3.25. Write U_0 for the real reference, η for the fine spacing, ξ_c for a field-row length and ξ_y for a site-top length. Let q_0 be the actual own-pillar site average, Q_0 the actual straightened field derivative and R_0 the real site projection. The site Laplacian and inverse are $\Delta_0 = D_0^\sharp D_0$ and $G_s = (\Delta_0 + q_0^\sharp a_s q_0)^{-1}$. Assume the actual bounds

$$\sup_p \mathsf{L}(p)^2 |F(U_0)(p)| \le \kappa_0, \qquad \sup_b \mathsf{L}(b)^3 |j_0(b)| \le \gamma_0, \qquad j_0 = Q_0^\sharp \omega_0. \tag{3.mxxviii}$$

Here j_0 is the actual Wilson current. The last equality is full physical stationarity in the declared straightened coordinates. The induced-current theorem gives $\sup_c \xi_c^3 |\omega_0(c)| \le C\gamma_0$. We take κ_0, γ_0 below fixed sufficiently small ceilings, with the strict collar room required by the strong and Schauder estimates. The separation is fixed large enough for their metric growth and scale-ratio reserves.

For a fine increment use $\|A\|_{\mathrm{str},\alpha}$ of eq. 3.dccclxxxvii, with its derivatives and short transports measured in the fixed reference U_0. Set

$$\|f\|_{3,\infty} = \sup_b \mathsf{L}(b)^3 |f(b)|, \qquad \|b\|_{1,\infty} = \sup_c \xi_c |b(c)|, \qquad \|\nu\|_{3,\infty} = \sup_c \xi_c^3 |\nu(c)|. \tag{3.mxxix}$$

The same symbol on fine forces and row multipliers denotes their respective displayed index sets. The site source and gauge norms are eq. 3.mxxiii and eq. 3.mxxiv.

Put $U_A = e^{i\eta A}U_0$ and $F(A) = A_{\Omega_0}(U_A)$. Let $q(A)$ be the actual re-centered straightened per-length constraint, so $q(0) = 0$, $q'(0) = Q_0$. We use the sign convention $D_0\lambda = \eta^{-1}(\lambda_- - \operatorname{Ad} U_0\lambda_+)$; its gauge curve is $g_t = e^{it\lambda}$. All complex transposes below are physical bilinear transposes.

Proposition 3.117 (Uniform proper critical continuation)**.** There are $r, \rho, C > 0$, independent of depth, compatible volume and the shapes of the separated regions, such that the following holds for the actual reference eq. 3.mxxviii. For every literal mixed datum $V_B(c) = e^{i\xi_c B(c)}V_0(c)$ with $\|B\|_{1,\infty} < \rho$, there is a holomorphic pair $(A(B), \nu(B))$ satisfying

$$\begin{aligned} q(A(B)) &= b(B), \qquad R_0 D_0^\sharp A(B) = 0, \\ F'(A(B)) &= q'(A(B))^\sharp(\omega_0 + \nu(B)), \\ \|A(B)\|_{\mathrm{str},\alpha} + \|\nu(B)\|_{3,\infty} &\le C\|B\|_{1,\infty}. \end{aligned} \tag{3.mxxx}$$

The reduced datum $b(B)$, defined next, includes every outward factor. A specified admitted fine gauge gives a literal field with determining mean exactly V_B. It is holomorphically constrained critical, and real for real B. It is the unique nearby critical orbit modulo fine gauges equal to one at all assigned tops. Its actual curvature and current, and its physical multipliers, obey the uniform continuation bounds proved below. Localized analytic response holds in the fixed determining geometry. ■

3.32.1. *The reduced datum at an outward endpoint.* Write $a_j(A)$ for the raw level-j straightened coordinate and $v_j[A]$ for its actual node factor. For each assigned top y put $v[A](y) = v_{j_y}[A](y)$. At an outward end z of a level-j row, z is assigned level $j-1$, and

$$v_j[A](z) = v_{j-1}[A](z)\, u_{W_{j-1}}(a_{j-1}(A))(z), \qquad W_{j-1} = M^{j-1}U_0. \tag{3.mxxxi}$$

The last factor is the actual one-step factor of eq. 3.mcclii. Its entire input block consists of the prescribed level-$(j-1)$ interior rows. There is no missing inward datum in this formula.

For a row c, let $u_-(q)$ or $u_+(q)$ be this factor at a lower assigned outward endpoint, and one at a same-level endpoint. Only one endpoint is lower. Removing the assigned node factor from the actual plain-mean diagram gives exactly

$$\mathcal{T}(q)_c = u_-(q)\{e^{i\xi_c q_c}V_0(c)\}u_+(q)^{-1}, \qquad M_{\mathbf{B}}(U_A) = \mathcal{T}(q(A))^{v[A]}. \tag{3.mxxxii}$$

This is eq. 3.cccxliv with its endpoint order retained. Interior rows are unchanged. Each outward factor reads only finer interior rows, which are themselves unchanged by $\mathcal{T}$. Its inverse is therefore explicit:

$$e^{i\xi_c b_c(B)}V_0(c) = u_-(B)^{-1}\{e^{i\xi_c B_c}V_0(c)\}u_+(B). \tag{3.mxxxiii}$$

For an interior-to-outer orientation this says $e^{i\xi_c b_c} = e^{i\xi_c B_c}\operatorname{Ad}(V_0(c))u_+(B)$, as in the original outward diagram. Reversing the stored row uses the inverse group equation and requires no new convention.

The one-step block contains C_L coarse coordinates, has a uniform relative analytic branch at the real reference and reads adjacent scales with ratio L. Consequently

$$b(0) = 0, \qquad \|b(B)\|_{1,\infty} \le C_L\|B\|_{1,\infty}, \qquad \|D^m b(B)\| \le C_{L,m} \tag{3.mxxxiv}$$

on a fixed smaller raw-angle ball. These derivative bounds use the displayed amplitude norms and bounded complete carriers. The same holds for the inverse datum chart. There is no product over levels: the factors depend on interior rows, never on an already corrected outward row. In particular solving $q(A) = B$ on outward rows without this reduction would solve a different literal problem.

3.32.2. *A quadratic residual for the actual Wilson equation.* The actual proper reference has local Coulomb potentials a_0 with uniformly small $C^{1,\alpha}$ norm after rescaling each nonbare box by its assigned length. This uses both the physical curvature and the actual current in eq. 3.mxxviii; it is not a curvature-only $C^{1,\alpha}$ assertion.

Lemma 3.118 (The complete re-centered Wilson residual)**.** Let $J(A) = F'(A)$ denote the physical normal-coordinate gradient. Then

$$N_F(A) = J(A) - J(0) - F''(0)A, \qquad \|N_F(A)\|_{3,\infty} \le C\|A\|^2_{\mathrm{str},\alpha}. \tag{3.mxxxv}$$

It is uniformly holomorphic on a fixed strong ball and has Lipschitz constant Cr there from the strong norm to the weighted force norm. ■

Proof. On a nonbare box scale its length to one and set $h = \eta/\xi$. In its Coulomb frame the actual product has potential

$$P_h(A) = \frac{1}{ih}\log(e^{ihA}e^{iha_0}).$$

The actual gradient in this frame is $D_A P_h(A)^\sharp J_h(P_h(A))$, with J_h the flat-coordinate Wilson gradient. The exact current calculation of Lem. 3.184 gives $J_h(a) = \mathrm{d}^\sharp \mathrm{d}a + N_h(a)$, with uniformly analytic $N_h : C^{1,\alpha} \to L^\infty$. Use cutoffs on one larger box if necessary; the current on the inner full stencil is unchanged.

Here are the divided-difference bounds needed for the coordinate composition. Put $P_0 = D_A P_h(0)$ and $E_h(A) = P_h(A) - a_0 - P_0 A$. Matrix multiplication and its logarithm are analytic functions of ha_0, hA, and division by h removes their zero of first order. Taylor's formula gives

$$\begin{aligned} |E_h(A)| &\le Ch|A|^2, \qquad \|DE_h(A)\|_\infty \le Chr^2, \\ \|D^2E_h(A)\|_\infty &\le Cr^2, \qquad |D_A P_h(A) - P_0| \le Chr, \\ |D_A P_h(A) - P_0 - D_A^2 P_h(0)[A]| &\le Ch^2r^2. \end{aligned} \tag{3.mxxxvi}$$

Here D denotes ordinary spatial differences and the parameter derivatives are written D_A; r bounds the rescaled strong norm of A. To check the only delicate second-difference line, each leading term is hAD^2A or $h(DA)^2$. Differentiating a coefficient with respect to a_0 supplies another h, so the remaining terms contain $h^2A^2D^2a_0$, h^2ADADa_0 or higher such powers. The elementary bounds $\|D^2A\|_\infty \le Ch^{-1}\|DA\|_\infty$ and $\|D^2a_0\|_\infty \le Ch^{-1}\|Da_0\|_\infty$ cancel every apparent mesh loss. The first differences of E_h and its bounded second differences also bound its $C^{1,\alpha}$ norm by Cr^2.

Now Taylor-expand $D_A P_h(A)^\sharp J_h(P_h(A))$ at $A = 0$. The constant and linear terms are exactly $J(0)$ and $F''(0)A$. The flat second-order term acting on E_h is bounded by eq. 3.mxxxvi. The term $(D_A P_h(A) - P_0)^\sharp \mathrm{d}^\sharp \mathrm{d}(P_0 A)$ is also bounded: its first factor is $O(hr)$, while the second is at most $Ch^{-1}r$. Spatial differences of P_0 have an additional h for each derivative of its dependence on a_0; the same rough second-difference estimate covers them. The quadratic remainder of $D_A P_h$ times $J_h(a_0)$ has bound Ch^2r^2 times $Ch^{-1}\|Da_0\|_\infty + C$, and is bounded by Cr^2. All terms containing N_h are bounded by its uniform Banach derivative estimates and the $C^{1,\alpha}$ coordinate bounds. This proves the complete gradient residual, rather than merely an action remainder.

At a bare cell $\xi = \eta$, its rescaled mesh is one. There are only a fixed number of incident inner plaquettes. Their exact finite matrix gradient has uniformly bounded analytic derivatives at a unitary reference. Direct Taylor subtraction therefore gives the same quadratic estimate, including a rough action boundary; no exterior Coulomb frame is used.

Rescaling back multiplies the gradient by ξ^{-3}. The complete carriers have comparable assigned lengths, proving eq. 3.mxxxv. The same estimates hold for complex A on a fixed larger ball. Banach-valued Cauchy estimates and $N_F(0) = DN_F(0) = 0$ give its Cr Lipschitz bound. No second derivative of A or of a_0 was assumed. □

3.32.3. *Actual constraint coefficients in the physical norms.* Put $C_q(A) = q(A) - Q_0 A$. On each determining row the actual two-leg coefficient bound is

$$\sup_e \sum_{e'} \|\partial_e \partial_{e'} q_c(A)\| \le C_L \xi_c (\eta/\xi_c)^4. \tag{3.mxxxvii}$$

It is eq. 3.dcii on the admitted complex increment ball about this actual regular reference. All fine input scales on the complete carrier are comparable to ξ_c within a fixed L factor. The physical transpose uses $\eta^{-4}\xi_c^4$. Thus, for joint amplitude at most r,

$$\begin{aligned} \|C_q(A)\|_{1,\infty} &\le C r^2, \\ \|(q'(A) - Q_0)^\sharp \nu\|_{3,\infty} &\le C r \|\nu\|_{3,\infty}, \\ \|(q'(A) - Q_0 - q''(0)[A])^\sharp \omega_0\|_{3,\infty} &\le C \|\omega_0\|_{3,\infty} r^2. \end{aligned} \tag{3.mxxxviii}$$

For the first line sum the fixed-leg bound over the $O((\xi_c/\eta)^4)$ legs and insert $|A| \le Cr/\xi_c$. For the second line its column density is $Cr(\eta/\xi_c)^4$, which cancels the physical transpose factors. For the last line apply Cauchy's estimate to the actual Hessian in its fixed-leg sum norm on the larger weighted increment ball, then integrate twice. Its column remainder is $Cr^2(\eta/\xi_c)^4$. This is not an inference of an absolute coefficient sum from an arbitrary second directional bound. There are only a bounded number of rows reading a fixed fine leg. All three maps have the corresponding quadratic Lipschitz bounds.

3.32.4. *The joint proper fixed point.* Let $H_{L,0} = F''(0) - \langle \omega_0, q''(0) \rangle$. The actual physical reference and the strong row-saddle theorem give an inverse $\mathcal{L}_0^{-1}$ of

$$(H_{L,0} + D_0 R_0 D_0^\sharp) A - Q_0^\sharp \nu = f, \qquad Q_0 A = b, \qquad \|A\|_{\mathrm{str},\alpha} + \|\nu\|_{3,\infty} \le C(\|f\|_{3,\infty} + \|b\|_{1,\infty}). \tag{3.mxxxix}$$

Choose a finite $p > 4/(1-\alpha)$ in eq. 3.cm; its force norm is bounded by the displayed supremum norm. Removing the artificial row mass changes its multiplier by $-a_f b$, which has exactly the displayed amplitude. No moving-slice inverse is being presumed here.

The actual penalized equations are

$$F'(A) + D_0 R_0 D_0^\sharp A - q'(A)^\sharp(\omega_0 + \nu) = 0, \qquad q(A) = b(B). \tag{3.mxl}$$

After subtracting the base equation they are precisely

$$\begin{aligned} (A, \nu) = \mathcal{L}_0^{-1}\big(&- N_F(A) + (q'(A) - Q_0 - q''(0)[A])^\sharp \omega_0 \\ &+ (q'(A) - Q_0)^\sharp \nu, \quad b(B) - C_q(A)\big). \end{aligned} \tag{3.mxli}$$

The residual estimates give quadratic size Cr^2 and Lipschitz constant Cr in the joint strong/multiplier ball. Choose r below all primitive ceilings with $Cr < 1/4$, and then choose ρ so $C\|b(B)\|_{1,\infty} < r/4$. The radius-$r/2$ ball is invariant and contractive. Iteration constructs a unique holomorphic pair, real for real data, with

$$\|A(B)\|_{\mathrm{str},\alpha} + \|\nu(B)\|_{3,\infty} \le C\|B\|_{1,\infty}. \tag{3.mxlii}$$

It remains to remove the penalty and identify the literal fibre.

3.32.5. *Strong site extensions in the actual reference.*

Lemma 3.119 (Average and node extensions)**.** There are real linear maps E_q, E_n from assigned top values to site functions such that

$$q_0 E_q = 1, \qquad \mathrm{ev}_{\mathrm{tops}}\, E_n = 1, \qquad \|E_q c\|_{Y^{2,\alpha}} + \|E_n c\|_{Y^{2,\alpha}} \le C\|c\|_\infty. \tag{3.mxliii}$$

Top data zero on the bare tops give site functions zero on the bare layer. Their supports and fine derivative collars have bounded overlap and bounded layer-metric radius. ∎

Proof. In a nonbare pillar use a local Coulomb frame of U_0 on its fixed complete surrounding box. The rescaled reference potential has its $C^{1,\alpha}$ bound from the actual current. Choose a smooth scalar bump supported strictly inside the pillar and positive at its center. Its sampled scalar average m_y is bounded above and below: fine meshes tend to its positive integral, and the finitely many coarse possibilities contain the center. The actual transported average of this bump times a constant colour is a three-by-three matrix N_y with $\|N_y - m_y I\| \le C\kappa_0 m_y$. The actual hierarchical transports have this bound by their geometric sum of physical lengths in the small local potential. Normalize by N_y^{-1}, including the unitary top-frame rotation, to obtain E_q. Normalize the bump's center value instead to obtain E_n.

Each covariant first derivative is a profile derivative plus the local reference potential times the profile. Two derivatives contain only $D^2\phi$, $a_0 D\phi$, $Da_0\phi$ and $a_0^2\phi$, with the indicated rescaled bounds. Their α differences therefore use $Da_0 \in C^\alpha$, not $D^2 a_0$. This proves eq. 3.mxliii on the fine meshes. For the finitely many smaller ratios ξ_y/η, direct center seeds have bounded weighted differences of every fixed order. At a bare top use its one site. Adjacent assigned scales differ by at most L, so its fine collars cost only a fixed L factor. The supports are disjoint inside pillars; their derivative collars have bounded overlap. These estimates are covariant under the real local frame changes and hence give the global norms stated above. They also prove the assertion about bare zeros and carriers.

If a required surrounding box does not embed in a small periodic volume, pass first to a finite periodic cover where it does. Construct the two extension operators there, and average each operator over simultaneous fine and top deck shifts. The actual reference, its averages and node evaluation commute with these shifts, so both right-inverse identities are retained. The local strong norms are convex and invariant under the shifts; the averaged operator has the same bound. It descends on invariant data with the same supremum and Hölder bounds and with the same carriers modulo the torus. No sheet count enters these norms. This treats small volumes without a nonembedded frame or a limit in the volume. □

The site block needed for a finite gauge is now an actual bounded inverse:

$$\lambda \longmapsto (q_0\lambda, R_0\Delta_0\lambda), \qquad \lambda = E_q c + G_s\{\rho - R_0\Delta_0 E_q c\}. \tag{3.mxliv}$$

The second formula uses eq. 3.mxxvi; its braces are in $\operatorname{ran} R_0$ and have bounded $\|\cdot\|_{\alpha,2}$ norm. The exact identities $q_0 G_s R_0 = 0$, $\Delta_0 G_s R_0 = R_0$ prove both equations. Uniqueness is eq. 3.mxxvii. If c is zero at bare tops, this inverse retains bare site zeros.

3.32.6. *The actual assigned effective gauge and its outward extension.* For a fine gauge g define at assigned tops

$$h_A(g) = v[A^g]^{-1} g|_{\mathrm{tops}} v[A], \qquad h_A(e^{it\lambda}) = 1 + it\tau_A\lambda + O(t^2). \tag{3.mxlv}$$

Apply plain gauge covariance to eq. 3.mxxxii. It gives the exact nonlinear identity

$$\mathcal{T}(q(A^g)) = \mathcal{T}(q(A))^{h_A(g)}. \tag{3.mxlvi}$$

This identity fixes the coarse action being differentiated; it does not replace an outward endpoint by a chosen top value.

For completeness the one-step derivative can be computed directly. Put $T_{\mathrm{cur}} T_{\mathrm{ref}}^{-1} = e^{iz_x}$, $m = L^{-4}\sum_x z_x$ and $u = e^{im}$, and let $\mathcal{E}_z w = \int_0^1 \mathrm{Ad}(e^{itz}) w\, dt$. Then

$$\tau^{(1)}_{W,a}\lambda(y) = \mathrm{Ad}(u^{-1})\left[\lambda(y) + \mathcal{E}_m L^{-4}\sum_x \mathcal{E}_{z_x}^{-1}\{-\lambda(y) + \mathrm{Ad}(T_{\mathrm{cur}})\lambda(x)\}\right]. \tag{3.mxlvii}$$

The left derivative of the relative transport is $i(\lambda(y) - \mathrm{Ad}(T_{\mathrm{cur}})\lambda(x))$; differentiating $u(A^g)^{-1} g(y) u(A)$ gives the displayed sign. At $a = 0$ all z_x, m are zero and this is exactly the real transported site average. One-step analytic differentiation gives an error at most $C_L\|a\|_\infty$ in the site supremum norm. The actual raw radii on a top's hierarchy are bounded by $C_L r\xi_s/\xi_y$,

with summable ratios. Telescoping the products, whose zero-increment factors are unitary averages, therefore proves

$$\|\tau_A - q_0\|_{\infty\to\infty} \le Cr, \qquad \tau_0 = q_0. \tag{3.mxlviii}$$

At a bare top $\tau_A\lambda = \lambda$ exactly.

At an outward endpoint, the higher-level effective parameter is eq. 3.mxlvii applied to all assigned finer parameters on its complete outer block. At zero this is precisely $L^{-4}\sum_w \mathrm{Ad}(T_{z,w}(W_{j-1}))\lambda(w)$, the extension in eq. 3.cdlxxxiii. At nonzero A the evaluation terms and the logarithmic differentials in eq. 3.mxlvii must remain. In particular it is not an independently chosen site average at the new field.

Let Γ_A be the normal-coordinate fine gauge generator. Differentiating eq. 3.mxlvi gives

$$q'(A)\Gamma_A\lambda = \mathcal{D}_A\tau_A\lambda, \qquad \mathcal{D}_A = \big[D\mathcal{T}(q(A))\big]^{-1} d^{\mathrm{lit}}_{\mathcal{T}(q(A))}. \tag{3.mxlix}$$

The derivative is left trivialized in the declared per-length group coordinates, as is the literal gauge gradient. At zero, $\mathcal{D}_0 = \bar{D}_{\mathrm{ext}}$ by the preceding explicit outer-block derivative and eq. 3.cdlxxxvii. Most importantly, $\tau_A\lambda = 0$ makes the left side zero on every interior and outward row.

3.32.7. *Surjective gauge tests and removal of the penalty.* The exact fine generator is

$$\Gamma_A\lambda = \mathcal{E}_{\eta A}^{-1} D_{U_A}\lambda. \tag{3.ml}$$

Covariant product differences give

$$\|(\Gamma_A - D_0)\lambda\|_{\mathrm{str},\alpha} \le Cr\|\lambda\|_{Y^{2,\alpha}}. \tag{3.mli}$$

Terms have the forms $A\lambda$, $\eta A D_0\lambda$ and their first covariant differences. The second site derivative and its α seminorm in $Y^{2,\alpha}$ control exactly those differences. On a carrier $\eta \le \xi$ and the physical powers cancel. This argument uses the fixed reference transports, not ordinary differences of an uncontrolled frame change.

For $\rho \in \operatorname{ran} R_0$ with finite $\|\rho\|_{\alpha,2}$ put $\lambda_0 = G_s\rho$ and

$$\lambda_A(\rho) = \lambda_0 - E_q(\tau_A E_q)^{-1}\tau_A\lambda_0. \tag{3.mlii}$$

The inverse exists since $\tau_A E_q = 1 + O(r)$. Then $\tau_A\lambda_A = 0$ and $\|\lambda_A - \lambda_0\|_{Y^{2,\alpha}} \le Cr\|\rho\|_{\alpha,2}$. Bare zeros are exact: λ_0 is zero at bare sites; τ_A there is evaluation; and the bare-output block of $\tau_A E_q$ is the identity with no nonbare input. Thus the correction's bare coefficients and site values are zero.

The boundedness of R_0 on the site source space, its range identities, and eq. 3.mli give

$$\mathscr{R}_A\rho = R_0 D_0^\sharp \Gamma_A\lambda_A(\rho), \qquad \|\mathscr{R}_A - 1\|_{\alpha,2\to\alpha,2} \le Cr \quad \text{on } \operatorname{ran} R_0. \tag{3.mliii}$$

A smaller r makes this invertible. For every site source $\sigma \in \operatorname{ran} R_0$ there is consequently a gauge parameter with $\tau_A\lambda = 0$ and $R_0 D_0^\sharp\Gamma_A\lambda = \sigma$.

For the fixed point, $\rho = R_0 D_0^\sharp A$ belongs to this source space, with norm at most $C\|A\|_{\mathrm{str},\alpha}$. Test eq. 3.mxl against these actual gauge vectors. Gauge invariance of the inner-plaquette action kills $F'(A)$; eq. 3.mxlix kills the constraint term. Thus

$$\langle\rho,\sigma\rangle_{\mathrm{bil},\eta} = 0 \quad (\sigma \in \operatorname{ran} R_0). \tag{3.mliv}$$

This forces $\rho = 0$ also at complex data. Indeed R_0 is the real reference projection in Pauli coordinates, so the coefficientwise conjugate $\overline{\rho}$ remains in its range and source space. Taking $\sigma = \overline{\rho}$ gives its positive physical squared norm. We have not used the false implication that a complex vector with zero bilinear self-pairing must vanish. The full equations eq. 3.mxxx are now proved.

3.32.8. *An admitted literal representative and the local mean slice.* For assigned node values $w = e^{i\zeta}$ define the actual fine extension $\mathfrak{E}(w) = e^{iE_n\zeta}$. Its node values are exactly w and its logarithm has the stated $Y^{2,\alpha}$ bound. Set

$$\widehat{U}(B) = U_{A(B)}^{\mathfrak{E}(v[A(B)]^{-1})}. \tag{3.mlv}$$

The datum diagram and eq. 3.mxxxiii give $M_{\mathbf{B}}\widehat{U}(B) = V_B$ exactly.

The finite gauge map has the uniform estimate

$$\|A^{e^{i\lambda}} - A - D_0\lambda\|_{\mathrm{str},\alpha} \le C(\|A\|_{\mathrm{str},\alpha} + \|\lambda\|_{Y^{2,\alpha}})\|\lambda\|_{Y^{2,\alpha}}. \tag{3.mlvi}$$

To see the mesh cancellation, write $\mathrm{Ad}(U_0)\lambda_+ = \lambda_- - \eta D_0\lambda$ inside the exact three exponential factors defining A^g. At $\eta = 0$ their product is one. Dividing its logarithm by η is analytic in $\lambda, A, D_0\lambda$, uniformly down to zero mesh. Covariant product rules use only the site $Y^{2,\alpha}$ norm for its first field derivative and its Hölder increment. This proves the bound and its local Lipschitz version. Thus the specified literal gauge leaves the increment in a fixed admitted strong ball after one decrease of the continuation radius. No general complex gauge saturation of a domain is assumed.

For an arbitrary nearby literal field define the assigned mean-slice map

$$\lambda \longmapsto (i^{-1}\log h_A(e^{i\lambda}),\ R_0 D_0^{\sharp} A^{e^{i\lambda}}). \tag{3.mlvii}$$

Its derivative at zero reference and zero parameter is $(q_0\lambda, R_0\Delta_0\lambda)$, whose actual inverse is eq. 3.mxliv. The effective site comparison and finite gauge bound make its derivative a small perturbation on the same fixed spaces. The explicit contraction with that linear inverse solves

$$h_A(e^{i\lambda}) = v[A], \qquad R_0 D_0^{\sharp} A^{e^{i\lambda}} = 0, \qquad \|\lambda\|_{Y^{2,\alpha}} \le C\|A\|_{\mathrm{str},\alpha}. \tag{3.mlviii}$$

At bare tops its target is one and its first coordinate is exactly λ, so bare zeros are retained during this contraction. The resulting potential $\overline{A}$ has $q(\overline{A}) = b(B)$ if the original literal datum is V_B, by eq. 3.mxlvi. Its node factor equals the node values of the chosen gauge. The subsequent literal extension therefore differs from the original field by a gauge exactly one at every assigned top.

No tangent of the full q fibre is lost by imposing Landau gauge: eq. 3.mliii corrects its Landau component by a gauge vector in $\ker\tau_A$, and hence in $\ker q'(A)$. The action is constant along that vector. These two analytic maps consequently identify all tangent directions of the local $q = b(B)$ and literal fibres modulo that residual gauge group, and preserve the action. The inverse of the specified literal extension solves the mean-slice equations at a mean-slice point; uniqueness of their contraction proves this assertion, including the full group values. Differentiating the action identities proves physical constrained criticality of eq. 3.mlv at complex as well as real data.

3.32.9. *Competing multipliers and uniqueness of the critical orbit.* Smallness of a competing field does not by itself assert a small multiplier. Here the necessary readout is available from the actual row lift. Let H_0 be the zero-force physical row lift at U_0, so $Q_0H_0 = 1$. The normalized energy columns in eq. 3.dcccxlv and their proper strong upgrade in eq. 3.cm give a uniformly bounded right inverse from the row amplitude norm to the strong norm. The actual two-leg density estimate, paired with those columns, also gives, for some $s > 0$,

$$T_A = q'(A)H_0 = 1 + E_A^{\mathrm{row}}, \qquad \|E_A^{\mathrm{row}}\|_{\mathrm{Schur},s} \le Cr. \tag{3.mlix}$$

The matrix here is normalized by $b_c = \xi_c^{-1}\beta_c$; the Schur norm is the maximum of its absolute weighted row and column sums in $d(c,c')$, the layer distance between completed carriers. To verify the estimate, fix a fine leg in the variation of q' and use eq. 3.mxxxvii. The factor $(\eta/\xi_c)^4$ sums its fine carrier and the remaining increment gives r. The lift column has exponential cell energy decay. Carrier enlargement and its finitely many neighboring scales change this exponential by a fixed factor. The geometric growth and scale-ratio reserves leave a summable exponential after

taking both normalized sums. Thus this is an absolute matrix estimate, not merely an unweighted operator bound. A Neumann series in this Schur algebra proves that

$$\mathscr{H}_A = H_0 T_A^{-1}, \qquad q'(A)\mathscr{H}_A = 1 \tag{3.mlx}$$

has the same exponentially decaying energy columns.

Suppose now that a competing mean-slice point A is critical on $q = b(B)$. Surjectivity just proved supplies its unique multiplier ω. Write $\nu = \omega - \omega_0$. For the unit energy datum $b_{c,e} = \xi_c^{-1} e$, the physical coarse pairing gives the exact identity

$$\xi_c^3 \langle \nu(c), e\rangle = \left\langle F'(A) - F'(0) - (q'(A) - Q_0)^\sharp \omega_0, \mathscr{H}_A b_{c,e} \right\rangle. \tag{3.mlxi}$$

This identity does not estimate $F'(A)$ in the fine supremum norm. Instead integrate the actual Wilson Hessian along tA and use its weak plaquette form. On a rescaled complete cell of length ξ, its absolute pairing is bounded by

$$C\left\{ \|D_0 A\|_\infty \|D_0 w\|_1 + \xi^{-1}(\|A\|_\infty \|D_0 w\|_1 + \|D_0 A\|_\infty \|w\|_1) + \xi^{-2}\|A\|_\infty \|w\|_1 \right\}. \tag{3.mlxii}$$

Indeed differentiating a plaquette twice gives the two first covariant differences, and terms without such a difference carry its small plaquette curvature. The normal coordinate correction contains $\eta[A, w]$ in the first variation. Sum its difference by parts onto this product; $\eta \le \xi$ bounds the resulting terms by the same display. This calculation uses only first differences of A, w and the actual curvature along tA, never $D^2 A$ or an estimate of its current. It is also valid on a bare cell, where the rescaled plaquette is a fixed finite matrix product.

For $w = \mathscr{H}_A b_{c,e}$, the column energy bound and Cauchy–Schwarz on a physical cell give $\|w\|_1 \le C\xi^3 e^{-sd}$ and $\|D_0 w\|_1 \le C\xi^2 e^{-sd}$. Every term in eq. 3.mlxii is therefore $C\|A\|_{\mathrm{str},\alpha} e^{-sd}$. The other term in eq. 3.mlxi has force bound $C\gamma_0 \|A\|_{\mathrm{str},\alpha}\xi^{-3}$ and the same summable column estimate. Summing proves

$$\|\omega - \omega_0\|_{3,\infty} \le C\|A\|_{\mathrm{str},\alpha}. \tag{3.mlxiii}$$

This also holds for complex competing points, since all pairings used to obtain the identity are bilinear and the estimates use their absolute values.

Choose the fixed orbit neighborhood small enough that its mean-slice field and eq. 3.mlxiii lie in the contraction ball. Both solve the complete penalized system with zero penalty, so the fixed-point uniqueness identifies them. The literal-to-mean-slice construction then identifies the two literal representatives by a gauge exactly one at all assigned tops. This proves the claimed local orbit uniqueness, without assuming a multiplier bound for a competing critical point.

3.32.10. *Physical continuation bounds and localized response.* The normal and left gradients are related by $F'(A) = \mathcal{E}_{\eta A}^\sharp j(U_A)$. The exact stationarity equation and the fixed-leg density of q' give

$$\|j(U_{A(B)}) - j_0\|_{3,\infty} + \|F(U_{A(B)}) - F(U_0)\|_{2,\infty} \le C\|B\|_{1,\infty}. \tag{3.mlxiv}$$

Here the curvature norm is the assigned plaquette norm with weight L^2. For the current, subtract $Q_0^\sharp \omega_0$ from $q'(A)^\sharp(\omega_0 + \nu)$, use eq. 3.mxxxviii, and multiply by $\mathcal{E}_{\eta A}^{-\sharp} = 1 + O(\eta A)$. For curvature, differentiate the four exact link factors; their first differences give $D_0 A$ and their commutators give A^2, with weights L^{-2}. The bare calculation is the same finite product with $\mathsf{L} = \eta$. The specified literal gauge has supremum distance $C\|B\|$ from one. Its adjoint action changes the reference curvature and current by at most $C\|B\|\kappa_0$ and $C\|B\|\gamma_0$. Thus eq. 3.mlxiv holds for $\widehat{U}(B)$ as well. In particular its actual curvature and current ceilings increase by at most $C\|B\|_{1,\infty}$.

There are two different coarse multipliers. The one in eq. 3.mxxx belongs to reduced straightened coordinates. The derivative of the literal critical action $S(B) = F(A(B))$ is instead

$$D_B S = Db(B)^\sharp(\omega_0 + \nu(B)) =: \mu_B, \qquad \mu_{\mathrm{left}}(B) = \mathcal{E}_{\xi B}^{-\sharp}\mu_B. \tag{3.mlxv}$$

The inverse datum chart has bounded normalized row and column sums on its adjacent complete carriers. Physical transpose therefore maps amplitude three to amplitude three: normalized dual variables are ξb and $\xi^3\omega$. Consequently

$$\|\mu_B - Db(0)^\sharp\omega_0\|_{3,\infty} + \|\mu_{\mathrm{left}}(B) - Db(0)^\sharp\omega_0\|_{3,\infty} \le C\|B\|_{1,\infty}. \tag{3.mlxvi}$$

This formula retains the outward datum derivative at zero; it need not be the identity. The local fibre coordinates and stationarity proved above show that this is the actual literal physical multiplier, not only a formal action derivative.

For clarity, the localization claim can be stated without assuming an all-order absolute tree sum. Give each completed cell a weight $w = e^{s\psi}$, where ψ is one-Lipschitz in the proper layer metric. Use w times each local norm, and the same weight at the associated row. The base exponential saddle columns, followed by the local finite-p bootstrap, give eq. 3.mxxxix in these weighted spaces for a fixed small $s > 0$. Enlarging a carrier changes w by at most a fixed factor. The residual's derivative consequently has weighted operator norm Cr. No derivatives of the artificial weight are needed: this is a cellwise norm estimate with bounded carrier comparisons. The differentiated fixed point therefore gives

$$\|DA(B)[h]\|_{\mathrm{str},\alpha;w} + \|D\nu(B)[h]\|_{3,\infty;w} \le C\|h\|_{1,\infty;w}. \tag{3.mlxvii}$$

The same bound holds at every point of a smaller fixed complex datum ball. Banach Cauchy estimates there give one weighted input slot and any fixed number $m-1$ of unweighted slots, with constant C_m independent of depth and volume. The explicit datum reduction and literal extension have bounded carriers and the same estimates. Choosing ψ to be distance from any selected source carrier proves, for point data $c_1, \dots, c_m$, normalized response at an output cell y bounded by

$$C_m e^{-s\max_i d(y,c_i)}. \tag{3.mlxviii}$$

This establishes localized holomorphic response in the fixed proper geometry. It asserts neither an all-arity summed connected kernel bound nor existence of a proper reference from arbitrary curvature-only coarse data. All inverse constants, branch choices, and admitted complex increments used above are uniform around the given real physical reference. This completes the proof of Prop. 3.117.

3.33. **Critical correction of a regular trial on the actual proper region.** The reference in Prop. 3.117 can be a regular trial rather than a critical point. Its stationarity defect must then remain in the equation. This gives actual critical fields on the proper image of sufficiently regular fine trials. It does not supply a fine trial for every proposed curvature-only mixed datum. The fixed one-step face lift is an explicit example; its existence theorem was already proved in § 3.8.

Retain the determining geometry, actual inner action, complete carriers, true bare boundary, physical pairings and strong norms of § 3.32. The reference U_0 is real, with its actual curvature and Wilson current satisfying

$$\|F(U_0)\|_{2,\infty} \le \kappa_*, \qquad \|j_0\|_{3,\infty} \le \gamma_*. \tag{3.mlxix}$$

The fixed ceilings have strict room inside the bounds for the current-dependent local $C^{1,\alpha}$ regularity and the site Schauder estimates. An independent real row multiplier ω_0 may be chosen with $\|\omega_0\|_{3,\infty} \le \gamma_{\omega,*}$, the precision ceiling. Define the actual defect

$$e_0 = j_0 - Q_0^\sharp\omega_0, \qquad \delta = \|e_0\|_{3,\infty}. \tag{3.mlxx}$$

There is no stationarity assumption. In particular $\omega_0 = 0$ is allowed and gives $\delta = \|j_0\|_{3,\infty}$.

Proposition 3.120 (Correction of an actual regular trial)**.** There are positive δ_*, ρ, r, C, independent of depth, compatible volume and the separated geometry, such that a trial satisfying eq. 3.mlxix

with $\delta < \delta_*$ has the following property. Write $V_0 = M_{\mathbf{B}}(U_0)$ and let $V_B(c) = e^{i\xi_c B(c)} V_0(c)$, with $\|B\|_{1,\infty} < \rho$. There is a holomorphic pair $(A(B), \nu(B))$, real at real B, satisfying

$$\begin{aligned} q(A(B)) &= b(B), \qquad R_0 D_0^\sharp A(B) = 0, \\ F'(A(B)) &= q'(A(B))^\sharp(\omega_0 + \nu(B)), \\ \|A(B)\|_{\mathrm{str},\alpha} + \|\nu(B)\|_{3,\infty} &\le C(\delta + \|B\|_{1,\infty}). \end{aligned} \tag{3.mlxxi}$$

Here $F(A) = A_{\Omega_0}(e^{i\eta A} U_0)$ and $b(B)$ is the actual outward-corrected datum in eq. 3.mxxxiii. An admitted specified fine gauge gives a literal constrained-critical representative $\widehat{U}(B)$ with $M_{\mathbf{B}}\widehat{U}(B) = V_B$. It is the unique critical orbit in a fixed neighborhood of the trial, modulo gauges one at all assigned tops. The curvature and current differences from the trial have weighted bounds $C(\delta + \|B\|_{1,\infty})$. The literal multiplier and fixed-order localized analytic responses have the corresponding bounds of the critical-reference theorem. ∎

Proof. We give the changes to the model proof explicitly. None of the following uses an inverse at a desired, as yet unknown orbit. Put $H_{L,0} = F''(0) - \langle \omega_0, q''(0) \rangle$. The real gap in eq. 3.dcccxxviii and the full strong saddle in eq. 3.cm apply to $H_{L,0} + D_0 R_0 D_0^\sharp + Q_0^\sharp a_f Q_0$ without stationarity. Removing its row mass by the stated multiplier shift gives the bounded full inverse $\mathcal{L}_0^{-1}$ in eq. 3.mxxxix. In particular no physical Ward identity is used to turn a slice equation into a full equation at the trial.

Use the complete actual gradient residual $N_F(A) = F'(A) - j_0 - F''(0)A$. The local Coulomb regularity needed in Lem. 3.118 comes from eq. 3.mlxix, not from criticality. Its proof therefore gives exactly the same quadratic bound and Cr Lipschitz constant. The actual constraint densities in eq. 3.mxxxviii also hold about this real regular reference, including the $\omega_0 q'''$ remainder. Subtracting the trial equation now gives the following complete fixed point:

$$\begin{aligned} (A, \nu) = \mathcal{L}_0^{-1}\big(&- e_0 - N_F(A) + (q'(A) - Q_0 - q''(0)[A])^\sharp \omega_0 \\ &+ (q'(A) - Q_0)^\sharp \nu, \quad b(B) - C_q(A)\big). \end{aligned} \tag{3.mlxxii}$$

The new term is the actual force $-e_0$, not an omitted linear remainder. The nonlinear part has size Cr^2 and Lipschitz constant Cr in the same joint strong/multiplier ball. Choose r below the primitive ceilings with $Cr < 1/4$, then choose δ_*, ρ so that $C(\delta_* + \rho) < r/8$. The same explicit iteration is invariant and contractive and gives the last bound in eq. 3.mlxxi. Its affine source does not affect differentiated contraction estimates.

The actual node diagram, outward datum map, and effective gauge cocycle are reference identities. Thus eq. 3.mxlvi and eq. 3.mxlix remain exact. The site extensions and the bound in eq. 3.mxxvi use the actual trial current already assumed in eq. 3.mlxix. They give the same corrected gauge tests in $\ker \tau_A$ and the surjectivity in eq. 3.mliii. Testing the full penalized equation at the fixed point therefore gives eq. 3.mliv, with arbitrary test $\sigma \in \operatorname{ran} R_0$. Its conjugate test removes the penalty also at complex data. There is no extra e_0 in this gauge identity: it is the exact Wilson equation being tested, not only its Taylor part.

The admitted literal extension and the mean-slice construction in eq. 3.mlv and eq. 3.mlviii likewise use no trial stationarity. They identify full fibres modulo precisely the top-fixed gauge group, including bare zeros and outward factors.

For uniqueness use the FULL penalized row lift H_0 at the trial. It has $Q_0 H_0 = 1$, the strong bound and the normalized exponential energy columns. It need not be a horizontal physical lift. Those are all the properties used to construct the right inverse $\mathscr{H}_A = H_0(q'(A)H_0)^{-1}$. For a competing critical mean-slice point with multiplier $\omega_0 + \nu$, its correct readout is

$$\xi_c^3 \langle \nu(c), e \rangle = \langle e_0 + F'(A) - j_0 - (q'(A) - Q_0)^\sharp \omega_0, \mathscr{H}_A b_{c,e} \rangle, \qquad b_{c,e} = \xi_c^{-1} e. \tag{3.mlxxiii}$$

The new first pairing is bounded by $C\delta$: its fine force is at most $\delta \xi^{-3}$ on a cell and the column's physical L^1 norm is $C\xi^3 e^{-sd}$. The weak Wilson readout in eq. 3.mlxii bounds the other terms.

Thus

$$\|\omega-\omega_0\|_{3,\infty}\le C(\delta+\|A\|_{\mathrm{str},\alpha}). \tag{3.mlxxiv}$$

A smaller fixed orbit neighborhood and δ_* put this pair in the contraction ball. The mean-slice and fixed-point uniqueness prove the claimed orbit uniqueness.

Finally subtract $j_0=Q_0^\sharp\omega_0+e_0$ from the new stationarity equation. The transpose density, normal-to-left gradient differential and fine literal gauge give

$$\|j(\widehat U(B))-j_0\|_{3,\infty}+\|F(\widehat U(B))-F(U_0)\|_{2,\infty}\le C(\delta+\|B\|_{1,\infty}). \tag{3.mlxxv}$$

The literal parameter multiplier is exactly $Db(B)^\sharp(\omega_0+\nu(B))$, with the left-gradient conversion in eq. 3.mlxv. Its difference from $Db(0)^\sharp\omega_0$ has the same defect-plus-datum bound. The weighted differentiated contraction and fixed-order Cauchy argument in eq. 3.mlxvii are unchanged. This proves the proposition. □

3.33.1. *What is obtained on the real proper image.* For the fixed determining geometry let $\mathscr{T}_{\mathrm{reg}}$ be the real fine trials obeying eq. 3.mlxix, with $\|j(U)\|_{3,\infty}<\delta_*/4$. Define the actual image

$$\mathscr{I}_{\mathrm{reg}}=\{M_{\mathbf{B}}(U):U\in\mathscr{T}_{\mathrm{reg}}\}. \tag{3.mlxxvi}$$

This is a definition by the given fine fields, not a characterization using coarse plaquettes alone. For every $V\in\mathscr{I}_{\mathrm{reg}}$, choose an actual preimage U_0. Apply Prop. 3.120 with $\omega_0=0$ and $B=0$. It produces a critical fine field with literal mean V. Thus the constrained-critical fibre is nonempty at every point of this real image. The same preimage gives a holomorphic critical branch on a uniform complex raw-angle ball about V, without presupposing a critical reference there.

The image is nonempty and contains genuinely nonflat examples. For instance use the identity reference and a smooth one-colour potential supported in a complete homogeneous layer patch of scale ξ. A rescaled fixed profile with amplitude t/ξ has actual fine curvature at most $C|t|\xi^{-2}$ and Wilson current at most $C|t|\xi^{-3}$. These estimates follow directly from its two bounded physical differences and the exact plaquette current; no unknown inverse is used. A cutoff equal to one on the complete carriers of a coarse plaquette may contain $a_2(x)=t(x_1-y_1)H/\xi^2$, $a_1=0$, for one fixed colour H. There all factors commute. The actual means reduce to line averages plus contour gradients; the latter cancel around the coarse plaquette. Its mean plaquette is therefore e^{itH}, whereas the cutoff makes the trial the identity outside the patch. For sufficiently small nonzero t this is a nonflat point of the image in eq. 3.mlxxvi, with bounds independent of the layer depth. This example requires the indicated complete patch; flat trials require none.

There is also a precise local independence of the chosen trial. Suppose two real trials are related by

$$U_1^g=e^{i\eta C}U_0,\qquad \|C\|_{\mathrm{str},\alpha;U_0}<\varepsilon_r, \tag{3.mlxxvii}$$

where g is unitary and one at all assigned tops. Reduce the trial-current ceiling and working datum balls once. The branches built about these trials then agree as physical orbits on their common datum domain, and their total Wilson actions agree.

Indeed covariance of the reference transports identifies the strong norms before the real gauge g. The relative connection after it is the divided logarithm of $e^{i\eta A_1}e^{i\eta C}$. Its Banach product estimate gives strong norm at most $C(\|A_1\|_{\mathrm{str},\alpha}+\|C\|_{\mathrm{str},\alpha})$. This is the same mesh-uniform relative BCH calculation used in eq. 3.mlvi. Choose ε_r and the working radii so this and the specified literal extension fit the U_0 uniqueness neighborhood. Both fields are then critical with the same literal datum. The mean-slice map and the competing-multiplier bound in eq. 3.mlxxiv identify them modulo a top-fixed fine gauge. The slice and extension are holomorphic in the datum, so the identification is holomorphic on the overlap. Gauge invariance identifies the actions. These transitions satisfy the cocycle where the controlled overlaps meet: their quotient fixes an invertible connection and all assigned tops, and propagation along each connected fine component forces it to be the identity.

The construction is also covariant under simultaneous arbitrary real unitary fine gauge changes of a trial and its datum. They conjugate the actual full saddle and all relative coordinates isometrically. Its unique small fixed point consequently transforms covariantly; different admitted literal extensions differ by a top-fixed gauge. The action is invariant. No smallness of the gauge function itself is required when the reference is transformed at the same time.

These facts give existence on the real image and holomorphic descent on controlled trial overlaps. Lem. 3.122 and Prop. 3.124 identify arbitrary real regular critical preimages of the same mixed datum, including those not initially given in a common trial chart. Their action is consequently canonical on the stated regular class. The existence proof there constructs regular backgrounds for every sufficiently small curvature datum by datum descent and critical ascent; it does not require a separately smoothed fine trial for that datum.

3.33.2. *The fixed one-step face lift as a concrete corollary.* For comparison with the already proved first-step result, fix $\eta = 1/L$ and the actual centered blocks. Given any real coarse V, set $U_0(V) = I$ on internal fine links and $U_0(V)(x,\mu) = V_\mu(y)$ on every positive edge crossing from $B(y)$ to $B(y+e_\mu)$; use the inverse on reversed edges. All coordinate-order internal paths stay in their block. Each length-one coarse line used in the actual mean crosses exactly one face. Thus its internal contour transport is I, its line transport is $V_\mu(y)$, and its central reference line is the same matrix. In the notation of the actual mean,

$$T_{y,x}(U_0(V)) = I, \qquad Z_x(U_0(V)) = I, \qquad \mathcal{M}U_0(V) = V. \tag{3.mlxxviii}$$

The logarithm taken here is $\log Z_x = 0$, never a logarithm or a group root of $V_\mu(y)$. Large and central holonomies present no obstruction.

Every fine plaquette is I unless both of its directions cross their block faces. In that case its four ordered factors are exactly the coarse plaquette, up to the frame conjugation or orientation. With $\epsilon = \sup_P \|V(\partial P) - I\|$ this gives

$$\|F(U_0(V))\|_\infty \le CL^2\epsilon, \qquad \|j(U_0(V))\|_\infty \le CL^3\epsilon. \tag{3.mlxxix}$$

The current estimate uses the bounded number of incident fine plaquettes and their exact sine terms with prefactor η^{-3}. For the homogeneous one-step geometry the assigned scale is one. Choose $\epsilon < \epsilon_L$ so these two bounds meet the trial ceilings. The proposition, at $B = 0$ and $\omega_0 = 0$, then constructs the actual one-step critical orbit of mean V.

This recovers the existence in § 3.8 through the new full proper-region inverse. The bounded-area block-contour comparison there puts every competing fixed-L regular field of that same mean into this trial neighborhood after a node-fixed axial gauge; all fixed strong differences cost constants depending only on L. Local uniqueness therefore identifies this branch with that previously constructed background, including its compatible complex continuations. Here coarse chart closeness really does give the required fine comparison: if $V_1 = e^{iB}V_0$, the relative fine potential of their face lifts is $\eta^{-1}B$ on crossing edges and zero internally. Since $\eta = 1/L$ is fixed, its covariant strong norm is at most $C_L\|B\|_\infty$; ordinary finite differences cost at most fixed powers of L, with unitary reference transports. Thus shrinking the coarse working balls makes their overlaps controlled in the sense of eq. 3.mlxxvii. The face-lift corollary concerns one bare step at fixed L. The multilevel construction in Prop. 3.124 uses the regular solution of the preceding truncation as its next real trial, with the explicit L^3 current loss and the subsequent uniform reset.

Indeed an iterated face lift concentrates rather than spreads curvature. Take one positive coarse link $e^{i\theta H}$, all other links I, on a coarse torus of side at least two, with $H^2 = I$ and small nonzero θ. After j face lifts, $\eta = L^{-j}$ and a fine corner plaquette still equals $e^{i\theta H}$. A face edge adjacent to exactly that nontrivial plaquette has current $\pm\eta^{-3}\sin\theta H$; the other incident plaquettes are I. Its action variation is $\eta\sin\theta$, and the physical pairing is η^4. Thus at assigned scale one,

$$\|F(U_{\mathrm{face},j})\|_\infty \ge L^{2j}|\theta|, \qquad \|j(U_{\mathrm{face},j})\|_\infty \ge L^{3j}|\sin\theta|. \tag{3.mlxxx}$$

Fixed small coarse curvature consequently does not make these iterated trials uniformly regular. Prop. 3.124 instead descends the coarse datum and solves a critical equation at each ascent, applying Lem. 3.123 before the next level. This controls the current as well as curvature uniformly in the depth.

3.34. **Regular backgrounds on separated regions.** The preceding proper-region inverse and trial correction complete the ascent through the determining sets of eq. 3.cccvi. We give the matching argument, including the current bound at the action boundary and uniqueness among all regular critical configurations. These determining sets have no inward rows. Every outward row and its entire lower endpoint block remain part of the construction.

Fix $0 < \alpha < 1$ and the geometric floors needed for Props. 3.88 and 3.120. Use $L \geq 13$, and the aligned separated geometry of § 3.11.23; increase its floors below when choosing a fixed local regularity patch. Constants may depend on these choices and L, α, but not on depth, the number of pillars, the volume, or the shapes and number of components of the regions. They apply to every truncation with these floors.

For a real field define

$$\mathcal{R}(U) = \max\left\{ \sup_{p} \eta^{-2}\mathsf{L}(p)^2|\partial U(p) - 1|, \sup_{b \text{ full}} \mathsf{L}(b)^3|J(U)(b)| \right\}. \tag{3.mlxxxi}$$

Here the first supremum is over inner plaquettes, and a full bond has all six incident plaquettes in the action region. Write $\mathcal{R}_{\mathrm{mat}}$ for the same expression with $\eta^{-2}|D_U^{\mathsf{T}}\partial U|$ in place of $|J(U)|$. The scalar and traceless parts of a plaquette give

$$\mathcal{R}(U) \leq \mathcal{R}_{\mathrm{mat}}(U), \qquad \mathcal{R}_{\mathrm{mat}}(U) \leq r + \tfrac{3}{2}r^2 \quad \text{if } \mathcal{R}(U) \leq r. \tag{3.mlxxxii}$$

Indeed write $\partial U(p) = c_p 1 + i\eta^2 F_p$. The scalar divergence at a full bond is a sum of three opposite differences of c_p, with $1 - c_p = |\partial U(p) - 1|^2/2$. Use $\eta \leq \mathsf{L}(b) \leq \mathsf{L}(p)$ on each incident plaquette. This proves the second inequality; the traceless part proves the first. Thus either regularity convention gives the other after a fixed reduction of its ceiling.

3.34.1. *The strong norm of a regular comparison.* The following observation permits use of the strong nonlinear chart for competitors initially specified only by curvature and current. It is an elliptic consequence of those currents, not an embedding of a discrete C^1 ball into a uniform $C^{1,\alpha}$ ball.

For a comparison based at U_0, write

$$\mathcal{N}_1(A) = \max\left\{ \|\mathsf{L}A\|_\infty, \|\mathsf{L}^2\nabla_{U_0}A\|_\infty \right\}. \tag{3.mlxxxiii}$$

This is the weighted first-order supremum norm used in the slice absorption estimate. The energy space X retains its physical L^2 definition in the inverse estimates.

Lemma 3.121 (Improvement of a comparison in the slice)**.** Let U_0 and $U_1 = e^{i\eta A}U_0$ be real, with $\mathcal{R}(U_i) \leq \varepsilon$. Suppose that $R_0 D_0^\sharp A = 0$ and $a = \|\mathsf{L}A\|_\infty$ is below a fixed small ceiling. Let $b = q(A)$ be the actual straightened per-length row coordinate. Put $\beta = \sup_c \xi_c|b_c|$. Then

$$\mathcal{N}_1(A) + \|\mathsf{L}^3 D_0^\sharp D_0 A\|_\infty + \|A\|_{\mathrm{str},\alpha} \leq C(\varepsilon + \beta). \tag{3.mlxxxiv}$$

The ceiling on a and the constant are uniform in the geometry. No critical equation for U_0 or U_1 is required. ∎

Proof. The covariant D_0 in $D_0^\sharp D_0 A$ is the curl, whereas the D_0 in the Landau condition is the site derivative. We first use the actual first-order slice calculation eq. 3.ccclxxiv. Its boundary and normalization checks are useful here. The exact differentiated plaquette product gives, at a full bond,

$$\mathsf{L}(b)^3|D_0^\sharp D_0 A(b)| \leq C\varepsilon + C_L a\mathcal{N}_1(A).$$

One obtains this by subtracting the two currents in their common normal coordinate. The normal-to-left logarithmic differential is $1 + O(\eta A)$. The linear curvature correction has size $C\varepsilon a$, and the nonlinear remainder has size $C_L a\mathcal{N}_1(A)$. These estimates use first covariant differences of A. In the paired plaquette terms a difference of a product places one difference on one factor; terms with two undifferenced potentials carry the remaining mesh factor. The elementary inequality $\eta|\nabla A| \le C \sup|A|$ on the same stencil pays that factor. It gives no inverse power of the fine mesh.

At a nonfull inner bond the bond and every bond in its action plaquettes belong to the bare determining layer. There ηA is the bare row coordinate. The at most six plaquette stencils therefore give the bound 24β for $\mathsf{L}^3|D_0^\sharp D_0 A|$. On an outward row the additional factor reads only the prescribed interior rows of the preceding level, so its group angle is at most $C_L\beta$. The same conclusion holds if β is initially measured after the triangular datum change eq. 3.mxxxiii.

For clarity, use the actual derivative $Q_0 = q'(0)$ in the completed operator, rather than an auxiliary comb derivative. The actual two-leg bound gives

$$\sup_c \xi_c|q(A)_c - Q_0 A(c)| \le Ca^2, \qquad \|\mathsf{L}^3 Q_0^\sharp a_f Q_0 A\|_\infty \le C(\beta + a^2).$$

In the second estimate $a_f(c)$ has size ξ_c^{-2}. The physical transpose density cancels the fine counting measure on the complete row carrier. This is precisely the fixed-leg estimate used in eq. 3.dcccxcv; it includes the outer block of an outward row.

Let $K_0 = K_{U_0,0}$ be eq. 3.dcccxcviii with zero independent multiplier. The exact identity in the slice is

$$K_0 A = D_0^\sharp D_0 A + \Delta'_{U_0} A + Q_0^\sharp a_f Q_0 A, \qquad \|\mathsf{L}^3 \Delta'_{U_0} A\|_\infty \le C_L \varepsilon a. \tag{3.mlxxxv}$$

To verify the last bound directly, the difference between the quadratic Wilson plaquette and the covariant curl square has coefficients bounded by $C\eta^{-2}|\partial U_0 - 1|$ on its finite four-link stencil. It therefore contributes at most $C\varepsilon \mathsf{L}^{-2}$ times the local maximum of $|A|$. Adjacent scales cost at most L.

The first-order consequence of Prop. 3.88 applied to this equation gives

$$\mathcal{N}_1(A) \le C_1(\varepsilon + \beta) + C_2(\varepsilon + a)\mathcal{N}_1(A).$$

Every norm is finite on the finite lattice, so absorption is legitimate before any uniform estimate has been obtained. Choose ε, a so that the last coefficient is at most $1/2$. This proves the first-order bound and then the displayed bound on $D_0^\sharp D_0 A$. Now the entire right side of eq. 3.mlxxxv has weighted supremum at most $C(\varepsilon + \beta)$. Its $\mathcal{F}_p$ norm has the same bound for each fixed finite $p > 4/(1-\alpha)$. Apply eq. 3.dcccxcix again to obtain the strong bound in eq. 3.mlxxxiv. □

Lemma 3.122 (Comparison of arbitrary regular fibres)**.** Suppose

$$\mathcal{R}(U_i) \le \varepsilon, \qquad \sup_c |M_{\mathbf{B}} U_1(c)(M_{\mathbf{B}} U_0(c))^{-1} - 1| \le \delta.$$

For $\varepsilon + \delta$ below a fixed ceiling, there are a real A and a unitary gauge g such that

$$U_1^g = e^{i\eta A} U_0, \qquad R_0 D_0^\sharp A = 0, \qquad g(y) = v[A](y) \quad (y \text{ a top}), \qquad \|A\|_{\mathrm{str},\alpha} \le C(\varepsilon + \delta). \tag{3.mlxxxvi}$$

The reduced datum is the literal datum difference under eq. 3.mxxxiii. In particular, equal literal data give $q(A) = 0$ on every row. If also $A = 0$, g belongs to $\mathcal{G}_{\mathrm{res}}$. ■

Proof. First use the preliminary gauge constructed in eq. 3.cccxix–eq. 3.cccxx. Here are the uniformity and seam checks. With $W_n = \mathcal{M}^n U_1$ and $W_{0,n} = \mathcal{M}^n U_0$, descend from $g_k = 1$ by

$$g_n = 1 \text{ on the level-}n \text{ tops}, \qquad g_n(x) = W_{0,n}(y,x)^{-1} g_{n+1}(y) W_n(y,x) \quad (x \in B(y)).$$

The blocks of the next level and the current tops partition the current member, and the zero-length contour equals one. Thus these formulas extend one another and define one fine gauge $\widehat{g}$. They align all the averaged internal contours and fix every final top.

In a double block the reconstructed link differs from its coarse mean by C_L times the local plaquette defect, by eq. 3.cccxviii. The coefficient of a difference of the coarse means is one, since all other factors are unitary. At a seam the inward comparison link belongs to the corridor of the outward row one level above. The latter's outer block lies in the lower layer; its internal paths use at most $2(L-1)$ prescribed lower rows. Telescoping gives an endpoint defect at most $2(L-1)\delta + C_L\varepsilon$. The other endpoint is already aligned. Along a deeper pillar the remaining errors sum as $C_L\varepsilon \sum_{n<j} L^{2(n-j)}$. Consequently every carried link, at every intermediate level, has relative group error at most $C_L(\varepsilon+\delta)$. This argument also controls the omitted inward comparison links; no inward constraint is added.

Ascend through the truncations, keeping these same two fine configurations; the fields are not replaced by their averages. If $\mathsf{L}^{(j)}$ is a truncated assigned scale in physical units, then $\mathsf{L}^{(j)} \le \mathsf{L}^{(k)}$ on each bond and plaquette. Both fields consequently have truncated regularity at most ε at every stage, directly from their full-depth bounds. The real gauge corrections preserve these bounds. At an intermediate truncation the carried-link estimate just proved bounds its literal datum difference by $C_L(\varepsilon+\delta)$; the triangular outward change therefore gives $\beta_j = \sup \xi|q^{(j)}(A)| \le C_L(\varepsilon+\delta)$. At the last truncation its bound is instead $C_L\delta$. At depth zero the relative logarithm has $\mathcal{N}_1$ norm at most $C_L(\varepsilon+\delta)$, because the mesh in its units is one. At the next level replace A^- by $A_0 = LA^-$; its $\mathcal{N}_1$ norm increases by at most L^2, and $\eta A_0 = \eta^- A^-$ leaves all old node factors unchanged. Apply the real site correction following eq. 3.ccclxxii. Prescribe the correction factor one at old tops and $v_{j-1}[A_0]^{-1}v_j[A_0]$ at promoted tops, with the multiplication order of the node diagram. The latter defect is at most $C_L\|\mathsf{L}A_0\|_\infty$. The site equation has the actual weighted inverse and fixes the Landau condition; its nonlinear remainders have the quadratic bounds displayed there. It therefore gives $\|\mathsf{L}A\|_\infty \le C_L\mathcal{N}_1(A_0)$ and the required normalized node values.

The first-order absorption in Lem. 3.121 now resets $\mathcal{N}_1(A)$ to $C_*(\varepsilon+\delta)$ at each level. Choose C_* first, then $\varepsilon+\delta$ so that $C_L L^2 C_*(\varepsilon+\delta)$ lies below the fixed site and slice ceilings. This is one choice for all levels, rather than an iteration of the factor L^2. On the last truncation the normalized datum is the actual literal difference, because $\widehat{g}$ fixes both endpoints of each determining row. The explicit triangular outward formula gives $\sup \xi|q(A)| \le C_L\delta$, including a reversed outward orientation. The strong conclusion follows from Lem. 3.121. If $\delta = 0$, all interior coordinates vanish, hence every outward node factor and outward coordinate also vanish. Finally $v[0] = 1$, and every node of the present determining set is a top, so $A = 0$ makes g a residual gauge. □

3.34.2. *Resetting the current as well as curvature.*

Lemma 3.123 (Uniform regularity reset)**.** There are a fixed geometric floor, a ceiling $a_c > 0$, and C_R such that every real constrained-critical field with $\mathcal{R}(U) \le a_c$ satisfies

$$\mathcal{R}(U) \le C_R\varepsilon \tag{3.mlxxxvii}$$

when all its ordinary and mixed datum test holonomies are within ε of one. The same conclusion, with twice the constant, holds for $\mathcal{R}_{\mathrm{mat}}$ after decreasing the ceiling. The constants are uniform over all truncations. ■

Proof. We apply the local calculation underlying eq. 3.ccclxxv, with the actual flat inverse and nonlinear equation now available. We record the admission checks needed for that application. First fix the auxiliary flat construction and its collar radius ρ_c. Next choose a fixed patch parameter $\sigma \ge L^2\rho_c$ that is a power of L, and only then increase the ambient separation floor to $\rho \ge L^2\sigma$. Put $R = 20L\sigma$ in layer distance. The auxiliary nested cubes described in the local datum-profile calculation have positive-level union inside $Q_{\sigma-2}$, a complete two-level inner patch, and a flat bare exterior. The local real gauge on Q_σ uses curvature and the actual full current. It gives potential, first difference, and flat second-order reads at most $C\sigma r_R(x)$ in local units. Its domain condition is $C\sigma a_c < c$.

Extend that potential by zero on the auxiliary torus. All cutoff plaquettes belong to the bare layer, so their physical current, including the terms created by the cutoff, has weighted bound $C\sigma r_R(x)$. In the positive-level members there was no cutoff. A constrained variation on the auxiliary geometry patches to a constrained variation of the original field: a row of lower assigned endpoints is fixed by induction in the actual averaging recursion; a row with an endpoint at its reading level is an auxiliary row and has its entire double block inside Q_σ. The outward endpoint block is included in this assertion. Every changed action plaquette is also inside Q_σ. The extended field is therefore critical at its own auxiliary datum.

Apply the local datum transport gauge and the real site correction relative to the identity. They give a preliminary slice potential of small weighted supremum and a datum of size $b_f \le C\sigma^2 r_R(x)$. The zero extension's current and Lem. 3.121 put this slice potential in the strong ball, with size $r_f \le C\sigma^2 r_R(x)$. Thus the actual flat case of Prop. 3.117 applies, and its local uniqueness identifies the auxiliary critical field with that solution. The required conditions are $C\sigma^2 a_c < \min(r, \rho)$, with the fixed flat chart radii r, ρ. They can be imposed after σ is fixed.

Split the flat saddle's exponentially decaying datum sum at distance $\sigma/8$. In the inner part a row at y has size $C(1 + |y - x|)v_R(x)$ in the datum transport gauge; its outward factor is one because its entire lower internal contour has been prescribed. The linear distance is summable against the kernel. The outer part contributes $Ce^{-c\sigma} b_f$. The exact nonlinear force and row remainders contribute Cr_f^2. The multiplier readout uses the same split and contributes $Ce^{-c\sigma}(b_f + r_f)$ outside and Cr_f^2 nonlinearly. At the full bond the exact equation $F'(A) = q'(A)^\sharp \omega$ reads only the complete carriers of nearby rows. Its physical transpose density bounds the current by that multiplier estimate. The first-order field estimate bounds curvature. Thus both readouts obey

$$r_U(x) \le K v_R(x) + \{C\sigma^2 e^{-c\sigma} + C\sigma^4 a_c\} r_R(x).$$

The original and auxiliary local scales differ by at most L at the readouts; this fixed factor is included in C, K. Bare points away from the next member use prescribed plaquettes directly and the sum of their six current terms.

Choose σ so the exponential term is at most $1/4$, and then a_c so the quadratic coefficient is at most $1/4$ and all preceding local and strong chart conditions hold. The result is $r_U(x) \le K v_R(x) + r_R(x)/2$. Let $P(x) = \sup_\tau e^{-\delta d_{\mathbf{B}}(x,\tau)} |\partial V(\tau) - 1|$, where $e^{\delta R} = \sqrt{2}$. For $t > 0$ maximize $r_U(x)/(P(x)+t)$. At a maximizing point its value S satisfies $S \le \sqrt{2}K + S/\sqrt{2}$; this uses $P(y)+t \le \sqrt{2}(P(x)+t)$ in the patch. Letting t decrease to zero gives $r_U \le 5KP$. The bounded displacement from a corner to the base of a readout changes this constant by a fixed factor. Since $P \le \varepsilon$, this proves eq. 3.mlxxxvii. Finally, eq. 3.mlxxxii gives the current assertion. □

3.34.3. *The mixed datum and the critical ascent.*

Proposition 3.124 (The regular proper background)**.** For the geometry fixed above there are $a_0, a_1, C_B > 0$, independent of depth and volume, with $C_B a_1 < a_0$, such that every real mixed datum whose ordinary and mixed test holonomies are within $\varepsilon \le a_1$ of one has a constrained-critical configuration $U(V)$ with

$$M_{\mathbf{B}} U(V) = V, \qquad \mathcal{R}_{\mathrm{mat}}(U(V)) \le C_B \varepsilon. \tag{3.mlxxxviii}$$

Any two critical configurations for the same datum with $\mathcal{R} \le a_0$ lie in the same residual gauge orbit. The orbit is covariant under real gauges of the datum. ■

Proof. The constants are chosen in the following order. Fix the inverse and site bounds, the regularity patch and its ceiling a_c, and a reset constant $B \ge \max(12, 2C_R)$. Fix the one-level trial-correction constant C_A below. Finally choose a_0 below the comparison, multiplier and PNC uniqueness ceilings, and choose a_1 so that

$$C_\downarrow a_1 < \varepsilon_\downarrow, \qquad C_A L^3 B C_\downarrow a_1 < \min(a_c, a_0), \qquad 6L^3 B C_\downarrow a_1 < \min(\kappa_*, \gamma_*, \delta_*), \tag{3.mlxxxix}$$

as well as the fixed RTC datum radius. Here $\kappa_*, \gamma_*, \delta_*$ are its real-trial ceilings. Enlarging a fixed constant or shrinking a_1 makes the inequalities strict without changing their uniformity.

Descend the datum by eq. 3.cdxxvi–eq. 3.cdxxvii. The two-radius argument there gives $V^{(n)}$ at every truncation, with all tests bounded by $\varepsilon' = C_{\downarrow}\varepsilon$ and with the new one-step mismatch at most ε'. There is no accumulated factor: a deep new plaquette is one or a single old coarse plaquette; every seam comparison uses the smaller-radius tests within six current-level spacings of the seam. Separation keeps that neighborhood outside the part changed at the previous descent.

At depth zero every inner bond is prescribed. The field $V_0^{(0)}$ is therefore critical in its singleton fibre. Its curvature is at most ε' and its full current is at most $6\varepsilon'$, in bare units. This starts the bound $\mathcal{R}_{\mathrm{mat}} \le B\varepsilon'$.

Suppose $U^{(n-1)}$ has that bound. Regard the same physical field on the determining set of depth n. An assigned scale increases by at most L. The curvature radius increases by at most L^2 and the full-current radius by at most L^3. Hence its new radius is at most $\alpha_0 = L^3 B\varepsilon'$. The inner action has not changed. A nonfull inner bond has a missing incident plaquette. Its endpoints and every bond in its remaining inner plaquettes are within 3η of Ω_0^c. The separation $\mathrm{dist}_\infty(\Omega_0^c, \Omega_1) > R_1\mathfrak{M}\eta > L^2\eta$ puts this entire stencil outside Ω_1. Every local scale on it is therefore η, and all its inner edges are bare determining rows. The exact current is a sum of at most six traceless plaquette terms with prefactor η^{-3}, so

$$\|J_{\Omega_0}(U^{(n-1)})\|_{3,\infty} \le 6\alpha_0. \tag{3.mxc}$$

This checks the actual force required by RTC, including the action boundary. A bound only on full bonds would not suffice for that application.

On a double block of a new row, every level-$(n-1)$ bond read by its one-step average lies in the last determining member of the old truncation. Exact local recursion gives

$$\mathcal{M}^n U^{(n-1)}(c) = \mathcal{M}(V_{n-1}^{(n-1)})(c).$$

All older row values remain the target values. Define the literal per-length displacement by $\xi_c B_c = i^{-1}\log(V_n^{(n)}(c)(\mathcal{M}^n U^{(n-1)}(c))^{-1})$ on new rows and by zero on older rows. Then $\|B\|_{1,\infty} \le (\pi/2)\varepsilon'$. At a new outward endpoint the reduced datum factor reads only older interior displacements, which are zero. Thus eq. 3.mxxxiii gives the same raw new displacement, with the exact orientation order.

Apply Prop. 3.120 with this actual real trial and independent row multiplier zero. Its defect is the force in eq. 3.mxc; the forced equation retains this entire defect. The physical continuation bounds give a real critical field at the target literal datum, of provisional regularity at most $C_A\alpha_0$. The literal node restoration is unitary, so it preserves curvature and the full current; the outward factors cancel exactly. The inequalities eq. 3.mlxxxix put this output inside a_c. Apply Lem. 3.123 at its new datum to return to $\mathcal{R}_{\mathrm{mat}} \le B\varepsilon'$. This completes the induction with one radius for all n. At the final level apply the reset once more using the original datum radius ε, obtaining eq. 3.mlxxxviii with a fixed C_B.

For uniqueness take any two real regular critical fields of the same datum. The action boundary obeys the same bound as eq. 3.mxc, so either field is an admitted physical critical reference after choosing a_0 sufficiently small. Apply Lem. 3.122 to the pair with $\delta = 0$. It gives a strong mean-slice point of size at most Ca_0 and zero reduced datum. This is a coordinate on the actual constraint fibre by the gauge parametrization in eq. 3.mlviii; constrained criticality therefore gives its full multiplier equation. The competing-multiplier readout eq. 3.mlxi bounds its multiplier displacement by Ca_0. Choose a_0 so both components lie in the fixed PNC contraction ball. They and the zero solution have the same datum; uniqueness gives $A = 0$. The last assertion of Lem. 3.122 makes the gauge residual. Covariance follows by transforming the entire actual equation and then applying this uniqueness. □

Corollary 3.125 (A fixed physical continuation ball)**.** For every orbit in Prop. 3.124, choose a real representative U_0. There is $r_G > 0$, uniform in the datum, depth and admitted geometry, such

that for $V_B(c) = e^{i\xi_c B_c} V(c)$ and $\|B\|_{1,\infty} < r_G$ there is a holomorphic literal critical representative $\widehat{U}(B)$ with $M_{\mathbf{B}}\widehat{U}(B) = V_B$. In its prescribed Landau coordinate,

$$\|A(B)\|_{\mathrm{str},\alpha} + \|\omega(B) - \omega(0)\|_{3,\infty} \le C\|B\|_{1,\infty}, \qquad \|F(\widehat{U}(B))\|_{2,\infty} + \|J_{\Omega_0}(\widehat{U}(B))\|_{3,\infty} \le C(\varepsilon + \|B\|_{1,\infty}). \tag{3.mxci}$$

The physical bounds hold on complete fine plaquette and current stencils. Their fixed-order localized responses are those of eq. 3.mlxviii. The construction requires no hereditary complex-domain hypothesis. ■□

Proof. The regular real reference just constructed has bounded inner current by the bare-boundary calculation above and bounded induced multiplier by the actual row lift. All hypotheses of Prop. 3.117 therefore hold, uniformly. Its literal node extension and eq. 3.mlxiv prove the assertion after one fixed decrease of its datum radius. If desired choose r_G so the right side of eq. 3.mxci is below any fixed small regularity ceiling on the full complex ball. This decreases a fixed radius and introduces no dependence on depth or ε.

For real B in this ball the output is a real regular critical orbit. Wherever it also lies in the real datum domain of Prop. 3.124, that theorem's uniqueness identifies it with the real background there. Thus these are continuations of the canonical real orbit. Changing a real representative conjugates the equations isometrically. On a common real datum neighborhood the physical orbits agree by uniqueness; their holomorphic germs, and their actions, agree by the identity theorem. No choice of a distant complex gauge representative is needed for these local continuations. □

3.35. **Uniform continuation on every tower.** The tower tests require a gain that is quadratic in the complex potential radius. A first derivative estimate alone gives a linear loss. The argument below obtains the quadratic gain from three real configurations, after constructing a common complex neighborhood on which the normalized curvature and current are bounded. The real background theorem supplies the three real estimates; the constrained Euler equation supplies the crude complex current estimate. The independent current of a regular pair does not enter this construction. This is the tower argument underlying Bałaban's construction [B87], with the determining rows, complex gauges and parameter neighborhoods specified here.

3.35.1. *The two erosion rules.* We use the two cube rules fixed in the localization geometry. Write $M_1 = M_1'$ in this subsection. All continuation and restriction statements below use determining sets with all inward rows removed. The box-datum lemma also states the variant in which those rows are retained. All lengths in the next lemma are in bare units. Thus level q has spacing L^q. The constants satisfy

$$L \ge 13, \qquad R_1 \ge L, \qquad M_1 \ge R_1\mathfrak{M}, \qquad M \ge L^4 M_1.$$

The background floors are imposed before these inequalities. The localization size M is then increased, if necessary; no constant chosen below depends on the cutoff, the tower depth or a coupling.

Lemma 3.126 (Protected stencils)**.** Let Z be a union of level-$(p-1)$ localization cubes, and construct either of its two towers $Z = \Omega_0 \supset \cdots \supset \Omega_p$. For every $n \le p$, the truncation at n is an admitted separated sequence with no inward determining rows. Its two-layer inset $Z^{\ominus 2}$ has distance at least ML^{p-1} from Ω_n^c. Every bare site within distance $4L^n$ of that inset lies in a free level-n pillar. In particular every plaquette and every full six-plaquette current stencil based in the inset lies in these pillars. ■

Proof. Let w_q be an upper bound on the distance from a discarded point to Z^c. The discarded cube at the next step either meets the old complement or fails its distance test. Its side plus the

rejected gap therefore gives

$$w_0 = 0, \qquad w_{q+1} - w_q = \begin{cases} R_1 \mathfrak{M} L^q + \mathfrak{M} L^{q+1}, & \text{first rule,} \\ 2M_1 L^{q+1}, & \text{second rule.} \end{cases}$$

Nested grids ensure that this argument also applies to a cube not contained in the previous member. Summing the geometric series gives $w_q \le ML^{p-3}$ for either rule and all $q \le p$. Consequently

$$\mathrm{dist}_\infty(x, \Omega_q^c) \ge \mathrm{dist}_\infty(x, Z^c) - ML^{p-3}. \tag{3.mxcii}$$

The two-layer inset has distance at least $2ML^{p-1}$ from Z^c, which proves the asserted distance bound.

Both rules give unions of the required aligned cubes and gaps greater than $R_1 \mathfrak{M} L^{q-1}$ at level q. At a nonempty localization the level-n torus side has at least $M/L \ge L^3 R_1 \mathfrak{M}$ sites, so the torus floor for the background theorem is satisfied. The statements remain valid when a member is empty; for the full torus every member is the full torus.

If x is within $4L^n$ of the inset, its level-n block has distance at least $(M/L - 5)L^n > L^{n-1}$ from Ω_n^c. Its only determining node is its top: a lower row has an endpoint outside Ω_n and length at most L^{n-1}, whereas a level-n node is a block center. This proves that the pillar is free. A current stencil reaches at most two bare steps, which are contained in the stated halo. □

For a separated sequence of depth n, put $\eta = L^{-n}$. Let $\ell_-(b)$ be the smaller assigned physical pillar length at the endpoints of b, and take the minimum over the corners for a plaquette. A level-q determining row and its full double-block read have $\ell_- \ge L^{q-1-n}$. This follows because the read has radius at most $3L^{q-n}/2$, while the preceding layer gap is greater than $R_1 \mathfrak{M} L^{q-1-n}$. Define

$$\|w\|_- := \sup_b \ell_-(b)|w(b)|. \tag{3.mxciii}$$

The real and imaginary Hermitian parts of w have no larger norm.

3.35.2. *A common complex ball.* The next lemma uses only the real mixed background and its physical datum chart, proved in Prop. 3.124 and Cor. 3.125. In particular, neither result is applied with a hereditary core as an input. We write b for a raw row logarithm: the datum is $e^{ib}V_0$. Thus $\|b\|_\infty$ is the norm called $\|B\|_{1,\infty}$ when $b(c) = \xi_c B(c)$.

Throughout this subsection, $\mathcal{H}_{\mathbf{B},V_0}(b)$ means the Landau component of the physical chart with *literal* datum $e^{ib}V_0$. Its evaluation includes the triangular conversion eq. 3.mxxxiii: if $\mathfrak{n}_{\mathbf{B},V_0}(b)$ denotes that converted per-length datum, the solved equation is $q(H) = \mathfrak{n}_{\mathbf{B},V_0}(b)$. The completed representative is

$$\Phi_{\mathbf{B},V_0}(b) = (e^{i\eta H}U_0)^{u_b}, \qquad M_{\mathbf{B}}(e^{i\eta H}U_0) = (e^{ib}V_0)^{u_b^{-1}|_{\mathrm{nodes}}}.$$

Thus H alone need not have the literal datum. Every estimate in the literal variable b includes this conversion and the node factors. Their finite carriers and uniform derivatives are part of eq. 3.mxxxiv and eq. 3.mlxvii.

Lemma 3.127 (Uniform analytic readouts)**.** There are $a_*, r_*, C_* > 0$, depending only on the fixed background geometry, with the following property. Let U be real and satisfy

$$|\partial U(P) - 1| < e_0 \eta^2 \ell_-(P)^{-2}, \qquad e_0 < a_*. \tag{3.mxciv}$$

For every $\|w\|_- < 2r_*$ the averaged datum $M_{\mathbf{B}}(e^{i\eta w}U)$ and its continued critical configuration $\Phi_U(w)$ exist and depend holomorphically on w. For a plaquette or full current stencil contained in free pillars of one level q, put $\xi = L^{q-n}$. Then

$$\left|\eta^{-2}\xi^2(\partial\Phi_U(w) - 1)\right| \le 1, \qquad |\xi^3 J_\eta(\Phi_U(w))| \le 1. \tag{3.mxcv}$$

The same r_* works for every depth, compatible volume, real base U satisfying eq. 3.mxciv, and either tower rule. ■

Proof. The actual averaging estimates give constants $a_{\mathrm{av}} > 0$ and $C_Q \geq 1$, independent of the number of iterations, such that

$$b(w) = \frac{1}{i}\log\{M_{\mathbf{B}}(e^{i\eta w}U)M_{\mathbf{B}}(U)^{-1}\}, \qquad \|b(w)\|_\infty \leq C_Q L\|w\|_- \tag{3.mxcvi}$$

is holomorphic when $L^2 e_0 < a_{\mathrm{av}}$ and $L\|w\|_- < a_{\mathrm{av}}$. Indeed the order-$q$ read has $L^q\eta|w| \leq L\|w\|_-$ and curvature at most $L^2 e_0 L^{-2q}$ on its whole double block. Apply Prop. 3.6 on that block. At level zero the formula is $b(w) = \eta w$. The same averaging estimate shows that the real datum $V_0 = M_{\mathbf{B}}(U)$ has every ordinary and mixed test bounded by $C_V e_0$. On a mixed plaquette the coarse bond reconstructed from the lower rows equals the actual next average, by the semigroup identity. No new seam defect occurs.

Choose a_* so $C_V a_*$ lies below the real datum ceiling. The real background theorem supplies its normalized critical representative U_0 and the bound

$$\eta^{-2}\ell(P)^2|\partial U_0(P) - 1| + \ell(b)^3|J_\eta(U_0)(b)| \leq C_B e_0. \tag{3.mxcvii}$$

Here and below a current is evaluated only at a full stencil; boundary forcing is retained in the regional equations used to construct U_0. The physical chart gives $W(b) = e^{i\eta H(b)}U_0$, holomorphic for $\|b\|_\infty < r_B$, with weighted potential and first differences at most $C_H\|b\|_\infty$. It also bounds the change of multiplier by $C_H\|b\|_\infty$.

We record why its current is bounded on that entire ball. If T_H is the differential of the exponential coordinate in left-trivialized physical variables, the equation after removal of the gauge penalty is

$$T_H^\sharp J_\eta(W(b)) = q'(H)^\sharp(\omega_0 + \nu(b)). \tag{3.mxcviii}$$

The adjoints in this identity include the physical row and bond densities. The actual row-transpose estimate and the multiplier readout of eq. 3.mlxvi give

$$\|\ell^3 J_\eta(W(b))\|_\infty \leq C(e_0 + \|b\|_\infty).$$

At $H = 0$, the multiplier also has a uniform bound. If R_0 is the actual right inverse of the retained row map, apply $R_0^\sharp$ to $J_\eta(U_0) = q'(0)^\sharp\omega_0$. The weighted row-lift estimate in eq. 3.mlx gives $\|\omega_0\|_{3,\infty} \leq C\|\ell^3 J_\eta(U_0)\|_\infty \leq CC_B e_0$. Thus both the base multiplier and its increment have the claimed bounds. The bondwise factors $T_H^{\pm 1}$ are bounded because $\eta|H| \leq \ell|H|$ is small. Thus this estimate comes from the Euler equation and its multiplier bound. It does not require a second-difference estimate inferred from the first-difference norm. The plaquette product similarly gives $\eta^{-2}\ell^2|\partial W(b) - 1| \leq C(e_0 + \|b\|_\infty)$.

We must also control the prescribed normalized representative. Fix a free pillar with top y at level t and let $h_y = \sup_{B^t(y)} \xi_y|H|$. For a level-$q$ segment of the ascent to y, retain its real reference contour as a unitary factor. Its condition number is 1; it need not be the identity. The actual relative contour logarithm is bounded by $C_\Gamma C_Q L^{q-t+1}h_y$. To see the scale, apply the actual mean estimate to the order-q double block: its relative row logarithm is at most $C_Q L^{q-t}h_y$. A one-step comb has at most $4(L-1)$ bonds; the finite product logarithm on the fixed chart costs at most twice their sum. Indeed, factoring each bond into its relative factor and its real reference factor rewrites the relative contour as a product of unitary conjugates of the relative factors. The same bound for the mean contour follows from the contraction defining that contour. The node factor at the top is a product of exponentials with logarithms bounded by $C_N L^{q-t}h_y$. These are the one-step site corrections in Prop. 3.6: at level q, their normalized input is $L^{q-t}h_y$, and the inverse derivative of the site mean is bounded on its fixed chart. The constant C_N depends on L, including the finite comb length, and not on q or t. The real reference node factors are unitary as well. Telescope these factors through the ascent; their conjugations preserve all norms in the estimates just obtained. Each ascent meets a level at most once. Therefore the gauge u_b which takes $W(b)$ to the prescribed

representative satisfies

$$|u_b(x)^{\pm1}| \le \exp\left(C_G h_y \sum_{q=0}^{t-1} L^{q-t}\right) \le e^{C_G h_y/(L-1)}, \qquad \Phi_U(w) = W(b(w))^{u_{b(w)}}. \tag{3.mxcix}$$

The identity holds at real data by the defining axial normalization and at complex data by holomorphy. All factors use the actual averaging contours and node correction. Choose $r_G \le r_B/2$ so $\|b\|_\infty < r_G$ makes the condition number of this gauge at most 2. Conjugation then costs at most 2 in both readouts. The entire stencil lies in the indicated free pillars, so it has no additional boundary term.

Finally choose, in this order,

$$r_* \le \frac{1}{4L}\min\{a_{\mathrm{av}}, r_G/C_Q\}, \qquad C(a_* + 2C_Q L r_*) \le \frac{1}{2}. \tag{3.mc}$$

The constants in the second inequality are the fixed plaquette, Euler-current and gauge constants just obtained. Decrease a_* and r_* once to satisfy it. Equations eq. 3.mxcvi, eq. 3.mxcviii and eq. 3.mxcix now prove eq. 3.mxcv throughout the ball $\|w\|_- < 2r_*$. □

3.35.3. *The quadratic gain.*

Lemma 3.128 (Three real configurations)**.** Let F be a matrix-valued holomorphic map on $\|w\| < 2r$, bounded there by 1, and write $w = w_{\mathrm{r}} + iw_{\mathrm{i}}$ with $\|w_{\mathrm{r}}\|, \|w_{\mathrm{i}}\| \le \|w\| \le r$. Then

$$|F(w)| \le |F(w_{\mathrm{r}})| + |F(w_{\mathrm{i}})| + |F(0)| + \frac{3\|w\|^2}{2r^2}. \tag{3.mci}$$

■

Proof. For each of the three vectors, the one-variable Taylor series on $|z| < 2r/\|w\|$ bounds the remainder after degree one by $\|w\|^2/(2r^2)$. Apply the triangle inequality to $F(w) - F(w_{\mathrm{r}}) - iF(w_{\mathrm{i}}) + iF(0)$. Its constant and linear terms vanish. The estimate follows by duality with norm-one linear functionals on the matrix space. □

Proposition 3.129 (Uniform tower bound)**.** There are $a_T > 0$ and $K_T \ge 1$ such that, on every separated sequence of depth n, the assumptions

$$\begin{gathered} |\partial U(P) - 1|, \quad |\partial(e^{i\eta f}U)(P) - 1| < e_0\eta^2\ell_-(P)^{-2}, \\ \|f\|_- < e_1, \qquad e_0 + e_1 < a_T, \end{gathered} \tag{3.mcii}$$

with U real imply, at every free level-q full read,

$$|\partial\Phi_U(f) - 1| < K_T(e_0 + e_1^2)\eta^2\xi^{-2}, \qquad |J_\eta(\Phi_U(f))| < K_T(e_0 + e_1^2)\xi^{-3}, \quad \xi = L^{q-n}. \tag{3.mciii}$$

The bounds also hold for $f = 0$. The configuration is holomorphic in f on the fixed ball of Lem. 3.127, regardless of whether the second curvature bound in eq. 3.mcii holds at other points of that ball. ■

Proof. Transport the four increments of a plaquette to its initial corner using U. Their sizes are at most $\eta e_1/\ell_-(P)$. The remainder after the linear term in their exponential product is bounded by $C\eta^2 e_1^2\ell_-(P)^{-2}$. The closing transport changes the linear curl by at most $C\eta|f|\,|\partial U - 1|$. Hence the two curvature bounds imply

$$\ell_-(P)^2|\mathrm{d}_U f(P)| \le C(e_0 + e_1^2).$$

Real unitary transports commute with taking Hermitian real and imaginary parts. Applying the same product estimate to f_{r} and f_{i} proves

$$|\partial(e^{i\eta f_\sigma}U) - 1| \le C_P(e_0 + e_1^2)\eta^2\ell_-^{-2}, \qquad \sigma \in \{\mathrm{r}, \mathrm{i}\}.$$

Choose $a_T \le \min\{r_*, a_*/(2C_P), 1/2\}$ and reduce it, if necessary, to meet the real datum ceiling for these two configurations. Their averaged data are regular, and the continued real fields are

their unique regular critical orbits by Prop. 3.124 and Cor. 3.125. Thus each normalized readout at $0, f_{\mathrm{r}}, f_{\mathrm{i}}$ is bounded by $C_R C_P(e_0 + e_1^2)$. Here the prescribed gauges at real points are unitary, so they preserve the norm.

Apply Lem. 3.128 to the two readouts in eq. 3.mxcv. It gives eq. 3.mciii with, for example, $K_T = 1 + 4C_R C_P + 2r_*^{-2}$. This number has no depth or real-base dependence. In the notation of eq. 3.ccclxxxvii, one may take $M = 1$ and $r_0 = r_*$ after the harmless conversion from a ball to the displayed two-variable polydisc. In particular $M/r_0^2 = r_*^{-2}$ is a fixed constant. No running normalization is part of this radius. □

Write $\mathcal{Q}_j(X; e_0, e_1, c_0)$ for the simple triple class of eq. 3.ccviii, with independent current bound c_0. We display this third radius in $\mathcal{C}_j$ when it differs from the curvature radius.

Corollary 3.130 (Both towers at every truncation)**.** Let $(U, A', \mathbf{J})$ satisfy the simple conditions on a level-j domain X, with radii (e_0, e_1, c_0) and $e_0 + e_1 < a_T$. For every tower address (p, Z), both erosion rules and $1 \le n \le p$, the tower at the actual averaged datum exists. In level-n units, on $Z^{\ominus 2}$ it satisfies

$$\begin{aligned} |\partial U_n(Z; \mathbf{U}) - 1| &< K_T(e_0 + e_1^2) L^{-(j-p)} L^{-2p}, \\ |J^{(n)}(U_n(Z; \mathbf{U}))| &< K_T(e_0 + e_1^2) L^{-(j-p)} L^{2(n-p)}. \end{aligned} \tag{3.mciv}$$

The same is true for the real factor. Consequently

$$e_0 \le b_0, \quad e_1 \le b_1, \quad K_T(e_0 + e_1^2) \le b_0 \quad \Longrightarrow \quad \mathcal{Q}_j(X; e_0, e_1, c_0) \subset \mathcal{C}_j(X; b_0, b_1, c_0). \tag{3.mcv}$$

The third radius denotes the independent current bound; when omitted it equals the first radius. ■□

Proof. First take $j = p$ and put $\lambda = L^{n-p}$. On changing from level p to level n, the potential becomes $\lambda A'$, the physical curvature gains λ^2, and the real gauge clauses remain valid. The simple input therefore satisfies eq. 3.mcii with $\epsilon_0 = \lambda^2 e_0$ and $\epsilon_1 = \lambda e_1$. The minimum length is at most 1, so these uniform bounds imply its weighted bounds. By Lem. 3.126, every required output stencil lies in free top pillars, where $\xi = 1$. The output curvature has factor $\lambda^2 L^{-2n} = L^{-2p}$, and its level-$n$ current has factor $\lambda^2 = L^{2(n-p)}$.

For a general address of a level-j domain, restriction to level p has simple radii $\mu e_0, \mu e_1$ with $\mu = L^{-(j-p)}$. The curvature and first difference actually gain μ^2, which is stronger than the radius asserted here. Apply the preceding result and use $\mu e_0 + \mu^2 e_1^2 \le \mu(e_0 + e_1^2)$. The independent current restricts by μ^3 and has no role in a tower's physical current. This proves every clause, without summing over addresses. For a bounded localization domain in $\mathbb{R}^4$, choose a torus large enough to contain it and every determining read injectively. The regional action, row constraints and normalization paths are then exactly the same finite objects. Uniqueness makes the tower independent of the chosen torus, so all assertions hold on that domain with the same constants. □

3.35.4. *Membership throughout parameter discs.*

Corollary 3.131 (Uniform parameter domains)**.** Let U be fixed and let $A'(z), \mathbf{J}(z)$ be holomorphic on an open polydisc D, with their values satisfying the simple bounds at fixed radii (e_0, e_1, c_0) throughout D. If the inequalities of eq. 3.mcv hold, the whole image of D lies in the target core. All tower maps are holomorphic on D, with the common bounds displayed in eq. 3.mciv. A strict inequality $K_T(e_0 + e_1^2) < b_0$ supplies a common strict margin, also on every smaller closed polydisc. No radius loss depending on the number of tower addresses is required. ■□

Proof. The mean and background compositions in Lem. 3.127 are defined before testing core membership. The simple bounds put each composition in its fixed ball at every point of D. Cor. 3.130 therefore applies pointwise with the same constants, and composition proves holomorphy. Taking

the supremum over all addresses preserves this common bound; no uniform strict margin is inferred merely from individual strict inequalities. The real factor and its real gauges are fixed; the independent current uses its own assumed simple inequality. □

Proposition 3.132 (Outer substitutions)**.** Fix $c_\natural \geq 1$. There is $c_O > 0$, depending only on the fixed geometry and $c_\natural$, such that the following holds. Suppose $0 < b_0 \leq b_1$, $b_1^2 \leq c_\natural b_0$, and $b_0 + b_1$ is below a fixed ceiling. Start from a triple in the core with radii $(b_0/2, b_1/2, c_0)$ and put $\mathbf{U} = e^{i\eta_j A'} U$. If

$$\max\{|A|, |\nabla_{\mathbf{U}} A|\} < c_O b_0, \qquad |\mathbf{J}'| < b_0,$$

then $(e^{i\eta_j z A}\mathbf{U}, \mathbf{J}')$ belongs to the core at radii (b_0, b_1, b_0) for every $|z| \leq 1$, with the real factor U and the principal Baker–Campbell–Hausdorff potential. The same conclusion is uniform in any other parameters for which the stated bounds hold on their whole polydisc. ■

Proof. Choose $R = 64K_T(1 + c_\natural)$, and then choose $c_O \leq (16C_O R)^{-1}$, where C_O bounds the first-order product and plaquette estimates on the fixed logarithm chart. For $|z| < R$,

$$A'_z = (i\eta_j)^{-1} \log(e^{i\eta_j z A} e^{i\eta_j A'})$$

is holomorphic. The product rule, including the change from $\nabla_{\mathbf{U}}$ to ∇_U, gives $|A'_z|, |\nabla_U A'_z| < b_1$ and $|\partial(e^{i\eta_j A'_z} U) - 1| < b_0 \eta_j^2$. Indeed the additional terms are bounded by $C_O(Rc_O b_0 + (Rc_O b_0)^2 + Rc_O b_0 b_1)$; reducing the fixed ceiling makes their sum smaller than $b_0/4$. The real gauges remain those of U. Thus the simple conditions hold on this entire auxiliary disc, although membership in the target hereditary core has not yet been used there.

At an address (p, Z) divide the two tower readouts by the factors $L^{-(j-p)}L^{-2p}$ and $L^{-(j-p)}L^{2(n-p)}$, respectively. By Cor. 3.130 each resulting holomorphic function $F(z)$ is bounded on $|z| < R$ by $K_T(1 + c_\natural)b_0$. Schwarz applied to $F(z) - F(0)$ gives

$$|F(z) - F(0)| \leq \frac{2K_T(1 + c_\natural)b_0}{R} \leq b_0/32 \qquad (|z| \leq 1).$$

The old core gives $|F(0)| < b_0/2$. This proves every complex tower test with room. Its real counterpart is unchanged. The simple conditions and $|\mathbf{J}'| < b_0$ complete the inclusion, uniformly over the auxiliary parameters. □

3.35.5. *Inner window substitutions.* We now prove the core inclusion for the actual inner window map. This application uses the upper triple's tower clause. That clause has either been retained from the upper core or has been established by Cor. 3.131; it is not an assumption used to prove Prop. 3.129.

Let $\square$ be the union of the 2^4 level-k localization cubes meeting a vertex, and let $\square_0 = \square^{\sim 5}$ be a box with an injective torus lift. Put $N = k + 1$, $\nu = N - j \geq 1$ and $\sigma = L^{-\nu}$. Let $\mathbf{B}^+$ be the first-rule tower of $\square_0$ to depth N, and $\mathbf{B}_j$ its truncation at j. For a dimensionless fine logarithm a write $\mathsf{q}_q(a) = i^{-1} \log \mathcal{M}^q(e^{ia})$ on the fixed near-trivial chart. This is the plain nonlinear mean logarithm; it is not the linear row map or the straightened constraint. The upper triple has radii $\alpha_\iota = (1 + 2\beta_s)A_\iota$, $0 < \beta_s \leq 1/4$. We require its simple conditions on $\square_0$ and its tower clause at $(N, \square_0)$. Thus its upper tower has curvature less than $\alpha_0 L^{-2N}$ and level-N current less than α_0 on $\square^{\sim 3}$.

Lemma 3.133 (The box datum)**.** For $M(\alpha_0 + \alpha_1)$ below a fixed ceiling, there are holomorphic maps at fixed real U, denoted V and v, with

$$M_{\mathbf{B}^+}(\mathbf{U}) = V^v, \qquad \|\log V\|_\infty \leq C_\square M\alpha_0, \qquad |v(x)|\,|v(x)^{-1}| \leq e^{C_\square M\alpha_1}. \tag{3.mcvi}$$

They use only the bare field on $\square_0$, agree under restriction from a larger domain, and are real at real potentials. The node gauge is normalized at the prescribed base point. The construction and these bounds also hold when all inward rows of the determining set are retained. At fixed real base

and fixed radii, the domain defined by the simple conditions and the upper tower clauses is open. Both maps commute with translations of the aligned box and with its injective lifts between tori. Under a real gauge h, their values become $h(y_0)Vh(y_0)^{-1}$ and $h(x)v(x)h(y_0)^{-1}$, respectively. ■

Proof. Choose the prescribed comb from the base point to each site and write $g(x)$ for its transport in $\mathbf{U}$. The comb has length at most CM in level-N units. Along it the real transports have norm one, while a complex increment has norm and inverse norm at most $e^{L^{-N}|A'|}$. Consequently $\mathrm{cn}(g) \le e^{CM\alpha_1}$. In the comb gauge, a bare link is the product of the plaquettes in the strip between the two combs. There are at most CML^N such plaquettes. Their transports have the preceding condition-number bound, and their defects are at most $\alpha_0 L^{-2N}$. The product bound therefore gives $|\mathbf{U}^g(b) - 1| \le CM\alpha_0 L^{-N}$, after reducing the fixed ceiling. This argument uses the complex curvature clause as well as the real base and the potential bound.

Write $\mathbf{U}^g = e^{ia}$ on this chart. Every order-q determining read has $L^q \sup|a| \le CM\alpha_0$, since $q \le N$. The actual near-trivial averaging estimate therefore gives $V = M_{\mathbf{B}^+}(\mathbf{U}^g)$ and $\|\log V\|_\infty \le C_\square M\alpha_0$. Complex covariance of each mean is valid on this same chart: the condition number above times its input diameter remains below the mean radius. Set $v = g^{-1}$ at the nodes. This proves the exact identity in eq. 3.mcvi. Paths, products, logarithms and means are holomorphic on the stated domain. Their definitions prove the restriction, reality and base-point assertions. Every determining row, including an inward row if it is retained, has its full read inside the box. The same construction therefore proves the asserted variant. All simple inequalities are strict inequalities between continuous functions on finitely many cells. For a fixed real base, each admitted tower clause uses a fixed holomorphic datum chart; its defining raw-log inequalities and its curvature and current inequalities are also strict and continuous. There are only finitely many truncations and cells on this box. Their intersection is open, including when it is empty because a real-base clause fails. This is a finite-dimensional openness argument; it makes no assertion of a uniform margin over increasing cutoffs. The common bounds used for parameter discs were established separately in Cor. 3.131. Finally the prescribed comb transports obey $g^h(x) = h(y_0)g(x)h(x)^{-1}$. This gives the displayed gauge laws; their paths and all averaging reads are preserved by the indicated translations and injective lifts, which proves the remaining claims. □

Lemma 3.134 (Restriction of a constrained critical field)**.** Let $\mathbf{B}$ be the determining set of a separated sequence $\Omega_0 \supset \cdots \supset \Omega_m$, with all inward rows removed. Let $Z \subset \Omega_m$, and let $\mathbf{B}'$ be the determining set of a separated sequence $Z = \Omega'_0 \supset \cdots \supset \Omega'_{m'}$, $m' \le m$, also with all inward rows removed. A critical field for $\mathbf{B}$ restricts to a critical field for $\mathbf{B}'$ at its induced datum. The same assertion holds when $\mathbf{B}'$ is the determining set of a truncation of the original sequence. ■

Proof. Write W for the old field and extend a competing field W' on Z by W outside the inner bare bonds of Z, obtaining $\widetilde{W}'$. Suppose $M_{\mathbf{B}'}W' = M_{\mathbf{B}'}W$. We first show $M_{\mathbf{B}}\widetilde{W}' = M_{\mathbf{B}}W$. Put $\Omega'_{m'+1} = \varnothing$. For $0 \le q \le m'$, let $P(q)$ assert equality of the two order-q averages at every row whose full blocks lie in Ω_0 and whose endpoints both avoid Ω'_{q+1}.

For $q = 0$, a changed bare bond satisfying this condition belongs to the frozen set Γ'_0, so $P(0)$ holds. Suppose $P(q-1)$ holds. If a row in $P(q)$ has an endpoint in Ω'_q, this endpoint is in $\Omega'_q \setminus \Omega'_{q+1}$. Separation puts its other endpoint and its complete read inside Ω'_{q-1}, and the row belongs to Γ'_q, including when it points outward. Its average is thus fixed by the induced datum. Otherwise both endpoints are outside Ω'_q. Since Ω'_q is a union of aligned level-q cubes, both predecessor blocks avoid Ω'_q. The one-step mean reads only these blocks, where $P(q-1)$ applies. This proves $P(q)$. At $q = m'$ all order-m' averages agree. The averaging semigroup therefore gives equality at every higher-order old row as well. An old row of order $q < m'$ has an endpoint outside $\Omega_{q+1} \supset Z$. Its length is L^q, whereas Ω'_{q+1} has distance greater than L^q from Z^c. Neither endpoint can lie in Ω'_{q+1}, so $P(q)$ also covers every such old row.

Every bare plaquette meeting Z^c has each corner within one bare step of Z^c. Separation therefore puts any of its inner bonds in Γ_0', where $W' = W$. All action terms crossing the boundary are constant along a constrained variation of W'. Extending that variation consequently preserves the old datum, and its old action derivative equals its regional action derivative. The first is zero by criticality, which proves the assertion.

For a truncation at depth t, the retained rows below t are unchanged. Its top rows include every order-t row needed in the read of an old row of order greater than t; this follows from the separation collar and the nested block identity. Equality of the top averages and the semigroup preserve these old rows. The underlying region is unchanged, so there is no crossing action term. The same variation argument applies. □

Proposition 3.135 (Inner substitution on its full domain)**.** There are fixed $M_0, C_I, c_2, c_3 > 0$ and, for $M \geq M_0$, a ceiling $a_I(M) > 0$ with the following property. Let $A_0, A_1, a_0, a_1 > 0$, and suppose

$$A_0 + A_1 < a_I(M), \quad a_0 + a_1 < a_I(M), \quad C_I M a_0 < a_1, \quad A_0 \leq 2\sqrt{1+\nu}\, a_0. \tag{3.mcvii}$$

Put $C_V = 2C_\square$. First allow an independent complex raw datum b_V on $\mathbf{B}^+$ in the ball

$$\|b_V\|_\infty < C_V M A_0, \tag{3.mcviii}$$

and set $H_+ = \mathcal{H}_{\mathbf{B}^+,1}(b_V)$. For the physical application, take the upper input and the data of Lem. 3.133 and put $b_V = i^{-1}\log V$. Equation eq. 3.mcvi places this datum in eq. 3.mcviii, since $\alpha_0 \leq 3A_0/2$. For a complex field A in level-k units and a raw row correction b' on $\mathbf{B}_j$, suppose $\|A\|_\infty < c_2 A_0$ and $\|b'\|_\infty < c_3 a_0$. Define the actual raw fine potential and row datum by

$$a = (i)^{-1}\log(e^{iL^{-k}A}e^{iL^{-N}H_+}), \qquad b(c) = \mathsf{q}_q(a)(c) \quad (c \in \Gamma_q), \qquad H = \mathcal{H}_{\mathbf{B}_j,1}(\tau b + b'), \quad 0 \leq \tau \leq 1. \tag{3.mcix}$$

The application of $\mathcal{H}$ in this formula includes $\mathfrak{n}_{\mathbf{B}_j,1}(\tau b + b')$ before the reduced saddle equations are solved. All maps are defined and holomorphic on the full indicated open balls in (b_V, A, b'). Whenever b_V comes from an upper input as above, their output on $\square^{\sim 3}$ satisfies

$$|H|, |\nabla H| < a_1/2, \qquad |\partial e^{iL^{-j}H} - 1| < a_0 L^{-2j}/8, \qquad |J^{(j)}(e^{iL^{-j}H})| < a_0/16. \tag{3.mcx}$$

For every $X \subset \square^{\sim 2}$ of level $j-1$, the triple $(1, H, J^{(j)}(e^{iL^{-j}H}))|_X$ lies in the core with radii $(a_0/4, a_1/2, a_0/4)$. These estimates and inclusions hold throughout every auxiliary parameter polydisc on which the upper input and the two increment bounds hold. The same inclusion holds on a larger level-$(j-1)$ domain whose complete simple-condition stencils lie in $\square^{\sim 3}$ and which is contained in the top member of the truncated window tower. ■

Proof. We give the choices and the estimates in their dependency order. The physical datum chart and eq. 3.mlxvii give constants $C, r, s > 0$ for the flat reference on every tower. Its potential, first difference, normalized curvature and physical current have Lipschitz constant C on $\|d\|_\infty < r$. If a change of d is supported at distance at least D from an output cell, its contribution is at most Ce^{-sD} times its supremum. For the current this follows by differentiating eq. 3.mxcviii; the weighted row-transpose density sums the differentiated multiplier columns. It therefore retains the same exponential bound. The output cell and the full current stencil are included in the distance convention.

We first admit the full product of input balls, without requiring b_V to arise from an upper field. On a complete order-q read of the truncated tower, the upper assigned length is at least L^{q-1-N}, by the geometry used in eq. 3.mxcvi. The weighted flat response therefore gives

$$L^q \sup_{\mathsf{P}^q(c)} |L^{-N}H_+| \leq C\|b_V\|_\infty, \qquad c \in \Gamma_q, \quad q \leq j.$$

The product logarithm and the actual mean on this read consequently give, uniformly for $0 \leq \tau \leq 1$,

$$\|\tau b + b'\|_\infty \leq C(\|b_V\|_\infty + L^{j-k}\|A\|_\infty) + \|b'\|_\infty.$$

Since $j \le k$, decreasing $a_I(M)$ makes the right side smaller than $r/2$ on the entire product of the three stated balls, and keeps all preceding raw logarithms and means in their fixed charts. This proves the full-domain holomorphy. Only the sharper readout estimates below use the actual upper input.

For any one of these readouts $R_x(d)$, with $R_x(0) = 0$, Cauchy on the fixed datum ball gives

$$|R_x(d) - DR_x(0)d| \le C\|d\|_\infty^2/r. \tag{3.mcxi}$$

For a split $d = d_{\mathrm{in}} + d_{\mathrm{out}}$, where the outer part is at distance D, apply this bound only to d_{in} and use the preceding Lipschitz estimate for d_{out}. This gives

$$|R_x(\tau d) - \tau R_x(d)| \le C(e^{-sD}\|d_{\mathrm{out}}\|_\infty + \|d_{\mathrm{in}}\|_\infty^2/r), \qquad 0 \le \tau \le 1. \tag{3.mcxii}$$

These are estimates of the actual current map, so no bound on second differences of an arbitrary complex input is being assumed.

Let $q_0 = \log M_{\mathbf{B}_j}(e^{iL^{-N}H_+})/i$. The uniform row bounds give

$$\|q_0\|_\infty \le CMA_0, \qquad \|q_{\mathrm{in}}\|_\infty \le CMA_0\sigma, \qquad \sup_{\square^{\sim 4}} |H_+| \le CMA_0.$$

Here an inner row is one whose complete double block is in $\square^{\sim 4}$. Such a row is a level-j row, by Lem. 3.126; its raw input has the extra factor $L^{j-N} = \sigma$. Every other row is at distance $D \ge cML^{\nu-1}$ from $\square^{\sim 3}$ in the level-j metric. This follows by stopping a path at the edge of $\square^{\sim 4}$; before that edge all pillar lengths are one in level-j units.

Choose M_0 so, for every $M \ge M_0$ and $\nu \ge 1$,

$$CMe^{-scML^{\nu-1}} \le 10^{-3}L^{-2\nu}. \tag{3.mcxiii}$$

Such a choice exists: with $t = L^{\nu-1} \ge 1$, the quantity t^2e^{-scMt} decreases for $scM \ge 2$. Next choose $a_I(M)$ so $CMa_I < r/8$ and $CM^2a_I/r < 10^{-3}$, as well as all preceding logarithm and gauge ceilings. Combining eq. 3.mcxi and eq. 3.mcxii then gives, for curvature and current,

$$|R_x(\tau q_0) - \tau R_x(q_0)| \le A_0\sigma^2/100. \tag{3.mcxiv}$$

For the potential and first difference they give the simpler bound $CMA_0\sigma$.

We identify the endpoint $\tau = 1$. Restriction of the upper critical field to the truncated sequence is critical at its full induced datum by Lem. 3.134. Real regular uniqueness identifies the restricted orbit. The equality extends to the common complex datum ball by holomorphy. Restoring the upper node gauge and both axial normalizations gives

$$e^{iL^{-j}\mathcal{H}_{\mathbf{B}_j,1}(q_0)} = (U_N(\square_0;\mathbf{U}))^G.$$

The local products in eq. 3.mxcix, the corresponding product for the flat nested tower, and eq. 3.mcvi give $\mathrm{cn}(G) \le \exp(CM(A_0 + A_1)) \le 4/3$ after decreasing $a_I(M)$. We check the real-base change in this identification. Write $V_0 = M_{\mathbf{B}^+}(U)$ and $e^{ib^U}V_0 = M_{\mathbf{B}^+}(\mathbf{U})$; the mean estimate gives $\|b^U\|_\infty \le C\alpha_1$. At the point in question use the polar factorization $v = v_re^{i\mu}$, with v_r unitary and $\|\mu\|_\infty \le CM\alpha_1$. Conjugating the exact datum identity by v_r^{-1} gives

$$e^{i\widetilde{b}^U(c)}V_0'(c) = e^{i\mu(c_-)}e^{ib_V(c)}e^{-i\mu(c_+)}, \quad V_0' = V_0^{v_r^{-1}}, \quad \widetilde{b}^U = \mathrm{Ad}(v_r^{-1})b^U.$$

Thus $V_0' = e^{ib_0}$ with b_0 real and $\|b_0\|_\infty \le CM(A_0 + A_1)$. The four logarithms $b_0, \widetilde{b}^U, \mu, b_V$ lie in a fixed smaller datum ball. At real values, global regular uniqueness gives both change of base and covariance under the node gauge. The two sides are holomorphic functions of the small logarithms on that ball, so the identity theorem gives these identities for their complex values. The polar factorization is used only to locate the given point in the common charts; no holomorphic dependence of its unitary factor is claimed. This proves the required base change and the endpoint identification on the actual domain. The upper tower clause and $\alpha_0 \le 3A_0/2$ now imply

$$L^{2j}|\partial e^{iL^{-j}\mathcal{H}_j(q_0)} - 1| \le 2A_0\sigma^2, \qquad |J^{(j)}(e^{iL^{-j}\mathcal{H}_j(q_0)})| \le 2A_0\sigma^3.$$

On their fixed common logarithm chart the actual means obey

$$|\mathsf{q}_q(a)(c) - \mathsf{q}_q(a_{\mathrm{ref}})(c)| \le CL^q \sup_{\mathsf{P}^q(c)} |a - a_{\mathrm{ref}}|. \tag{3.mcxv}$$

Here $a_{\mathrm{ref}} = L^{-N} H_+$. Apply Cauchy to the segment $a_{\mathrm{ref}} + z(a - a_{\mathrm{ref}})$ on the radius $c_{\mathrm{av}}/(2L^q \sup|a - a_{\mathrm{ref}}|)$, where the mean is bounded by $C_Q c_{\mathrm{av}}$; Schwarz applied after subtracting its value at zero gives the displayed inequality. The product logarithm in eq. 3.mcix satisfies $|a - a_{\mathrm{ref}}| \le CL^{-k}|A|$. Consequently $\|b - q_0\|_\infty \le CL^{j-k}\|A\|_\infty$. Choose c_2, c_3 so

$$C\|\tau(b - q_0) + b'\|_\infty < a_0/128$$

in every readout norm above. This is a fixed choice, because $2\sqrt{1+\nu}L^{-(\nu-1)} \le 2\sqrt{2}$. It also puts the entire datum in $\|d\|_\infty < r/2$, and so proves the asserted holomorphy on the full product of increment balls. The resulting curvature and current bounds are, respectively,

$$(2 + 1/100)A_0\sigma^2 + a_0/128, \qquad 2A_0\sigma^3 + A_0\sigma^2/100 + a_0/128.$$

Since $2\sqrt{1+\nu}L^{-2\nu} < 0.0168$ and $2\sqrt{1+\nu}L^{-3\nu} < 0.0013$, these are smaller than $a_0/8$ and $a_0/16$. For the potential and first difference the bound is $CMA_0\sigma + a_0/128$. Choose C_I large enough that eq. 3.mcvii, together with $2\sqrt{1+\nu}L^{-\nu} < 0.218$, makes it smaller than $a_1/2$. This proves eq. 3.mcx.

It remains to check every nested tower, without paying the large constant K_T against this fixed fractional radius. Let (p, Z) be any address of X, use either rule, and truncate at $n \le p$. The whole Z is inside the top member of the level-j window tower. The constraint and boundary-action checks in Lem. 3.134 identify its normalized critical continuation with $(e^{iL^{-j}H}|_Z)^w$. All its mean logarithms have size at most $C_Q \sup_Z |H|$ and are inside the common datum ball by the choice of a_I. Its normalization gauge is the product of its free ascent contours. At level q their logarithms are bounded by $CL^{q-j}\sup_Z|H|$; summing $q < n$ and including the top node factor yields $\mathrm{cn}(w) \le e^{Ca_1} < 6/5$. Thus the identity with its bound is

$$U_n(Z; e^{iL^{-j}H}) = (e^{iL^{-j}H}|_Z)^w, \qquad \mathrm{cn}(w) < 6/5. \tag{3.mcxvi}$$

For real window data this is the residual-gauge identity from regular uniqueness. Holomorphy on the common product ball proves it for all the present complex parameters.

By Lem. 3.126, the full stencils of every inset lie in Z. Conjugation and the change from level j to level n therefore give

$$|\partial U_n - 1| < \frac{6}{5}\frac{a_0}{8}L^{-2j} < \frac{a_0}{4}L^{-(j-p)}L^{-2p},$$
$$|J^{(n)}(U_n)| < \frac{6}{5}\frac{a_0}{16}L^{-3(j-n)} < \frac{a_0}{4}L^{-(j-p)}L^{2(n-p)}.$$

The second comparison uses $2j - p - n \ge 0$; the first uses $p \le j$. The real factor is 1, whose towers are identically 1. Its gauge clause holds with zero potential. The independent current chosen in the statement is the physical current already bounded in eq. 3.mcx. Thus every core clause holds on the whole parameter domain, including every nested tower and both rules. The proof used $X \subset \square^{\sim 2}$ only to put its complete simple stencils in $\square^{\sim 3}$ and its nested regions in the top member. This proves the last assertion as well. □

3.36. **Tower response in the ambient metric.** We now prove the weighted tower comparison used at settled elements of a deeper sequence. The determining tower is fixed during this comparison. The ambient sequence specifies the input norm and the output weights; it does not change the constrained problem.

Let $1 \le p \le i$. Take separated sequences $(\Omega'_q)_{q\le p}$ and $(\Omega^\flat_q)_{q\le i}$, with $\Omega'_q \subset \Omega^\flat_q$ for $q \le p$, and put $Z = \Omega'_0$. The determining set $\mathbf{B}'$ has all inward rows removed. All rows, outward endpoint blocks and physical pairings retain their actual conventions. Work in level-p units, so $\eta = L^{-p}$ and $\xi_q = L^{q-p}$. Assume each torus period contains at least 6ρ level-p sites, where $\rho = R_1\mathfrak{M}$. All volume-uniform assertions below refer to this admitted class. Sup distances between torus points

mean their shortest periodic sup distance. At a bare site x, let $\lambda'(x)$ and $\lambda^\flat(x)$ be the largest indices of the two sequences containing x, with value zero outside their first members, and set

$$\xi'(x) = \xi_{\lambda'(x)}, \qquad l(x) = \xi_{\lambda^\flat(x)}, \qquad s(x) = l(x)/\xi'(x) \geq 1.$$

Write d' and $d^\flat$ for the corresponding weighted path metrics, with density the reciprocal of the assigned scale. For a real field U and a complex potential v on the inner bare bonds of Z, define

$$\epsilon_U(P) = \eta^{-2} l(x_P)^2 |\partial U(P) - 1|, \qquad n_b(v) = \max\{l(x_b)|v(b)|,\ l(x_b)^2 |\nabla_U v|_Z(b)\}. \tag{3.mcxvii}$$

Only differences whose entire three-bond read lies in Z enter the last term. Put $n(v) = \max_b n_b(v)$ and

$$E_U^\delta(x) = \max_P e^{-\delta d^\flat(x,x_P)} \epsilon_U(P), \qquad E_v^\delta(x) = \max_b e^{-\delta d^\flat(x,x_b)} n_b(v).$$

The maxima use positively oriented inner plaquettes and bonds. An output element is an inner plaquette or a full bond, the latter meaning that all six incident plaquettes are inner. Its base x is settled if $\lambda'(x) = \min\{\lambda^\flat(x), p\}$. For the normalized critical continuation $\Phi_U(v) = \Phi_{\mathbf{B}', M_{\mathbf{B}'} U}(b(v))$, with the literal raw datum $b(v)$ of eq. 3.mxcvi, define

$$\mathcal{G}_U(v; P) = \eta^{-2} l(x_P)^2 (\partial \Phi_U(v)(P) - 1), \qquad \mathcal{G}_U(v; b) = l(x_b)^2 \xi'(x_b) J_\eta(\Phi_U(v))(b). \tag{3.mcxviii}$$

In particular, the current weight is $l^2 \xi'$. These are the weights of eq. 3.cdxix.

Lemma 3.136 (The two metrics and local scales)**.** Let $\rho = R_1 \mathfrak{M}$ be the separation in layer units. For bare sites x, y and for a row c of level q, with a bond b in its complete read, one has

$$\begin{aligned} d'(x,y) &\geq d^\flat(x,y), \qquad d'(x,y) \geq |x-y|_\infty/\xi_p, \\ s(x)/s(y) &\leq L^{2+2d'(x,y)/\rho}, \qquad d'(y_c, x_b) \leq C_L, \qquad \xi_q \leq L\xi'(x_b). \end{aligned} \tag{3.mcxix}$$

If $|x-y|_\infty \leq 3l(x)$, then $L^{-1} l(x) \leq l(y) \leq L l(x)$ and $d^\flat(x,y) \leq C_L$. If x is settled and $|x-y|_\infty > l(x)$, then $s(x) \leq 1 + d'(x,y)$. ■

Proof. Containment of the sequences gives $\xi' \leq l$ at every point of each bare path. Also $\xi' \leq \xi_p$. Integrating these two pointwise inequalities and taking infima proves the first two statements. To pass between layers with indices $a < a'$, a connected path must cross each intermediate collar. The collar at level q has width greater than $\rho\xi_q$ and path density ξ_q^{-1}, so each intermediate layer costs at least ρ. Thus the change of either index is at most one plus the corresponding weighted distance divided by ρ. Apply this to both indices and use $d^\flat \leq d'$ to bound their difference, giving the ratio of s in the display.

The complete order-q read lies in the preceding member; its endpoint blocks have diameter $O(\xi_q)$ and every site there has scale at least ξ_{q-1}. A path through these blocks has weighted length C_L. This includes the lower block at an outward endpoint and proves both row-read bounds. A ball of radius $3l(x)$ cannot cross two ambient layers, since the intervening collar is wider than that ball once $\rho \geq 6L$. Its scales differ by at most L, and coordinate paths in that ball give the local distance estimate. Finally, at a settled site either $s(x) = 1$ or $\lambda'(x) = p$. In the latter case, a far point satisfies $d'(x,y) \geq |x-y|_\infty/\xi_p > l(x)/\xi_p = s(x)$. □

Lemma 3.137 (Physical readouts on the fixed datum ball)**.** There are fixed $r, C, m > 0$ such that, at every sufficiently regular real datum V_0, the following holds on $\|b\|_\infty < r$. At any output element with base x, define $F_x(b)$ as the curvature or current readout normalized by $\xi'(x)$ rather than $l(x)$ in eq. 3.mcxviii. Then F_x is holomorphic, $|F_x(b)| \leq C$, and

$$|F_x(b_1) - F_x(b_0)| \leq C \max_c e^{-m d'(x,y_c)} |b_1(c) - b_0(c)|. \tag{3.mcxx}$$

The constants cover full current stencils across layer seams. ■

Proof. Use Cor. 3.125 on a smaller fixed raw datum ball. The naturalizer and literal node extension are included, as specified before Lem. 3.127. Apply eq. 3.mlxvii with the cell weight $e^{-md'(x,\cdot)}$. It is an admitted Lipschitz weight. The potential, first difference and multiplier derivatives therefore have the right-hand side of eq. 3.mcxx in their physical local norms.

For the current differentiate the literal constrained Euler identity eq. 3.mxcviii. The terms differentiate the local bond factor, the actual constraint transpose and the multiplier. The transpose retains its physical row density and the full outward endpoint read. Its weighted row sum, and the corresponding sum of its differentiated coefficients, are bounded by the actual carrier estimates. Thus the current derivative has the same bound in grade three. This step uses the equation of the continued critical field; it does not bound second differences of an arbitrary C^1 potential. Plaquette products give the curvature derivative in grade two.

The representative's gauge must also be differentiated. On each free ascent its factors have logarithmic differences bounded by CL^{q-t} times the weighted local difference of the Landau fields, as in eq. 3.mxcix. Each factor's complete read lies within distance C_L of the pillar top, and the site being normalized has distance at most 2 from that top. The geometric sum over $q < t$ is bounded. The top node factor has the same local bound from the site-mean inverse. Real reference factors are unitary; telescoping relative factors preserves the bounds. Consequently the gauge derivative and its inverse have the same weighted bound. Differentiating conjugation of the physical readout adds its already bounded value times this gauge derivative.

Every corner in a full stencil is at most two bare steps from x. Its assigned scale differs from $\xi'(x)$ by at most L. Absorb these fixed grade-two and grade-three factors and the bounded metric displacement in C. This treats seams without omitting any plaquette. At a nonfull boundary bond no full-current claim is made; the regional Euler equation still retains its boundary terms. Integrating the derivative along the segment from b_0 to b_1 proves the display. □

Proposition 3.138 (Ambient tower bound and response)**.** There are fixed $a, K_a, K_T, \delta > 0$ such that the following holds, uniformly in both sequences, their depths and volume. Suppose $\max_P \epsilon_U(P) < a$ and $n(w) < a$. The actual tower configuration and its full current exist. For fixed U they are holomorphic on this open convex set of potentials. At each settled output element with base x,

$$|\mathcal{G}_U(w)| \le K_a(E_U^\delta(x) + E_w^\delta(x)) \le 1. \tag{3.mcxxi}$$

For $n(w_0), n(w_1) < a$,

$$|\mathcal{G}_U(w_1) - \mathcal{G}_U(w_0)| \le K_T E^\delta_{w_1 - w_0}(x). \tag{3.mcxxii}$$

These statements include both erosion rules and their truncations whenever they are contained in the indicated ambient sequence. ■

Proof. Fix a common smaller rate m for Lem. 3.137 and the real local profile proved in Lem. 3.123. These primitive estimates are uniform above their fixed geometric floors. Increase the separation floor so that $4 \log L/\rho \le m/16$, and put $\delta = m/8$. Choose all amplitude ceilings after these choices.

The input norm $\|w\|_-$ of eq. 3.mxciii is at most $n(w)$. The averaged real datum is regular by the same full-read argument as eq. 3.mxcvi. That equation and Prop. 3.124 and Cor. 3.125 therefore define the tower holomorphically on a fixed ball $\|w\|_- < r_w$. Its current is a polynomial in its bond matrices and inverses on a full stencil. The conditions $n(w) < a$ are finitely many continuous linear seminorm bounds, so their intersection is open and convex.

We first need a spatial real estimate. If W is real with $\sup \epsilon_W$ small, the actual mean on a tested mixed plaquette τ of level q has defect bounded by

$$|\partial M_{\mathbf{B}'} W(\tau) - 1| \le C \max_{P \text{ in its complete read}} s(x_P)^{-2} \epsilon_W(P). \tag{3.mcxxiii}$$

Indeed the averaging estimate costs ξ_q^2 times the physical fine curvature, and $\xi_q \le L\xi'(x_P)$ on that read. At a mixed seam the reconstructed lower row is the actual next average by the semigroup

identity, so the same calculation includes the outward endpoint block. At level zero this is the prescribed plaquette itself. The read has d'-diameter C_L. In detail, the local real profile obtained from the proof of Lem. 3.123 is

$$r_{U(V)}(x) \le C \max_{\tau} e^{-md'(x,\tau)} |\partial V(\tau) - 1|. \tag{3.mcxxiv}$$

Here r is the maximum of the grade-two curvature and grade-three full-current norms at x in the tower scales, and τ ranges over the actual ordinary and mixed datum tests. To recall the implication, that proof gives $r(x) \le K v_R(x) + \frac{1}{2} \sup_{d'(x,y)\le R} r(y)$. For $P(x) = \max_\tau e^{-md'(x,\tau)} |\partial V(\tau) - 1|$ choose m small enough that $e^{mR} \le \sqrt{2}$. Maximizing $r(x)/(P(x) + t)$, $t > 0$, gives $S \le \sqrt{2}K + S/\sqrt{2}$, hence $r \le 5KP$ as $t \downarrow 0$. This proves the displayed profile with the stated metric and tested datum, including its local full-current readout. Multiply that profile by $s(x)^2$ and use Lem. 3.136 in eq. 3.mcxxiii. The factor $s(x)^2/s(x_P)^2$ costs at most $L^4 e^{4(\log L) d'(x,x_P)/\rho}$, which the reserved decay absorbs. Hence the real critical field at $M_{\mathbf{B}'}W$ has ambient readout at x bounded by $C E^\delta_W(x)$.

Write $F(w) = \mathcal{G}_U(w; x)$ and $s = s(x)$. For a real g the plaquette product expansion gives

$$\epsilon_{e^{ing}U}(P) \le 2\epsilon_U(P) + C \max_{b \subset P} n_b(g),$$

when $n(g)$ is small. The quadratic remainder is bounded by $Cn(g)^2$ and is absorbed into the displayed linear term. Real global uniqueness matches the critical field just estimated to the real point of the fixed chart. Consequently

$$|F(g)| \le C(E^\delta_U(x) + n(g)), \qquad |F(0)| \le C E^\delta_U(x). \tag{3.mcxxv}$$

On the whole complex ball $\|w\|_- < r_w$, the crude bound from Lem. 3.137 is $|F(w)| \le Cs^2$.

Choose a scalar cutoff on positive bonds, equal to one for $|x_b - x|_\infty \le l(x)$, equal to zero beyond $2l(x)$, and linear in between. Denote it by $\chi(b)$ and extend the resulting form by its reversal convention. Call a bond near if $|x_b - x|_\infty \le 3l(x)$, and write $n_{\mathrm{near}}(v) = \max_{b \text{ near}} n_b(v)$. The discrete product rule and Lem. 3.136 give

$$n(\chi v) \le C_\chi n_{\mathrm{near}}(v), \qquad \|\chi v\|_- \le C_L s^{-1} n(\chi v), \qquad n_{\mathrm{near}}(v) \le e^{C_L \delta} E^\delta_v(x). \tag{3.mcxxvi}$$

For the first inequality the cutoff difference is at most $\eta/l(x)$; adjacent ambient scales differ by at most L. For the second, if $s > 1$ the output is in the tower's top layer and every tower scale is at most $\xi_p = l(x)/s$; if $s = 1$, use $\ell_- \le l$. These arguments also hold when a difference stencil meets the edge of the support.

Apply Lem. 3.128 to χw on the fixed $\|\cdot\|_-$ ball. Its remainder is at most $Cs^2 \|\chi w\|_-^2 / r_w^2 \le Cn(\chi w)^2 / r_w^2$. Together with eq. 3.mcxxv, this proves

$$|F(\chi w)| \le C(E^\delta_U(x) + n_{\mathrm{near}}(w)) \tag{3.mcxxvii}$$

on a smaller fixed amplitude ball. This is the two-power gain for near forcing; it uses no positive travel distance.

For far forcing let $u = w - \widetilde{w}$ vanish on $|x_b - x|_\infty \le l(x)$. Cauchy on the actual averaging chart gives, row by row,

$$|b(w)(c) - b(\widetilde{w})(c)| \le C\xi_q \sup_{b \in \mathsf{P}^q(c)} |u(b)| \le C \max_{b \in \mathsf{P}^q(c)} s(x_b)^{-1} l(x_b) |u(b)|.$$

Put $D = d'(x, x_b)$. A contributing bond is far, so $s \le 1 + D$. The scale ratio and row-read distance give

$$s^2 e^{-md'(x,y_c)} s(x_b)^{-1} \le C(1 + D) e^{-(m - 2\log L/\rho)D} \le C e^{-2\delta D}. \tag{3.mcxxviii}$$

Apply eq. 3.mcxx, remembering that $F = s^2 F_x$, and then use $d' \ge d^\flat$. We obtain

$$|F(w) - F(\widetilde{w})| \le C E^\delta_u(x). \tag{3.mcxxix}$$

The bound is uniform on a common smaller fixed ball. Combining it with eq. 3.mcxxvii, with $\widetilde{w} = \chi w$, proves eq. 3.mcxxi on $n(w) < \bar{a}$ after fixing K_a and reducing $\bar{a}$.

For the Lipschitz assertion put $v = w_1 - w_0$ and split the difference through $w_0 + \chi v$. The far bracket is bounded by eq. 3.mcxxix. Put $n_v = C_\chi n_{\mathrm{near}}(v)$ and $E = E^\delta_U(x) + E^\delta_{w_0}(x)$. If $n_v = 0$, the near bracket vanishes. Otherwise set $R = 1 + E/n_v$. For $|z| \le R$,

$$n(w_0 + z\chi v) \le a + n_v + E \le (3 + 2C_\chi)a.$$

Choose $a < \bar{a}/(4 + 2C_\chi)$. The a priori estimate applies on a neighborhood of this disc and bounds $F(w_0 + z\chi v)$ by $K_a(2E + n_v)$. Schwarz's lemma, after subtracting the value at zero and testing by norm-one linear functionals, bounds the near bracket by

$$\frac{2K_a(2E + n_v)}{1 + E/n_v} \le 4K_a n_v \le CE^\delta_v(x).$$

Together with the far bracket this proves eq. 3.mcxxii. Finally choose $2K_a a \le 1$. No constant counts cells, addresses or truncations. □

Corollary 3.139 (Covariance and reality)**.** For a real gauge u on Z, let $\widetilde{u}$ equal $u(y)$ throughout each pillar with top y. Then the domain and bounds above are unchanged by $(U, w) \mapsto (U^u, \mathrm{Ad}(u)w)$, and

$$\Phi_{U^u}(\mathrm{Ad}(u)w) = \Phi_U(w)^{\widetilde{u}}.$$

The output readout is conjugated by $\widetilde{u}(x)$. For w^* obtained by taking the adjoint at positive bonds,

$$\Phi_U(w^*) = \Phi_U(w)^{\mathfrak{c}}, \qquad \mathfrak{c}(X) = (X^{-1})^*, \qquad |\mathcal{G}_U(w^*)| = |\mathcal{G}_U(w)|.$$

For Hermitian w the tower is its real normalized critical representative. Also $\Phi_1(0) = 1$ and $\mathcal{G}_1(0) = 0$. ■□

Proof. Unitary covariance preserves the input plaquette and derivative norms. The actual means transform by u at their nodes. The prescribed axial normalization extends this node gauge constantly on each pillar, so real uniqueness gives the first identity at real potentials; holomorphy gives it on the complex domain. Plaquettes and the complete current transform by conjugation at the stated base. The anti-holomorphic involution $\mathfrak{c}$ fixes the real group. The map $w \mapsto \mathfrak{c}(\Phi_U(w^*))$ is holomorphic and agrees with $\Phi_U(w)$ on the real slice, which proves the second identity. The current is changed to its adjoint. For $X \in \mathrm{SL}(2, \mathbb{C})$, $X^{-1} - 1 = \mathrm{adj}(X - 1)$; the two singular values of the adjugate are interchanged. Thus $|X^{\mathfrak{c}} - 1| = |X - 1|$ in the operator norm, proving the curvature norm assertion as well. Finally the identity configuration has identity averages, zero action derivative and the prescribed normalization; real uniqueness identifies it with $\Phi_1(0)$. Its current and curvature vanish. □

Corollary 3.140 (Localizations and deeper top metrics)**.** Let the ambient sequence extend from depth i to depth $t \ge i$, with the same members through i. Write d_t for its metric and $y_t(x)$ for the top of the pillar containing x. The bounds of Prop. 3.138 remain valid with $d_t(y_t(x), y_t(x_b))$ in the input envelopes, after multiplying their constants by $e^{4\delta}$.

For a region X made of localization cubes at level zero, let $X_{[q]}$ be its second-rule erosion and put $\Omega'_q = \Omega^\flat_q \sqcap X_{[q]}$, $q \le p$. Assume $M_1 \ge \rho$ and $M \ge L^3 M_1$. Retain the preceding period floor at depth p; a period floor at the deeper level t implies it. Define $X^{\wr p}$ as the union of the level-$(p-1)$ localization cubes whose two-layer enlargements lie in X. The new sequence is separated. Every output element whose base is within $2\xi_p$ of $X^{\wr p}$ is settled, provided its full stencil belongs to Ω'_0. Thus the same weighted response holds for these actual localized towers. ■□

Proof. Extending the ambient sequence only increases assigned scales, so $d_t(x, z) \le d^\flat(x, z)$. Each site is within weighted distance 2 of its own top. The triangle inequality gives

$$d_t(y_t(x), y_t(z)) \le d^\flat(x, z) + 4,$$

which proves the first assertion for both envelopes.

All intersections are taken cube-wise on nested aligned grids. Their next-member gaps are bounded below by the minimum of the two original gaps, so the localized sequence is separated. For the second-rule erosion, every discarded point at stage q is within distance $2M_1\sum_{r=1}^{q}\xi_r < 3M_1\xi_p$ of X^c. This is the rejected-cube induction in Lem. 3.126, which only requires that the initial region be a union of the aligned smaller cubes. On the other hand, $\operatorname{dist}_\infty(X^{\wr p}, X^c) \geq 2M\xi_{p-1}$. A point within $2\xi_p$ of that inset therefore has distance at least $(2M/L-2)\xi_p > 3M_1\xi_p$ from X^c. It lies in every $X_{[q]}$ through p. At such a bare site, membership in Ω'_q is exactly membership in $\Omega^\flat_q$, so the tower index is the ambient index truncated at p. This is precisely the settled condition. If the coarse partition is absent the inset is empty and the assertion about its neighborhood is vacuous. The assumption on the full stencil retains all physical current terms at the localized boundary. □

Corollary 3.141 (Multiplicative shifts in the ambient norm)**.** Let (U, w) satisfy the hypotheses of Prop. 3.138, and put $\mathbf{U} = e^{i\eta w}U$. For a complex shift A, set

$$u_b = \max\{l(x_b)|A(b)|,\ l(x_b)^2|\nabla_{\mathbf{U}}A|_Z(b)\}, \qquad w \boxplus A = (i\eta)^{-1}\log(e^{i\eta A}e^{i\eta w}).$$

Let u_b^+ be the maximum over b and its forward translates that occur in a difference stencil in Z. After decreasing the fixed ceiling a, the conditions $u_b \leq (256L^2)^{-1}$ and $n_b(w) + 2u_b^+ < a$ imply

$$|\mathcal{G}_U(w \boxplus A) - \mathcal{G}_U(w)| \leq 2e^{\delta}K_T \max_b e^{-\delta d^\flat(x,x_b)}u_b \tag{3.mcxxx}$$

at every settled output. The shifted tower exists on this whole domain and has the literal product $e^{i\eta A}\mathbf{U}$ as the input to its actual average. ■□

Proof. Take $a \leq a_* = (64L^2)^{-1}$. The product logarithm lies in the fixed chart since $\eta|w| \leq a_*$ and $\eta|A| \leq a_*/4$. Write $\log(e^Xe^Z) = X + Z + \ell(X, Z)$. The absolutely convergent logarithm and exponential series on $|X|, |Z| \leq 1/16$ give the derivative bound $8(|X| + |Z|)$ for the remainder. As $\ell(0, Z) = 0$, Schwarz in X also gives $|\ell(X, Z) - \ell(X, Z')| \leq 16|X||Z - Z'|$. Apply these estimates to neighboring bonds after transporting them to the same base by U. The product rule gives

$$l(b)|(w \boxplus A - w)(b)| \leq (1 + 10a_*)u_b,$$

and the first-difference bound has coefficient at most

$$(1 + 10a_*)(1 + 2.1a_*L) + 16a_* < 2$$

times $\max(u_b, u_{b^+})$. Here the term $2.1a_*L$ comes from replacing $\nabla_U A$ by $\nabla_{\mathbf{U}}A$: $|1 - \mathrm{Ad}(e^{i\eta w})| \leq 2.1\eta|w|$, and neighboring scales differ by at most L. Thus $n_b(w \boxplus A - w) \leq 2u_b^+$ and the stated margin puts $w \boxplus A$ in the same domain as w. The product identity holds at positive bonds by exponentiating the logarithm and at reverse bonds by inversion. Apply eq. 3.mcxxii. Adjacent bare sites have ambient distance at most one, so replacing u_b^+ by u_b in the weighted maximum costs at most e^{δ}. This proves the bound and the actual-input assertion. □

3.37. **Changing the localization of a tower.** The response in Prop. 3.138 keeps the determining sequence fixed. We next compare the two constrained problems obtained when a localization is cut and its tower is rebuilt. All determining sets in this subsection have their inward rows removed. A common row means a common geometric row with its complete averaging read; a common free pillar includes its prescribed normalization paths.

Use the notation of § 3.36. Let $\widehat{\mathbf{B}}$ be a finer localization of $\mathbf{B}'$, of the same depth p, inside the same ambient sequence of depth i. Its first member is $\widehat{Z} \subset Z$. Finer means that its members are contained in the old members, so that the exact restriction identity eq. 3.cccxciii applies. Denote their weighted metrics by d' and $\widehat{d}$. Both dominate $d^\flat$. An old interior or outward row cannot become inward in the finer sequence: an old layer endpoint stays outside the next old member and hence outside the next finer member. Thus removing all finer inward rows does not remove an old retained row needed by the restriction identity. Write $\mathcal{C}$ for the new determining rows together with rows whose complete reads have changed. Enlarge $\mathcal{C}$ once to include the complete preceding

blocks of its outward rows and the old pillars containing its endpoints; call the resulting carrier $\mathcal{C}^+$. It is a set of reads, not a new set of constraints.

For $W = e^{i\eta w}U$, where U is real, set

$$A(z) = \max\{\epsilon_U(P), n_b(w) : x_P = z \text{ or } x_b = z\}, \qquad A_\delta(y) = \max_z e^{-\delta d^\flat(y,z)} A(z). \tag{3.mcxxxi}$$

Empty maxima are zero. Complete stencils can instead be based at any of their corners, at a fixed change in the constant. All amplitudes below lie below one fixed smaller ceiling than the ceilings of Cor. 3.125 and Prop. 3.138.

Lemma 3.142 (Alignment of the induced and literal data)**.** There are fixed $C, r, \delta > 0$ with the following property. The literal finer datum of W and the datum induced by the old critical continuation can be put in one physical datum chart on $\widehat{\mathbf{B}}$, holomorphically in w. In this chart their logarithms $b_0(w), b_1(w)$ satisfy $\|b_\nu(w)\|_\infty < r$, and

$$b_1(c) - b_0(c) = 0 \quad (c \notin \mathcal{C}), \qquad |b_1(c) - b_0(c)| \le C A_\delta(y_c) \quad (c \in \mathcal{C}). \tag{3.mcxxxii}$$

The segment joining these logarithms stays in the chart. At an unchanged free pillar, the normalized finer continuations at its two endpoints are respectively the new and the old tower in exactly the same node frame. ■

Proof. First fix the gauges and the real centre of the chart. On every old pillar of height j put the ascent gauge equal to one at its top. If $W_q = \mathcal{M}^q W$ and $T_q(z, x; W_q)$ is the actual level-q mean contour from the parent centre z, its descent is

$$g_j = 1, \qquad g_q(x) = g_{q+1}(z) T_q(z, x; W_q), \quad q < j. \tag{3.mcxxxiii}$$

This is the contour convention of eq. 3.cccxvii; reverse orientations use inverses. The contour from a centre to itself is one, so the descent extends the gauge already assigned at coarser sites. Covariance of the actual mean makes the internal mean contours one. At layer tops set $g = 1$. The pillar partition makes these assignments compatible. Thus every retained old datum is unchanged, including an outward row and its lower endpoint block. The old critical field is already in the canonical old normalization, so its own descent is the identity on its old pillars. We do not apply the raw input's gauge to that critical field. The two separately normalized fields still have the same old datum.

For completeness this construction is uniform on the complex ball. Retain each real contour as a unitary factor. The relative level-q factor on a pillar of height j has logarithm bounded by CaL^{q-j} when $n(w) < a$. The local mean estimate and its site correction give this bound exactly as in eq. 3.mxcix. Moving the real factors to the right and telescoping the relative factors gives

$$\|g(w)g(0)^{-1} - 1\| \le Ca \sum_{q<j} L^{q-j} \exp\left(Ca \sum_{q<j} L^{q-j} \right), \qquad \|g(w)^{\pm 1}\| \le e^{Ca/(L-1)}.$$

The real factors have norm one. All means and inverses are holomorphic on their fixed charts, so this also proves the holomorphy and the uniform condition number of the descent. There is no factor raised to the number of levels.

We spell out the comparison of new rows. At a real input the two fields just normalized have the same old datum. In an old pillar of height j, averaging a curvature bound at level $q < j$ gives $C\epsilon L^{2(q-j)}$. The finite contour reconstruction eq. 3.cccxvii–eq. 3.cccxx therefore compares both fields to the same face lift of their old datum. For the complex version use relative products, rather than unitary invariance. If E_q is the normalized bond discrepancy at the current level, its exact factorization has the form

$$E_q = (\widehat{W}_q \widehat{W}_{q+1}^{-1})(\widehat{W}_{q+1} L_{q+1}^{-1}).$$

Here L_{q+1} denotes the face lift in the common old frame. The two level-$(q+1)$ quantities in this identity mean their actual face lifts evaluated at the same level-q bond as $\widehat{W}_q$. Thus all three factors

belong to one matrix fibre. The one-step lift consistency proved with eq. 3.cccxcvi gives this exact product. For matrices near one, $|AB-1| \le |A-1| + (1+|A-1|)|B-1|$. Consequently

$$e_q \le C\epsilon_q + (1+C\epsilon_q)e_{q+1}, \quad \epsilon_q \le C\epsilon L^{2(q-j)}, \qquad \prod_{q<j}(1+C\epsilon_q) \le \exp\left(\frac{C\epsilon}{L^2-1}\right). \tag{3.mcxxxiv}$$

The endpoint discrepancy at an old retained row is zero. At an inward link, use the outward link one level higher and its complete preceding block, as in the inward calculation following eq. 3.cccxx. This adds a fixed number of lower internal links, not another constraint. Summing eq. 3.mcxxxiv proves a uniform raw discrepancy.

Here the local ϵ can be replaced by $CA_\delta(y_c)$. For the real critical field this follows from eq. 3.mcxxiv and the complete-read datum estimate eq. 3.mcxxiii. For its complex variation, differentiate the physical datum chart from the real input to w. The raw variation of a level-q input row is bounded by $C\xi_q|w|$ on its complete read, hence by $Cn(w)$. The weighted potential and first-difference response in eq. 3.mlxvii, and the differentiated literal pillar factors from the proof of Lem. 3.137, give the same weighted estimate for the continued field. A plaquette in an old pillar of height j then has defect bounded by $CA_\delta(y_c)L^{2(q-j)}$ at level q. Indeed its physical curvature is bounded in scale ξ_j; averaging to level q multiplies it by ξ_q^2. The complete reconstruction reads remain within bounded d'-distance of that pillar top. The ambient metric is smaller, and the convolution of the two weighted suprema uses a smaller fixed δ. This proves the local form of the estimate in eq. 3.mcxxxiv. The input field obeys the same curvature bound by the plaquette product formula and the C^1 norm in eq. 3.mcxvii. No second difference of the input is used.

Take as finer real reference the regular critical orbit at the finer datum of $U^{g(0)}$. Its existence follows from Prop. 3.124. At $w=0$ the preceding descent places the datum induced by the old real critical field within $C\sup A$ of this reference datum. The variation of either endpoint datum on the whole complex ball is Ca: this follows for the input from the mean derivative and the bound on g, and for the old field from its physical chart and the fact that a new-row scale does not exceed the old scale on its complete read, up to a single factor L. Choose $C(\sup\epsilon_U + a) < r/4$. Both endpoints then lie in the concentric half-ball of one finer physical chart. Their logarithms and the segment joining them lie in that chart. The logarithm has bounded derivative there, so the raw discrepancy just proved gives eq. 3.mcxxxii.

Every common old row is fixed exactly by the gauge at its endpoints, and the two fields have identical old data. Thus their finer data, and their raw logarithms relative to the same reference, agree on common rows. Passing to the reduced datum does not produce a chain of new supports: eq. 3.cccxiv says that its off-diagonal part reads interior columns into outward rows and that $TD^{-1}T = 0$. Hence differentiation or subtraction enlarges the changed support by at most one complete preceding block.

It remains to identify the endpoints as fields, rather than merely as data. For real w, restriction of the old critical field is critical at its induced finer datum by eq. 3.cccxciii. Its regularity improves in the finer scales. Global regular-fibre uniqueness from Lem. 3.122 identifies it with the finer physical chart at that datum. These identities extend to the whole complex ball by the identity theorem: both sides, their constraints, and all normalization factors are holomorphic there, and the real ball is a uniqueness set. Only the transformed raw data are admitted to this common physical chart. No invariance of a hereditary core under complex gauge transformations is asserted or required.

Finally the gauge eq. 3.mcxxxiii fixes every old top. Gauge covariance of a normalized finer representative uses the pillar-constant extension of its values at the new tops. On a common free pillar its top is an old top, so this extension is exactly one. Normalizing the old restriction on the finer sequence also acts identically on such a pillar: its mean contours there already have the prescribed old normalization. These statements hold as matrix identities also at complex data. In

particular the readout frames agree; a bound on the condition number alone is not used to identify their magnitudes. □

Proposition 3.143 (Comparison after a geometric cut)**.** Suppose the complete read at x lies in unchanged free pillars and is settled for both towers. Work in the units of the earlier ambient level i, so that $l \le 1$. Suppose every changed complete datum carrier is at physical distance at least $D \ge 2$ from x. Let $\mathcal{R}(z) > 0$ be an allowance profile satisfying

$$A(z) \le C_0 \mathcal{R}(z), \qquad \mathcal{R}(z) \le C_1 \mathcal{R}(x) e^{\kappa d^\flat(x,z)}, \quad \kappa < \delta/4. \tag{3.mcxxxv}$$

Then the difference of the two matrix readouts in eq. 3.mcxviii, in their prescribed common frame, is at most

$$C C_0 C_1 e^{-c\delta D} \mathcal{R}(x). \tag{3.mcxxxvi}$$

The assertion includes full current stencils across a common layer seam. All constants are independent of depths and volume. ■

Proof. Apply Lem. 3.137 on the finer chart of Lem. 3.142. Its proof includes the reduced datum, the literal node correction and the full physical Euler current. Thus it gives the native estimate

$$|\widehat{F}_x - F_x| \le C \max_{c \in \mathcal{C}^+} e^{-m\widehat{d}(x,y_c)} A_\delta(y_c). \tag{3.mcxxxvii}$$

All source measures are included in its weighted row sum. There is no cardinality factor for the collar. The support enlargement described above is why the distance hypothesis uses the complete carrier.

The ambient readout is the native one times $s(x)^2$ for both curvature and current. At a settled read either $s = 1$ or $\xi'(x) = \xi_p$. In the latter case $\widehat{d}(x, y_c) \ge |x - y_c|_\infty / \xi_p \ge D/\xi_p$ and $s = l/\xi_p \le 1/\xi_p$, so $s \le 1 + \widehat{d}(x, y_c)$. A fixed part of the exponential in eq. 3.mcxxxvii pays s^2. This is the extra scale argument needed for a changed geometry; the current retains the weight $l^2 \xi'$.

For any c, z, the triangle inequality and $\widehat{d} \ge d^\flat$ give

$$d^\flat(x, z) \le \widehat{d}(x, y_c) + d^\flat(y_c, z).$$

Insert eq. 3.mcxxxv in the definition of A_δ. Reserve one part of each exponential for this triangle inequality and another part for the factor s^2. The remaining decay is at most $\exp(-c\delta \widehat{d}(x, y_c)) \le \exp(-c\delta D)$, since $\xi_p \le 1$ in the present units. This proves eq. 3.mcxxxvi. The frame identities in Lem. 3.142 make it a matrix difference estimate. The reverse triangle inequality therefore gives the same estimate for the change of magnitude. The full-stencil convention and the physical Euler derivative in Lem. 3.137 cover a common seam without discarding any incident plaquette. □

The distance hypothesis in Prop. 3.143 holds for the geometric restriction of an earlier address. Here $p \le r \le i$, its nominal layer is at most i, and the read retains its r-window. The accumulated erosion reach through level q is at most $C_L M_1 \xi_q$, by the geometric sum in the proof of Lem. 3.126. Therefore a new row at level $q \le p$ is within $C_L M_1 \xi_p$ of the deleted set. Its complete backward read adds $C_L \xi_p$. An old parent pillar adds at most $C_L \xi_i = C_L$ in physical distance, even when its new endpoint has smaller assigned scale. Thus increasing the fixed cut halo from $3M_1$ to $C_{\mathrm{cut}} M_1$ puts every changed complete carrier at distance at least D when the read starts at distance $D + C_{\mathrm{cut}} M_1$ from the deleted set. There is no additional spacing assumption on discarded components. Indeed every old erosion test and complete read has a connected backward carrier contained in Z when it is retained. Follow such a carrier from the retained component toward a point removed by the component selection. If it stays in $Z \cap R$, it connects the two components, contrary to their definition. Its first exit must therefore meet $Z \setminus R$. A contact with Z^c was already an old boundary and cannot cause a new membership change. The same geometric bound on the backward carrier therefore locates the changed row near the actual cut, also in this case. The constant C_{cut} is chosen before the localization floor M is increased. Equivalently retain the original hypothesis $D + 3M_1$

and increase K_{cl} in $D \geq K_{\mathrm{cl}}M$ so that $(C_{\mathrm{cut}}-3)_+M_1 \leq D/2$. Then every changed complete carrier has distance at least $D/2$, which changes only the fixed decay rate in eq. 3.mcxxxvi. This argument uses physical distance and $l \leq 1$. It does not assert that an arbitrary Euclidean collar has bounded width in the ambient weighted metric.

3.38. **A selected nonlinear extension at an independent current.** We specify a nonlinear auxiliary action whose Hessian is the canonical second precision. Its small constrained solution agrees with the physical critical germ at physical inputs. Away from those inputs it is a selected independent-current extension, not a claim of Wilson stationarity.

The distinction between two output fields is essential. The auxiliary potential has first derivative H_1 in the reduced datum. Its finite gauge completion has first derivative SH_1. These agree at a physical pair, where the second lift is horizontal, and can differ off current. Literal outward data also retain their actual datum differential.

3.38.1. *The fixed chart and the strong spaces.* Fix $0 < \alpha < 1$, and a given real regular reference U_* on the actual determining geometry, with strict room in its curvature and physical-current ceilings. The reference need not be critical. Its local real Coulomb potentials have the scaled $C^{1,\alpha}$ bounds supplied by the current-regular construction. All choices of local frames and node extensions in this subsection are made in this fixed reference chart.

Let

$$U = e^{i\eta E}U_*, \qquad \|E\|_{\mathrm{str},\alpha;U_*} < \varepsilon.$$

This is a weighted $C^{1,\alpha}$ tube, stronger than the C^1 tube used for energy inverses. Let $\mathcal{A}_\alpha$ be the fine strong space in eq. 3.dccclxxxvii, measured in U_*, and let $\mathcal{Y}_{2,\alpha}$ be the site gauge space in eq. 3.mxxiv. Its source space $\mathcal{C}_{\alpha,2}$ is eq. 3.mxxiii, including comparisons across neighbouring pillar faces on complete boxes. Use the amplitude norms

$$\|f\|_{\infty,3} = \sup_b \mathsf{L}(b)^3|f(b)|, \quad \|h\|_{\infty,4} = \sup_x \xi_x^4|h(x)|, \quad \|b\|_{\mathcal{B}} = \sup_c \xi_c|b(c)|, \quad \|\nu\|_{\mathcal{W}} = \sup_c \xi_c^3|\nu(c)|. \tag{3.mcxxxviii}$$

The site scale and the field-row scale retain their different assigned levels at outward endpoints. The finite-p force norm is $\mathcal{F}_p$ of § 3.25.

The independent fine current has a full amplitude $\|J\|_{\infty,3} < \gamma_*$. This is convenient for the updated-current assertion below. The actual Wilson current j_U at a complex U is not assumed to have this bound. Its possibly large value will be subtracted only as an exact linear centering. All transposes and scalar pairings in an analytic formula are physical bilinear ones.

For this fixed U, retain its actual D, q, Q, G_s, R and put

$$\Lambda = G_sRD^\sharp, \qquad S = 1 - D\Lambda. \tag{3.mcxxxix}$$

Define G, H, ω, G_1, H_1 in the order of § 3.26, with $\omega = H^\sharp J$. In particular the lift in ω is the first lift. Their completed operators are uniformly admitted on a smaller tube by the energy and strong inverse results already proved.

3.38.2. *Completed restoration and the two adjoint bounds.*

Lemma 3.144 (Strong restoration on the stronger tube)**.** After shrinking the fixed $C^{1,\alpha}$ tube,

$$\|\Lambda A\|_{\mathcal{Y}_{2,\alpha}} \leq C_\alpha \|A\|_{\mathcal{A}_\alpha}. \tag{3.mcxl}$$

This map is holomorphic in the background on that tube. It is an estimate for the completed operator. It does not assert a $C^{2,\alpha}$ bound for every individual inverse-walk coefficient. ∎

Proof. The first physical divergence maps $\mathcal{A}_\alpha$ into $\mathcal{C}_{\alpha,2}$. The site projection R preserves that source space. Indeed its nonidentity part is $\widehat{F}\widehat{M}^{-1}\widehat{F}^\sharp$. The completed site-column point and first-difference bounds, the normalized coarse inverse and their exponential sums control its scaled C^α norm. All normalizations are those of eq. 3.cmxcv.

For $\lambda = G_s R D^\sharp A$, the exact identities $qG_sR = 0$ and $\Delta_U G_s R = R$ give

$$q\lambda = 0, \qquad \Delta_U \lambda = RD^\sharp A.$$

The zero-average energy estimate supplies its weighted mass and first differences. The local scalar bootstrap supplies the $C^{1,\alpha}$ bound needed on the right of the interior Schauder estimate. On a fixed complete nonbare box the coefficients of Δ_U have their C^α bounds because the potential is $C^{1,\alpha}$. At a true boundary the bare values of λ are exactly zero and the remaining atomic stencils have their scaled bounds. The proof of eq. 3.mxxvi therefore gives eq. 3.mcxl.

For completeness, at complex U compare with the real reference Laplacian. Its difference is a first-order term with C^α coefficients and a zeroth-order term with C^α coefficients, bounded by the $C^{1,\alpha}$ tube. Apply the real Schauder estimate to this equation, using the already controlled $C^{1,\alpha}$ solution norm. No $C^{2,\alpha}$ conclusion from merely C^1 coefficients is used. The energy inverse is holomorphic, and the uniform stronger bound on the smaller tube gives its holomorphy in these displayed Banach norms. □

Lemma 3.145 (Adjoints in their actual force classes)**.** For site and field forces respectively,

$$\begin{aligned} \|\Lambda^\sharp h\|_{\infty,3} &\le C\|h\|_{\infty,4}, \\ \mathcal{F}_p(\Lambda^\sharp D^\sharp f) &\le C_p\|f\|_{\infty,3}, \qquad 4 < p < \infty. \end{aligned} \tag{3.mcxli}$$

The completed operators in these assertions are holomorphic on a common smaller physical tube. There is no endpoint $p = \infty$ in the second line. ■

Proof. The balanced site family $G_s : Y^\flat \to Y$ gives bounded local Y norm for $u = G_s h$: a site force of amplitude four has uniformly bounded local $Y^\flat$ norm. Its equation is

$$\Delta_U u = h - q^\sharp a_s q u.$$

The average qu is bounded by its cell L^2 norm, and $q^\sharp$ extends the transported density. Thus the rescaled forcing is bounded. The scalar L^2-to-L^3-to-L^8 bootstrap gives $\xi_y^2|u| + \xi_y^3|Du| \le C\|h\|_{\infty,4}$. It uses no derivative of h. Subtract $Pu = \widehat{F}\widehat{M}^{-1}\widehat{F}^\sharp u$. Its normalized coarse coefficients are bounded by the column sum, then by the coarse ℓ^∞ inverse. The completed F columns and their first differences give that same point bound for Pu, DPu. Since $\Lambda^\sharp = DRG_s$, this proves the first line.

For the second line use the exact identity

$$\Lambda^\sharp D^\sharp f = f - S^\sharp f.$$

The finite-p force-restoration estimate of § 3.25 applies to this variational divergence source. It gives the stated bound without a pointwise differentiation of f. Its proof on the complex physical tube uses the same energy inverse and local finite-p bootstrap. The absolute estimates are uniform on a smaller tube; the analytic inverse formulas give the claimed holomorphy. □

3.38.3. *The finite gauge chain as a strong analytic map.* For $A \in \mathcal{A}_\alpha$, set $\lambda = \Lambda A$ and define

$$\Pi_U(A)_b = \frac{1}{i\eta} \log\{e^{-i\lambda(b_-)} e^{i\eta A_b} e^{i\,\mathrm{Ad}(U_b)\lambda(b_+)}\}, \qquad \Xi_U(A) = \Pi_U(A) - SA. \tag{3.mcxlii}$$

This is the finite chain already selected for the canonical current convention. Its associated fine gauge is $e^{-i\lambda}$. The exact equality

$$\mathrm{Ad}(U_b)\lambda(b_+) = \lambda(b_-) - \eta D\lambda(b)$$

makes division by η uniform: at $\eta = 0$ the three factors multiply to one. Thus Π_U is an analytic local function of $A, \lambda, D\lambda$, with

$$\Pi_U'(0) = S, \quad \|\Pi_U(A)\|_{\mathcal{A}_\alpha} \le C_\alpha \|A\|_{\mathcal{A}_\alpha}, \quad \|\Xi_U(A)\|_{\mathcal{A}_\alpha} \le C_\alpha \|A\|_{\mathcal{A}_\alpha}^2. \tag{3.mcxliii}$$

Covariant product rules use at most two site differences of λ. They prove these bounds also for the gradient Hölder seminorm. If $RD^\sharp A = 0$, then $\lambda = 0$ and $\Pi_U(A) = A$ exactly. No claim that $\Pi_U(A)$ lies in that slice for a general A is made.

The physical adjoint of the derivative requires more than an abstract strong-space norm. Pair a local function of $A, \lambda, D\lambda$ with a bounded force f. Differentiating its three arguments gives the exact form

$$f_0 + \Lambda^\sharp f_\lambda + \Lambda^\sharp D^\sharp f_d. \tag{3.mcxliv}$$

Here f_0, f_d are field forces of amplitude three and f_λ is a site force of amplitude four. Endpoint injections cost only the fixed number of incident bonds. The two bounds in eq. 3.mcxli therefore control this expression in finite $\mathcal{F}_p$, without differentiating f.

In particular $\langle J, \Xi_U''(0)[u,v]\rangle = \langle u, B_U[J]v\rangle$ by the exact finite-chain calculation. Subtracting that quadratic jet in eq. 3.mcxliv gives

$$\mathcal{F}_p\{\nabla\langle J, \Xi_U(A)\rangle - B_U[J]A\} \le C_{p,\alpha}\|J\|_{\infty,3}\|A\|^2_{\mathcal{A}_\alpha}. \tag{3.mcxlv}$$

Indeed the remaining three local coefficients are quadratic in the scaled variables $\xi A, \lambda, \xi D\lambda$. Their amplitude grades are exactly those just listed. This proves the residual in a force norm; an arbitrary Banach adjoint is not presumed to preserve pointwise bounds.

3.38.4. *The centered Wilson residual at a complex base.* Put $F_U(A) = A_{\Omega_0}(e^{i\eta A}U)$, $j_U = F_U'(0)$, and $H_U = F_U''(0)$. The centering in the next lemma is essential even when U belongs to the complex strong tube.

Lemma 3.146 (Uniform residual after linear subtraction)**.** On a fixed strong ball in the displayed tube,

$$\|F_U'(A) - j_U - H_U A\|_{\infty,3} \le C_\alpha \|A\|^2_{\mathcal{A}_\alpha}. \tag{3.mcxlvi}$$

The difference is uniformly holomorphic in U, A. Its Lipschitz constant on a radius-r strong ball is at most $C_\alpha r$. No amplitude bound for j_U at that complex base is used. ■

Proof. On a nonbare box rescale its physical length to one, and write $h = \eta/\xi$. In a fixed real reference frame the complex base has potential a_0 with bounded $C^{1,\alpha}$ norm. The relative logarithm is

$$P_h(A) = \frac{1}{ih}\log(e^{ihA}e^{iha_0}).$$

Let $P_0 = D_A P_h(0)$ and $E_h(A) = P_h(A) - a_0 - P_0 A$. The divided finite matrix expansion gives

$$\|E_h(A)\|_\infty + \|DE_h(A)\|_\infty \le Chr^2, \qquad \|D^2E_h(A)\|_\infty \le Cr^2,$$

and

$$\|D_A P_h(A) - P_0\| \le Chr, \qquad \|D_A P_h(A) - P_0 - D_A^2 P_h(0)[A]\| \le Ch^2r^2.$$

The second spatial difference contains hAD^2A and $h(DA)^2$; when a coefficient is differentiated in a_0, it supplies an additional h. The elementary bounds $\|D^2A\|_\infty \le Ch^{-1}\|DA\|_\infty$ and $\|D^2a_0\|_\infty \le Ch^{-1}\|Da_0\|_\infty$ therefore remove every apparent mesh loss.

In flat logarithmic coordinates the exact Wilson gradient is $\mathrm{d}^\sharp\mathrm{d}\,a + N_h(a)$, with the uniform local analytic remainder proved in the actual Wilson calculation. The relative gradient is $D_A P_h(A)^\sharp\{\mathrm{d}^\sharp\mathrm{d}P_h(A) + N_h(P_h(A))\}$. Subtract its constant and linear terms before estimating. The term with $\mathrm{d}^\sharp\mathrm{d}E_h$ is bounded by Cr^2. The first derivative difference $O(hr)$ times $\mathrm{d}^\sharp\mathrm{d}(P_0A)$ is bounded by $Chr\,h^{-1}r$. The remaining quadratic derivative coefficient $O(h^2r^2)$ multiplying the rough base $\mathrm{d}^\sharp\mathrm{d}a_0$ is bounded by $Ch^2r^2h^{-1}\|Da_0\|_\infty$. All terms containing N_h obey its uniform Banach derivative bounds. This is the same relative-BCH calculation as in Lem. 3.118; it uses the complex base's first differences, rather than a bound for its second-difference current.

At a bare cell the rescaled mesh is one and the finite incident plaquette calculation gives the same analytic Taylor estimate. Rescaling the gradient back multiplies it by ξ^{-3}. All estimates hold

on a larger complex ball. Their uniform holomorphy and the double zero give the stated Lipschitz bound by Cauchy. □

3.38.5. *An explicit auxiliary action with the second precision.* Write $\mathfrak{q}_U(A)$ for the actual re-centered straightened per-length field constraint of PNC; this notation distinguishes it from the site average q. Put

$$N_q(x) = \mathfrak{q}_U(x) - Qx, \qquad r_U(A) = \mathfrak{q}_U(\Pi_U(A)). \tag{3.mcxlvii}$$

Then $r_U(0) = 0$ and $r'_U(0) = Q$, because $QS = Q$. The latter equality uses the actual extended outward endpoint intertwining.

Define the following scalar function on the fine strong ball:

$$\begin{aligned}\mathcal{L}_{U,J}(A) = F_U(A) - F_U(0) - \langle j_U, A\rangle \\ - \langle J, \Xi_U(A)\rangle - \langle \omega, N_q(\Pi_U(A))\rangle \\ + \tfrac{1}{2}\langle RD^\sharp A, RD^\sharp A\rangle_{\mathrm{site}} + \tfrac{1}{2}\langle r_U(A), a_f r_U(A)\rangle_{\mathrm{rows}}.\end{aligned} \tag{3.mcxlviii}$$

Every pairing is bilinear, including the gauge penalty. Thus this is a holomorphic scalar function at complex inputs. The multiplier $\omega = H^\sharp J$ is fixed when differentiating in A.

Lemma 3.147 (The exact auxiliary Hessian)**.** The action satisfies

$$\mathcal{L}'_{U,J}(0) = 0, \qquad \mathcal{L}''_{U,J}(0) = G_1^{-1}. \tag{3.mcxlix}$$

■

Proof. The first derivative of the nonlinear current term is zero. Its second derivative is $-B_U[J]$, by the finite-chain identity. Since $N_q(0) = DN_q(0) = 0$, the constraint term contributes $-S^\sharp \Delta_U^{(2)}[\omega]S$. The projection identities $R^\sharp = R$, $R^2 = R$ make the penalty contribution $DRD^\sharp$, also on the complex bilinear continuation. Finally $r'_U(0) = Q$ makes the row-mass contribution $Q^\sharp a_f Q$. Together with H_U, these are exactly the terms in the canonical G_1^{-1}. □

This formula selects a nonlinear off-current convention. Equality of its second jet with the canonical precision does not identify it with a separately prescribed nonlinear core map.

Lemma 3.148 (Constraint and composed-adjoint residuals)**.** For $\|A\|_{\mathcal{A}_\alpha} \le r$, the actual constraint obeys

$$\begin{aligned}\|r_U(A) - QA\|_{\mathcal{B}} &\le Cr^2, \\ \mathcal{F}_p\{(r'_U(A) - Q)^\sharp \nu\} &\le C_{p,\alpha} r \|\nu\|_{\mathcal{W}}, \\ \mathcal{F}_p\{r'_U(A)^\sharp a_f r_U(A) - Q^\sharp a_f Q A\} &\le C_{p,\alpha} r^2, \\ \mathcal{F}_p\{\nabla\langle \omega, N_q(\Pi_U(A))\rangle - S^\sharp \Delta_U^{(2)}[\omega] S A\} &\le C_{p,\alpha}\|\omega\|_{\mathcal{W}} r^2.\end{aligned} \tag{3.mcl}$$

These are estimates for finite $4 < p < \infty$. ■

Proof. The actual fixed-leg two-leg estimate and its analytic remainder, in eq. 3.mxxxvii and eq. 3.mxxxviii, give

$$\|N_q(x)\|_{\mathcal{B}} \le C\|x\|^2_{\mathcal{A}_\alpha}, \qquad \|(D\mathfrak{q}_U(x) - Q)^\sharp \nu\|_{\infty,3} \le C\|x\|_{\mathcal{A}_\alpha}\|\nu\|_{\mathcal{W}}.$$

After subtracting its linear term, $DN_q(x)^\sharp \omega$ has a force remainder bounded by $C\|\omega\|_{\mathcal{W}}\|x\|^2_{\mathcal{A}_\alpha}$. These are actual column-density estimates on the common admitted row ball, also when the base is in the smaller complex tube. Physical row transposition cancels the fine density $(\eta/\xi_c)^4$; the recentering and complete outward carriers are retained.

The value estimate follows by $\Pi_U(A) = SA + O(A^2)$ and $QS = Q$. For the adjoints use

$$r'_U(A)^\sharp = \Pi'_U(A)^\sharp D\mathfrak{q}_U(\Pi_U(A))^\sharp.$$

The operator $S^\sharp$ is bounded only in the finite force class needed here. The difference $\Pi'_U(A)^\sharp - S^\sharp$ has bound $C_{p,\alpha} r$ from a bounded amplitude-three force into $\mathcal{F}_p$. This is eq. 3.mcxliv, before subtracting its quadratic jet, together with Lem. 3.145. In particular this argument never differentiates the fine force supplied to that adjoint.

The identity $S^\sharp Q^\sharp = Q^\sharp$ cancels the constant part in the multiplier residual. The remaining two factors give its second line. For the row mass, use $a_f \asymp \Xi_\Gamma^{-2}$, so it converts datum amplitude one into multiplier amplitude three, and insert the first two lines. For the last line put $x = \Pi_U(A)$ in the subtracted DN_q estimate and apply the same adjoint formula. Terms with $\Xi_U(A)$ and $\Pi'_U(A) - S$ are quadratic after their displayed leading term is removed. □

Combining the preceding lemmas, set

$$N_{\mathcal{L}}(A) = \mathcal{L}'_{U,J}(A) - G_1^{-1} A.$$

For fixed small current ceiling they give

$$\mathcal{F}_p(N_{\mathcal{L}}(A)) \le C_{p,\alpha} \|A\|^2_{\mathcal{A}_\alpha}. \tag{3.mcli}$$

All maps in this subtracted expression are uniformly holomorphic on a larger strong ball. Their double zeros consequently give Lipschitz constant $C_{p,\alpha} r$ there.

3.38.6. *The quantitative auxiliary germ.* Let $b_U(B)$ be the explicit actual outward datum in eq. 3.mxxxiii, relative to the present base U. Its finite complete carriers and analytic bounds hold on a smaller common tube. In particular $b_U(0) = 0$ and $\|b_U(B)\|_{\mathcal{B}} \le C_L \|B\|_{\mathcal{B}}$. Choose a finite $p > 4/(1-\alpha)$.

Proposition 3.149 (A selected independent-current critical germ)**.** There are fixed positive radii $\varepsilon, \gamma_*, r, \rho$ such that the following holds on this fixed determining geometry. For U in the smaller displayed $C^{1,\alpha}$ tube, $\|J\|_{\infty,3} < \gamma_*$, and $\|b\|_{\mathcal{B}} < \rho$, the system

$$\mathcal{L}'_{U,J}(A) - r'_U(A)^\sharp \nu = 0, \qquad r_U(A) = b \tag{3.mclii}$$

has a unique solution in a fixed joint strong ball. It is holomorphic in U, J, b, real at real data, and

$$\|A\|_{\mathcal{A}_\alpha} + \|\nu\|_{\mathcal{W}} \le C_{p,\alpha} \|b\|_{\mathcal{B}}. \tag{3.mcliii}$$

The radii and constants are independent of depth, compatible volume and admitted proper-region shape. At $b = 0$, $A = \nu = 0$ for every admitted pair, and the exact first derivatives are

$$D_b A(0) = H_1, \qquad D_b \nu(0) = (Q G_1 Q^\sharp)^{-1}, \qquad D_b(\Pi_U(A))(0) = S H_1. \tag{3.mcliv}$$

For literal data set $b = b_U(B)$; the first and third derivatives then acquire the right factor $D b_U(0)$. ■

Proof. The actual second-variant row saddle has the strong inverse

$$G_1^{-1} A - Q^\sharp \nu = f, \qquad QA = d, \qquad \|A\|_{\mathcal{A}_\alpha} + \|\nu\|_{\mathcal{W}} \le C_{p,\alpha}\{\mathcal{F}_p(f) + \|d\|_{\mathcal{B}}\}.$$

This is the completed canonical inverse, with its row mass retained. It is valid for an independent current and the common complex background tube. Write this inverse as $\mathfrak{I}_{U,J}$. Then eq. 3.mclii is exactly the preconditioned fixed point

$$(A, \nu) = \mathfrak{I}_{U,J}\big(-N_{\mathcal{L}}(A) + (r'_U(A) - Q)^\sharp \nu, \quad b - (r_U(A) - QA)\big). \tag{3.mclv}$$

The displayed residual estimates give size $C_{p,\alpha} r^2$ and Lipschitz constant $C_{p,\alpha} r$ in a radius-r joint ball. Choose r so this constant is less than $1/4$, then ρ so its affine input is less than $r/4$. Iteration is invariant and contractive. Its bound, realness and holomorphy prove the first assertions. All choices are made after fixing α, p, but use only the fixed uniform constants. The current ceiling can be kept inside the already admitted energy ceiling; shrinking the strong and datum radii pays the finite-p nonlinear constants.

At zero data the zero solution is exact. Every nonlinear residual on the right has zero first derivative there. Differentiation therefore gives the full canonical row-saddle response, $A' = G_1Q^\sharp(QG_1Q^\sharp)^{-1}b'$ and $\nu' = (QG_1Q^\sharp)^{-1}b'$. Applying $\Pi_U'(0) = S$ proves the third identity. Composition with the actual outward datum proves its last assertion. The argument uses the preconditioned residual map; no uniform boundedness of an un-subtracted second-order gradient on a $C^{1,\alpha}$ ball is presumed. □

Denote $C(B) = \Pi_U(A(b_U(B)))$. It satisfies $\mathfrak{q}_U(C(B)) = b_U(B)$ and lies on the same fine gauge orbit as the auxiliary field. Off current it is not asserted to satisfy the fixed linear Landau condition. In particular the auxiliary identity $D_bA(0) = H_1$ is not an identity for this completed field. A specified literal node extension adds its further fine gauge vector to the first jet.

3.38.7. *Exact matching at physical pairs.*

Proposition 3.150 (The auxiliary germ equals the physical germ)**.** Suppose the base is an admitted real physical pair,

$$J = j_U = Q^\sharp\omega_{\mathrm{phys}}. \tag{3.mclvi}$$

Then $\omega = H^\sharp J = \omega_{\mathrm{phys}}$. For reduced datum $b = b_U(B)$, let $(A_{\mathrm{phys}}, \nu_{\mathrm{phys}})$ be the physical PNC germ in the Landau slice fixed at the present base U, namely $R_UD_U^\sharp A = 0$. The reference U_* fixes comparison frames, norms and the node extension; this slice and Λ_U vary with the base U. On a common smaller datum ball,

$$A = A_{\mathrm{phys}}, \qquad C = A_{\mathrm{phys}}, \qquad \nu = \nu_{\mathrm{phys}} + a_fb. \tag{3.mclvii}$$

The same identity holds on the already proved holomorphic physical critical graph wherever the displayed strong and current admission holds. ■

Proof. The row identity $QH = 1$ identifies the first-lift readout with the physical multiplier. Fine gauge invariance gives $F_U(A) = F_U(\Pi_U(A))$ for the exact finite chain. Its first Ward identity gives $\langle j_U, D\Lambda A\rangle = 0$. Substitute $J = j_U = Q^\sharp\omega$ in eq. 3.mcxlviii. The three linear and current terms combine exactly as

$$-\langle j_U, A\rangle - \langle j_U, \Pi_U(A) - SA\rangle - \langle \omega, \mathfrak{q}_U(\Pi_U(A)) - Q\Pi_U(A)\rangle = -\langle \omega, r_U(A)\rangle.$$

Thus the scalar action is

$$\begin{aligned}\mathcal{L}_{U,j_U}(A) = {} & F_U(\Pi_U(A)) - F_U(0) - \langle \omega, r_U(A)\rangle \\ & + \tfrac{1}{2}\langle RD^\sharp A, RD^\sharp A\rangle + \tfrac{1}{2}\langle r_U(A), a_fr_U(A)\rangle.\end{aligned} \tag{3.mclviii}$$

This is an equality of scalar functions on the admitted ball, not merely a second-jet comparison.

The physical solution has $RD^\sharp A_{\mathrm{phys}} = 0$, hence $\Pi_U(A_{\mathrm{phys}}) = A_{\mathrm{phys}}$. Its complete stationarity equation is

$$F_U'(A_{\mathrm{phys}}) = D\mathfrak{q}_U(A_{\mathrm{phys}})^\sharp(\omega + \nu_{\mathrm{phys}}).$$

Differentiate eq. 3.mclviii at this field. The pullback of the first two nonconstant terms is $r_U'(A_{\mathrm{phys}})^\sharp\nu_{\mathrm{phys}}$; the gauge penalty is zero and the row mass adds $r_U'(A_{\mathrm{phys}})^\sharp a_fb$. Therefore this field, with $\nu = \nu_{\mathrm{phys}} + a_fb$, solves eq. 3.mclii. The fixed-point uniqueness proves eq. 3.mclvii.

For continuation along an already admitted holomorphic physical graph, consider the fixed-slice equation, constraint and full physical stationarity just proved as fine-coordinate functions of its graph parameters and B. They are holomorphic and vanish on the real parameter neighbourhood. The identity theorem therefore makes them vanish on the common complex neighbourhood. This proves the stated physical continuation without presuming a new reference or stationarity for an arbitrary off-current input. □

3.38.8. *A bounded updated current and a literal field.* Before the final literal gauge correction put

$$\begin{aligned} U_{\mathrm{new}} &= e^{i\eta C(B)}U, \qquad \omega_{\mathrm{new}} = \omega + \nu - a_f b_U(B), \\ J_{\mathrm{new}} &= \mathcal{E}^{-\sharp}_{\eta C(B)} \left\{ D\mathfrak{q}_U(C(B))^{\sharp}\omega_{\mathrm{new}} + (J - Q^{\sharp}\omega) \right\}. \end{aligned} \tag{3.mclix}$$

Here $\mathcal{E}_z v = \int_0^1 \mathrm{Ad}(e^{itz})v\,dt$. The last expression is an explicit independent-current selection at off-current inputs. Its coefficient ω_{new} is in the displayed original re-centered row coordinates; it is not declared to be a new first-lift readout at the output pair.

Proposition 3.151 (The updated independent current)**.** The update is holomorphic and satisfies

$$J_{\mathrm{new}}(0) = J, \qquad \|J_{\mathrm{new}} - J\|_{\infty,3} \le C_{p,\alpha}\|B\|_{\mathcal{B}}, \qquad \|J_{\mathrm{new}}\|_{\infty,3} \le \|J\|_{\infty,3} + C_{p,\alpha}\|B\|_{\mathcal{B}}. \tag{3.mclx}$$

Its field and curvature increments have the corresponding strong and weighted bounds. At a physical input it is exactly the left Wilson current of U_{new}. ■

Proof. The actual transpose column bounds send row amplitude three into fine force amplitude three. The difference $(D\mathfrak{q}_U(C) - Q)^{\sharp}\omega$ has norm at most $C\|\omega\|_{\mathcal{W}}\|C\|_{\mathcal{A}_\alpha}$. Also $\|\nu - a_f b_U(B)\|_{\mathcal{W}} \le C\|B\|_{\mathcal{B}}$ and $\mathcal{E}^{-\sharp}_{\eta C} - 1$ has point norm at most $C\eta|C|$. Subtract the value at $C = 0, \nu = 0, B = 0$ in eq. 3.mclix. These estimates and eq. 3.mcliii prove eq. 3.mclx. The curvature increment follows from the four exact link factors and the first difference of C. No actual Wilson derivative of U_{new} has been used in this off-current estimate.

At a physical input eq. 3.mclvii gives $\omega_{\mathrm{new}} = \omega + \nu_{\mathrm{phys}}$, and the residual $J - Q^{\sharp}\omega$ vanishes. The physical normal and left gradients satisfy

$$F'_U(C) = \mathcal{E}^{\sharp}_{\eta C} j(U_{\mathrm{new}}).$$

Insert physical stationarity from the preceding proof. Equation eq. 3.mclix is then exactly $J_{\mathrm{new}} = j(U_{\mathrm{new}})$. □

Finally choose the fixed real-reference node extension E_n of Lem. 3.119. Apply it to the small logarithm of the assigned factor $v_U[C(B)]^{-1}$, and exponentiate to obtain the admitted fine gauge $g(B)$. Its node values are exactly that factor; its bare values are one. The literal output pair is

$$\widehat{U}(B) = U_{\mathrm{new}}^{g(B)}, \qquad \widehat{J}(B)_b = \mathrm{Ad}(g(B)_{b_-})J_{\mathrm{new}}(B)_b. \tag{3.mclxi}$$

The actual outward diagram gives $M_{\mathbf{B}}\widehat{U}(B) = V_B$. The finite gauge estimate in eq. 3.mlvi preserves the strong field bound, and its bounded point adjoint preserves the current bounds. At physical inputs this is the physical critical orbit and its actual current in the specified literal gauge.

All choices here belong to the fixed reference chart. A different admissible node extension differs by a fine gauge one at assigned tops, but no global off-current chart-descent or externally specified core convention has been identified by this construction.

3.38.9. *Fixed-order spatial response.* The global strong estimates above can retain a spatial weight. Let $w_y = e^{s\psi(y)}$, where ψ is one-Lipschitz in the proper layer metric and $s > 0$ is fixed sufficiently small. Weighted strong and source norms multiply each local norm by w_y. Hölder seminorms are still taken on the same complete local boxes; the artificial weight is not differentiated.

Proposition 3.152 (Localized jets of the completed germ)**.** The first datum response satisfies

$$\|D_B A[h]\|_{\mathcal{A}_\alpha;w} + \|D_B\nu[h]\|_{\mathcal{W};w} \le C_{p,\alpha}\|h\|_{\mathcal{B};w}. \tag{3.mclxii}$$

The same conclusion holds for the completed field and the literal output pair in their displayed strong and current norms. For each fixed m, the normalized response at an output cell y to point data at $c_1, \dots, c_m$ is bounded by

$$C_m e^{-s\max_i d(y,c_i)}. \tag{3.mclxiii}$$

These constants are uniform in depth and volume. No all-arity absolute connected-kernel bound is asserted. ■

Proof. The actual completed energy inverses, normalized row kernels and readouts have exponential cell bounds. Their local scalar and finite-p upgrades retain the cell weight, since the ratios w_z/w_y are bounded on each fixed complete neighbouring box. This proves the weighted canonical strong row-saddle inverse. For $\Lambda : \mathcal{A}_\alpha \to \mathcal{Y}_{2,\alpha}$, use its weighted zero-average energy estimate and the completed source equation $\Delta_U \lambda = RD^\sharp A$. The projection R preserves the weighted C^α source norm by its completed exponential column sums. The local Schauder estimate then gives the weighted site bound. The same argument gives the weighted first adjoint bound in eq. 3.mcxli; the finite-p force-restoration proof gives the weighted second bound.

In the derivative of every local residual keep one perturbation slot weighted and all background slots in the unweighted small ball. All point products, complete row moments and the adjoint factory have the same bounds with that one weight. The derivative of the preconditioned fixed-point map therefore has weighted norm at most $C_{p,\alpha} r < 1/2$. Its derivative equation gives eq. 3.mclxii. The explicit outward datum, finite gauge chain, node extension and current update have the same one-slot weighted bounds.

These estimates hold on a fixed larger complex datum ball. Cauchy in its other slots gives the corresponding mixed derivative with one weighted slot and $m-1$ unweighted slots. Choose ψ to be distance from the carrier of any selected point datum. Symmetry of the m derivative slots allows the farthest such datum to be selected. This proves eq. 3.mclxiii. The use of the completed source equation in the Schauder step is essential; no individual walk term was assigned a $C^{2,\alpha}$ site bound. □

This construction supplies a strong analytic auxiliary germ, a literal mean-preserving field/current update, and exact physical matching on the admitted critical graph. It keeps the H_1, SH_1 and outward datum first jets distinct. It does not construct a reference from arbitrary curvature-only coarse data, identify an externally prescribed off-current core convention, or establish full proper history domains and deletion laws. Independent enlarged cube inputs and a complete nonlinear connected-carrier norm remain separate requirements.

3.39. **Local biharmonic formulas for strong gauge restoration.** The completed restoration $G_s R$ gains two Hölder derivatives on a Hölder source. A decomposition through second-order site inverses need not have that property term by term: an individual averaging-mass source can jump at a pillar face. We obtain a different local decomposition from a fourth-order positive operator. Its auxiliary Laplacian absorbs that jump before the final Schauder estimate.

The construction uses the actual site graph, own-pillar averages and physical measures. It neither clips an average at an artificial boundary nor replaces the determining region by a periodic model. The final carrier scale is chosen separately from a prescribed history scale.

3.39.1. *The operator and its physical normalization.* Retain the geometry, comparison length ℓ, assigned site scales ξ, and actual covariant site Laplacian $\Delta = D_U^\sharp D_U$ of § 3.19. Let q take values in raw top coordinates equipped, in this section, with counting measure. Its adjoint for that measure is

$$q^* = q^\sharp \Xi^{-4}. \tag{3.mclxiv}$$

The sharp on the right is the physical top transpose. Consequently the local fourth-order operator is

$$K_4 = \Delta^2 + q^* q = \Delta^2 + q^\sharp \Xi^{-4} q, \qquad G_4 = K_4^{-1}. \tag{3.mclxv}$$

At real unitary coefficients its form is

$$a_4(u,v) = \langle \Delta u, \Delta v \rangle_{\mathrm{fine}} + \langle qu, qv \rangle_{\mathrm{count}}.$$

All analytic continuations use the bilinear form. In particular q^* in an analytic formula is not a conjugate transpose of a complex coefficient.

Use the graph norm

$$\|u\|_{V_2}^2 = \|\Delta u\|_2^2 + \|\ell^{-1} D_U u\|_2^2 + \|\ell^{-2} u\|_2^2. \tag{3.mclxvi}$$

It controls the full covariant second differences on complete interior stencils. At the true boundary we use the original graph and the bare atomic norm; the latter pays any omitted-neighbour stencil. Local norms $V_{2,y}$ use a fixed complete enlargement of the assigned cell.

Lemma 3.153 (A site lift with two energy derivatives)**.** For real curvature-small admitted data there is a local right inverse E of the actual q such that

$$qE = 1, \qquad \|Eb\|_{V_2} \le C\|b\|_{\ell^2(\mathrm{count})}. \tag{3.mclxvii}$$

The support and collars of its seeds have bounded overlap. No physical-current bound is needed for this energy estimate. ■

Proof. Use the normalized compact bump seed from Lem. 3.58 in a local real Coulomb frame on a complete nonbare cube of side $C_L\xi_y$. Its normalization matrix is the actual transported bump average and is uniformly invertible. The supremum of the connection is $C_L\kappa/\xi_y$. The finite-p Coulomb estimate, used at $p = 2$, gives $\|Da\|_2 \le C_L\kappa$ on the rescaled cube. These facts follow from curvature alone by Cor. 3.83.

For a seed of value b_y, the ordinary second differences of the scalar bump have L^2 norm $C|b_y|$. Expanding the covariant second differences adds $aD\chi$, $(Da)\chi$ and $a^2\chi$, with the same bound. No pointwise bound for Da is used. The first and zeroth weighted norms in eq. 3.mclxvi have that bound by the existing site-lift estimates. Its Laplacian is a sum of these second differences. The physical support volume is $O(\xi_y^4)$, so all four powers of length cancel against the two derivatives. This is precisely a counting-top bound, rather than a physical-top bound.

For the finitely coarse meshes, including a bare pillar, use the original transported atomic seed. Here η/ξ_y has a fixed positive lower bound; each second difference is bounded by $C\eta^{-2}$ times its value and the physical volume is $O(\xi_y^4)$. Thus the same bound holds. For fine meshes the compact bump and its two-step collar lie inside its pillar. The bounded overlap and adjacent scale comparability sum these estimates.

If a frame cube does not embed, perform this entire seed construction on a sufficiently large periodic cover and average over simultaneous deck shifts. The exact equation $qE = 1$, the quadratic energy bound and its support description descend. This is an averaging of linear maps, not an assertion about partition functions on different volumes. □

Proposition 3.154 (The full fourth-order gap)**.** For the same real data,

$$c\|u\|_{V_2}^2 \le a_4(u,u) \le C\|u\|_{V_2}^2. \tag{3.mclxviii}$$

The constants are uniform in depth, compatible volume and admitted proper-region shape. The corresponding zero-extension Dirichlet compressions have the same gap in the energy of their zero extension. ■

Proof. Write $u = u_0 + Equ$, where $qu_0 = 0$. The exact zero-average estimate eq. 3.dcclxxxiv gives

$$\|u_0\|_{V_2} \le C\|\Delta u_0\|_2 \le C\{\|\Delta u\|_2 + \|qu\|_{\mathrm{count}}\}.$$

Use Lem. 3.153 for the other term. This proves the lower bound. Jensen's inequality for the transported average gives

$$\sum_y |qu(y)|^2 \le C \sum_y \xi_y^{-4} \|u\|_{2,B_y}^2 \le C\|\ell^{-2}u\|_2^2,$$

which proves the upper bound. For the component second derivatives apply the zero-average Hodge estimate eq. 3.dcclxxxviii to u_0, and the seed bound to Equ. The bare mass controls its two-step outer collar.

If E_D injects site fields supported in a fine set D, the compression is $E_D^\sharp K_4 E_D$. Its form is $\|\Delta E_D u\|_2^2 + \|qE_D u\|_{\mathrm{count}}^2$. It retains the full Laplacian and every full crossing row evaluated on the zero extension. Restricting the already proved inequality proves the assertion; there is no partial-row inf-sup assumption. □

For the strong estimates fix $0 < \alpha < 1$ and a class $\mathscr{U}_{\alpha,C_0}$ of these real connections whose local Coulomb potentials on the complete boxes have scaled $C^{1,\alpha}$ norm at most C_0. The current-regular references used for the nonlinear germ of § 3.38 belong to this class. Write $\mathcal{A}_\alpha$ for the fine strong space of eq. 3.dccclxxxvii. We work on a fixed smaller weighted $C^{1,\alpha}$ tube about a chosen member. All constants below may depend on α, C_0, L. Curvature alone is the premise of eq. 3.mclxviii; it is not being asserted to give these stronger coefficient bounds. On the complex tube, the Banach norms are measured in the fixed real-reference comparison frames. Covariant norms at the varying base are uniformly equivalent on that tube.

3.39.2. *A source class suited to a local fourth-order inverse.* The source must allow two derivatives of a Hölder function without requiring their pointwise bound. Let $\mathcal{S}_\alpha$ consist of finite site arrays with a representation

$$\rho = \Delta f + D_U^\sharp g + h, \tag{3.mclxix}$$

where

$$\|f\|_{\alpha,2} = \sup_y \{\xi_y^2 \|f\|_{\infty,B_y^+} + \xi_y^{2+\alpha}[f]_{\alpha,B_y^+}^U\}, \quad \|g\|_{\infty,3} = \sup_b \mathsf{L}(b)^3 |g(b)|, \quad \|h\|_{\infty,4} = \sup_x \xi_x^4 |h(x)|.$$

The Hölder comparisons use complete boxes across pillar faces. The norm $\|\rho\|_{\mathcal{S}_\alpha}$ is the infimum of the sum of these three norms over all representations. Local source spaces $\mathcal{S}_{\alpha,z}$ use representations supported on a fixed complete enlargement of B_z. The output space is $Y^{2,\alpha}$ of eq. 3.mxxiv. The source norms at nearby bases are uniformly equivalent to the fixed-reference norm. Indeed $(\Delta_U - \Delta_*)f$ can be put in $D_*^\sharp g_1 + h_1$ using bounded values of f and the connection difference and its first difference. Likewise $(D_U^\sharp - D_*^\sharp)g$ is a grade-four point source. Thus this comparison does not differentiate the Hölder function f or the bounded field g.

Smooth localization is bounded on this source class. Indeed $\chi\Delta f = \Delta(\chi f) - [\Delta, \chi]f$. The last commutator can be put in the form $D^\sharp g_\chi + h_\chi$, with coefficients $D\chi$ and $D^2\chi$ multiplying shifted values of f. It differentiates no f. The same product rule applies to $\chi D^\sharp g$. Consequently a fixed smooth cell partition localizes $\mathcal{S}_\alpha$ with bounded overlap and bounded norm. We use this localization for block products; sharp characteristic functions are not multipliers on the Hölder part of the source space. Use its bounded reconstruction and restriction maps in the cell-block norm. Multiplying that norm by their fixed bound makes the product norm submultiplicative; this constant is absorbed in the local commutator constant below.

Every local source is a bounded functional on V_2. For example, for a unit source at scale ξ_z,

$$\|f\|_2 \le C, \qquad \|g\|_2 \le C\xi_z^{-1}, \qquad \|h\|_2 \le C\xi_z^{-2}.$$

Pair these with $\Delta u, D_U u, u$, respectively. Thus its dual energy norm is uniformly bounded.

Lemma 3.155 (Strong local fourth-order columns)**.** Let $I_D = E_D(E_D^\sharp K_4 E_D)^{-1} E_D^\sharp$. On a region strictly inside its artificial boundary,

$$\|I_D \rho_z\|_{Y^{2,\alpha}(B_y^+)} \le C_\alpha e^{-s_0 d(y,z)} \|\rho_z\|_{\mathcal{S}_{\alpha,z}}. \tag{3.mclxx}$$

The interior collar contains all stencils and all complete averaging carriers used in the estimate. The same statement holds at a true boundary with the bare atomic convention. It holds uniformly on the stated smaller complex $C^{1,\alpha}$ tube. ■

Proof. First obtain a weighted energy estimate. A raw metric distance is only Lipschitz and is insufficient for this fourth-order step. Smooth the truncated distance from B_z at the local ℓ scale using the weighted smooth partition of Lem. 3.99, with a fixed radius multiple in place of m. If its squared normalized weights are $p_x(y)$, use $\psi(y) = \sum_x p_x(y) d(x, B_z)$. On an overlapping support, centre distances differ by at most C_L. Subtract one such constant before differentiating $\sum_x p_x = 1$. The cutoff derivative estimates, extended through order three by the same bump calculation, give

$$|\psi - d(\cdot, B_z)| \le C_L, \quad |D\psi| \le C_L \ell^{-1}, \quad |D^2\psi| \le C_L \ell^{-2}.$$

For $w = e^{s\psi}$, the exact covariant product rule therefore gives

$$\|w^{-1}\Delta(wu) - \Delta u\|_2 \le C_L|s|\{\|\ell^{-1} D_U u\|_2 + \|\ell^{-2} u\|_2\}.$$

The oscillation of $\log w$ on a full averaging carrier is $O_L(s)$. The conjugated bilinear form $a_4(w^{-1}u, wv)$ differs from $a_4(u, v)$ by at most $C_L|s|\|u\|_{V_2}\|v\|_{V_2}$. Choose s below the gap constant. Multiplication by w preserves the zero-extension space, so the weighted estimate holds for every compression. It gives

$$\|I_D \rho_z\|_{V_{2,y}} \le C e^{-s_1 d(y,z)} \|\rho_z\|_{\mathcal{S}_{\alpha,z}}. \tag{3.mclxxi}$$

There is no endpoint scale ratio: both the source dual norm and the site H^2 norm are dimensionless in four dimensions.

Now put $u = I_D \rho_z$ and $v = \Delta u - f$. On a complete interior box its exact equation is

$$\Delta v = D_U^\sharp g + h - q^* q u, \qquad \Delta u = f + v. \tag{3.mclxxii}$$

The local L^2 norm of v is controlled by eq. 3.mclxxi and the local norm of f. The actual average satisfies $|qu(y)| \le C\xi_y^{-2}\|u\|_{2,B_y}$. The physical density of q^* then bounds q^*qu by $C\xi_y^{-4}$ times the nearby energy. Complete carriers change only fixed local constants.

Rescale this box to length one. The finite-p divergence-source bootstrap used in Prop. 3.89 bounds v in $W^{1,p}$ for every finite p, using its local L^2 norm, g in L^∞, and the bounded scalar forcing. First testing its equation against a squared-cutoff multiple of v supplies the local H^1 bound from those same quantities. On the complex tube use the real-reference comparison in this energy test. Lower-order covariant coefficients have their admitted bounds. Choose $p > 4/(1-\alpha)$. Morrey gives a C^α bound for v; no derivative of g is taken. Thus $f + v$ is a C^α source for the second equation. The scalar finite-p bootstrap first gives the lower $C^{1,\alpha}$ norm of u, and the interior Schauder estimate eq. 3.mxxii gives its full $C^{2,\alpha}$ norm. Its coefficient premise is exactly the displayed $C^{1,\alpha}$ background class. Applying this on fixed nested boxes preserves the exponential factor in eq. 3.mclxxi.

At the true boundary $\xi = \eta$. Each required cell has a fixed number of sites; its rescaled values, differences and Hölder seminorm are bounded directly by its local H^2 energy. No boundary Schauder theorem for a rough region is being inferred. Artificial boundaries are outside all boxes on which the strong assertion is used.

Finally, a small complex C^1 perturbation changes $\Delta : V_2 \to L^2$ and $q : V_2 \to \ell^2(\text{count})$ by a uniformly small operator. The weighted forms and every compression remain invertible by Neumann series. The stronger $C^{1,\alpha}$ tube bounds the coefficients of the two scalar equations above in their required Hölder norms. The same estimates then prove eq. 3.mclxx there. This uses bilinear perturbation of real positivity, rather than complex Hermitian positivity. □

The gain in this lemma explains the fourth-order choice. The discontinuous density q^*qu is a source for v, so v is Hölder. It is not a discontinuous source for the final Schauder equation $\Delta u = f + v$.

3.39.3. *A strong local walk for G_4.* Use the actual weighted cover eq. 3.cmxlix, with $r_x = m\ell(x)$ and $m\delta$ sufficiently small. Its smooth bump proof gives, for every fixed order, $|D^a \chi_x| \le C_a r_x^{-a}$. Take a compression patch D_x of radius $4r_x$ and retain all full crossing stencils, rows and geometry-decision

collars. The support of χ_x and its fixed complete cell enlargements lie strictly inside that artificial boundary. Put $I_x = I_{D_x}$.

Lemma 3.156 (The fourth-order cutoff error)**.** The error columns obey

$$\|[K_4, \chi_x] I_x \chi_x\|_{\mathcal{S}_{\alpha,z} \to \mathcal{S}_{\alpha,y}} \le \frac{C_\alpha}{m} e^{-s_2 d(y,z)}. \tag{3.mclxxiii}$$

Their representations and coefficients read only the declared local compression data and collars. ■

Proof. For a local strong output u, use the exact identity

$$[\Delta^2, \chi]u = \Delta[\Delta, \chi]u + [\Delta, \chi]\Delta u.$$

The first term has the source form Δf_χ, where $f_\chi = [\Delta, \chi]u$. The covariant product rule and $u \in Y^{2,\alpha}$ show

$$\|f_\chi\|_{\alpha,2} \le C_\alpha m^{-1} \|u\|_{Y^{2,\alpha}}.$$

Only one cutoff derivative is needed for the leading term; higher cutoff derivatives are smaller. For the second term apply summation by parts to the commutator itself, rather than differentiating Δu. For any site array w, the exact two-shift product rule writes

$$[\Delta, \chi]w = D_U^\sharp g_\chi(w) + h_\chi(w),$$

where the coefficients are shifted values of $D\chi$ and $D^2\chi$ times transported values of w. Explicitly, for the orientation $D_U w(b) = \eta^{-1}(w_- - T_b w_+)$, take

$$g_\chi(w)(b) = (D\chi)(b)(w_- + T_b w_+), \qquad h_\chi(w)(x) = -(\Delta_{\mathrm{scalar}}\chi)(x) w(x).$$

The scalar Laplacian uses exactly the edges of the original graph. With $w = \Delta u$, its weighted L^∞ size has grade two. Therefore

$$\|g_\chi(\Delta u)\|_{\infty,3} + \|h_\chi(\Delta u)\|_{\infty,4} \le C_\alpha m^{-1} \|u\|_{Y^{2,\alpha}}.$$

This step contains no third difference of u. The summation-by-parts formula holds on the original graph, so missing outer edges do not create an unrecorded boundary term.

For $[q^* q, \chi]u$, insert the cutoff value at the row top. Each difference on the complete row carrier is at most C_L/m. The actual physical row and column density bounds give a point source of grade four with norm at most $C_L m^{-1} \|u\|_{Y^{2,\alpha}}$. Bare identity rows commute exactly. At a rough true boundary all remaining fourth-order entries have size $O(\eta^{-4})$; the atomic output and a cutoff difference give the same source bound directly.

Apply Lem. 3.155 on the cutoff support and its collars. Input localization is bounded on $\mathcal{S}_\alpha$, and all local weights are comparable. This proves eq. 3.mclxxiii with a smaller decay rate. Every formula uses the original compressed matrix and its declared finite carriers. □

Define

$$\mathcal{M}_4 = \sum_x \omega_x \chi_x I_x \chi_x, \qquad T_4 = \sum_x \omega_x [K_4, \chi_x] I_x \chi_x. \tag{3.mclxxiv}$$

Compression and the strict support collar give $\chi_x K_4 I_x \chi_x = \chi_x^2$ as exact finite operators. Thus

$$K_4 \mathcal{M}_4 = 1 + T_4. \tag{3.mclxxv}$$

In smooth cell blocks, use the maximum of the row and column sums with weights $e^{sd(y,z)}$. The weighted overlap eq. 3.cmli and the local column estimates give

$$\|\mathcal{M}_4\|_{\mathcal{S}_\alpha \to Y^{2,\alpha};\mathrm{Sch},s} \le C_\alpha, \qquad \|T_4\|_{\mathcal{S}_\alpha \to \mathcal{S}_\alpha;\mathrm{Sch},s} \le C_\alpha/m.$$

For fixed output or input cell the sum of contributing centre weights is bounded. The remaining cell sum is exponential. A whole-patch energy norm, which would introduce a power of m, has not replaced these column estimates.

File each local matrix on its full carrier as in the positive-walk construction. Include its patch, full crossing-row collar, local geometry-decision collar, canonical input/output tags and fixed short joins.

For sufficiently large carrier cube integer M_0, each local factor uses at most B_L tags, independently of m. With $\sigma_0(X) = b_L + d_{c,0}(X)$, include the short join in $X \vee Y$, so $\sigma_0(X \vee Y) \le \sigma_0(X) + \sigma_0(Y)$. For any prescribed finite rate κ_1, choose parameters in the order

$$\alpha, C_0, \kappa_1; \quad m; \quad \delta; \quad M_0; \quad \rho, \qquad (C_\alpha/m)e^{\kappa_1 B_L} < 1/2.$$

Here $m\delta$ is small, $M_0 \ge C_L/\delta$, and ρ pays the full collars and metric growth reserve. Only after these choices shrink the common complex tube. There is no dependence on depth or volume.

Proposition 3.157 (Strong fourth-order inverse carriers)**.** The exact series

$$G_4 = \mathcal{M}_4 \sum_{n\ge 0} (-T_4)^n \tag{3.mclxxvi}$$

is absolutely convergent in the strong carrier Schur norm from $\mathcal{S}_\alpha$ to $Y^{2,\alpha}$, at the chosen carrier rate. Every coefficient is holomorphic on its complete local background $C^{1,\alpha}$ tube and depends only on its declared local determining data. ■

Proof. The source-to-source family norm of T_4 is less than $1/2$. Joined carrier products are submultiplicative, so the series converges with the asserted output norm. Multiplication by K_4 and eq. 3.mclxxv identify its sum with the positive energy inverse. Every local inverse is a finite Dirichlet matrix with its full coefficients. Its uniform complex invertibility and the strong column estimate give holomorphy into the displayed local Banach spaces. Every output factor includes its smooth cutoff, so zero extension across its artificial boundary preserves $Y^{2,\alpha}$.

The coefficient difference under a small $C^{1,\alpha}$ background change is bounded in the same family norm. Choose the final tube inside a slightly larger common complex tube on which the weighted strong local columns and cutoff commutators have the bounds just proved. Their finite matrices are holomorphic, and the source-space equivalence identifies their input spaces with fixed Banach spaces. Banach-valued Cauchy on the larger tube therefore bounds the change of each cutoff local column and error column by $C\varepsilon$, with the same exponential weight and full local carrier. The weighted centre sum and the convergent walk preserve this bound in the absolute family norm. This argument uses strong regularity only on the output and commutator collars. It does not assign a global $Y^{2,\alpha}$ norm to an uncut Dirichlet solution across its artificial boundary. □

3.39.4. *A positive coarse inverse and the exact restoration.* Define on counting top space

$$M_4 = qG_4q^* = qG_4q^\sharp \Xi^{-4}. \tag{3.mclxxvii}$$

This is already in counting normalization. It is not obtained by treating a physical transpose as an ordinary transpose.

Lemma 3.158 (The fourth-order coarse gap)**.** At real coefficients,

$$cI \le M_4 \le I. \tag{3.mclxxviii}$$

It has an actual local carrier family in counting coordinates at any required fixed intermediate rate. On a smaller common complex tube its inverse has the local carrier family supplied by Prop. 3.103. ■

Proof. Set $u = G_4q^*b$. Then $a_4(u,u) = \langle b, M_4 b\rangle$. The exact lift E gives

$$\|b\|^2 = \langle q^*b, Eb\rangle = a_4(u, Eb) \le C a_4(u,u)^{1/2}\|b\|.$$

This proves the lower bound. For the upper bound, $K_4 \ge q^*q$; equivalently $\|qK_4^{-1/2}\| \le 1$, giving $M_4 \le I$.

A unit counting top source q^*e_z has actual point density at most $C\xi_z^{-4}$ on its complete pillar, so it is a unit grade-four h source. The strong fourth-order family sends it to a dimensionless site field; the actual output average q is bounded on that field. Its input/output columns therefore have

no missing physical length factors. Composition gives the actual family of M_4, with exponentially summable cell blocks and its declared full carriers. The number of top species is fixed.

Apply the positive coarse inversion algorithm of Prop. 3.103 to this matrix. Request the primitive family at a stronger intermediate rate first. Full-carrier truncation, combined short powers and reblocking then give the inverse at the requested final rate, with its finite parameter and separation choices. The family perturbation bound proved above supplies its common complex tube. No indefinite local compression is used. □

For a site source f, put

$$\mathcal{T}_4 f = G_4 \Delta f - G_4 q^* M_4^{-1} q G_4 \Delta f. \tag{3.mclxxix}$$

The notation $\mathcal{T}_4$ is distinct from the parametrix error T_4.

Proposition 3.159 (Exact constrained least squares)**.** For every site source on the finite graph,

$$\mathcal{T}_4 f = G_s R f. \tag{3.mclxxx}$$

Consequently

$$\Lambda = \{G_4 - G_4 q^* M_4^{-1} q G_4\} \Delta D_U^{\sharp}. \tag{3.mclxxxi}$$

These equalities hold also on the admitted bilinear complex continuation. ■

Proof. At real data the unique minimum of $\|\Delta\lambda - f\|_2^2$ subject to $q\lambda = 0$ exists by the zero-average gap. Adding $\|q\lambda\|^2$ to the normal operator does not change its constrained equation. Its saddle system is

$$K_4\lambda + q^*\mu = \Delta f, \qquad q\lambda = 0.$$

Its Schur elimination is exactly eq. 3.mclxxix. The residual $\Delta\lambda - f$ is orthogonal to $\Delta \ker q$. The actual identities $qG_sR = 0$ and $\Delta G_s R = R$ show $\operatorname{ran} R \subset \Delta \ker q$. The zero-average gap makes Δ injective on $\ker q$, and both spaces have dimension equal to the site dimension minus the top dimension. Hence $\Delta \ker q = \operatorname{ran} R$. Since $\Delta\lambda$ belongs to that range, the normal equation gives $\Delta\lambda = Rf$. Its zero-average solution is $G_s R f$.

All matrices are holomorphic on the common complex tube and their admitted inverses remain defined. Alternatively replace real orthogonality by the identities of the bilinear projection R. Either argument extends the exact formula. Finally set $f = D_U^{\sharp} A$. □

Proposition 3.160 (Local strong restoration coefficients)**.** Fix α, C_0 and a finite requested carrier rate κ. After the fixed parameter, separation and tube choices above, $G_s R$ has an exact local family from $\mathcal{C}_{\alpha,2}$ to $Y^{2,\alpha}$, and Λ has an exact local family from $\mathcal{A}_\alpha$ to $Y^{2,\alpha}$. In smooth complete cell blocks these families satisfy

$$\max\left\{ \sup_y \sum_{z,X} e^{sd(y,z)+\kappa\sigma_c(X)} \|\mathcal{T}_{4,yz}[X]\|_{\alpha,2\to Y^{2,\alpha}}, \sup_z \sum_{y,X} e^{sd(y,z)+\kappa\sigma_c(X)} \|\mathcal{T}_{4,yz}[X]\|_{\alpha,2\to Y^{2,\alpha}} \right\} \le C_{\alpha,\kappa}. \tag{3.mclxxxii}$$

The analogous bound holds for Λ with the strong field norm in its input. Each coefficient, including its extended output, has the stated $C^{2,\alpha}$ site norm. Its holomorphic dependence reads only its full local background and determining-data carrier. The constants are uniform in depth and volume. ■

Proof. The injection $f \mapsto \Delta f$ is bounded from $\mathcal{C}_{\alpha,2}$ to $\mathcal{S}_\alpha$ by definition. Compose the strong fourth-order family, the local q, q^* maps and the counting inverse M_4^{-1} in eq. 3.mclxxix. Keep full endpoint tags and short joins in each product. Their carrier norm is submultiplicative and the stronger intermediate rate pays the one coarse reblocking. The final carrier cube integer M_c and its separation are chosen after these finitely many operations. Smooth cell localization preserves the displayed source and output spaces. This proves the first family bound.

The first divergence maps the strong field space to the complete-box source space $\mathcal{C}_{\alpha,2}$. Its finite stencils give a bounded local input family. Applying eq. 3.mclxxxi proves the second assertion,

without taking a second difference of A. The exact identities identify the sums with the original restoration. A coefficient of this new family need not obey $q\lambda = 0$ by itself. Its strong bound comes from the fourth-order local equation, not cancellation of its averaging-mass source. □

All primitive patches, frame cubes and the aligned coarse inversion grids are first constructed on one sufficiently large periodic cover. Perform the entire matrix construction there before any carrier projection. The exact operators commute with deck shifts; average their families over those shifts and descend. The $C^{2,\alpha}$ local norms are convex, and lifted endpoint sums cover the original Schur sums, so no sheet factor is introduced. Retain every lifted carrier before projection, including winding paths and the full data collar. Bilinear matrix identities and inverses restrict to the deck-invariant sector by uniqueness. This proves the small-period case for both the primitive and coarse stages.

The new family supplies coefficientwise strong restoration in the fixed $C^{1,\alpha}$ chart. It does not upgrade the old second-order walk coefficients, or remove the need to construct connected coefficient families for the nonlinear germ of § 3.38. Independent background cube domains, complete history admission and an externally prescribed off-current core convention remain separate.

3.40. **Strong local families for the current row saddle.** The energy families alone do not give a strong Banach space in which to expand a nonlinear equation. We construct the required strong families in the same prescribed order as the current precisions. The fourth-order restoration in Prop. 3.160 is used for its new local $C^{2,\alpha}$ site coefficients. No such conclusion is assigned to the older second-order site pieces.

Fix $0 < \alpha < 1$, a finite $p > 4/(1-\alpha)$, and a finite requested carrier rate κ. Let U_* be a real current-regular reference on an admitted determining geometry, with strict curvature and current margins. Use a fixed smaller weighted $C^{1,\alpha}$ tube $U = e^{i\eta E}U_*$. The independent current J is bounded in its full amplitude norm. The actual j_U need not have that bound at a complex input. All spaces and their comparison frames are fixed at U_*.

Write $\mathcal{A}_\alpha$ for the strong field space of CNG, $\mathcal{Y}_{2,\alpha}$ for its site gauge space, and $\mathcal{F}_p$ for the force space of § 3.25. More explicitly the force cell norm is

$$\|f\|_{\mathcal{F}_{p,y}} = \xi_y^{3-4/p}\|f\|_{L^p(B_y^+)}. \tag{3.mclxxxiii}$$

The cell enlargements include all stencils and row collars. A family norm is the maximum of its weighted row and column Schur sums between these normalized cell Banach spaces, with the joined full carriers of eq. 3.cmlxxxvii. Use a smooth local partition to reconstruct strong fields from their cell slots. Its profiles, differences and Hölder differences have their scaled bounds on complete collars. The product rule bounds this reconstruction independently of the number of fine coordinates. The fixed reconstruction constant is included in the algebra norm.

3.40.1. *The positive field primitive on finite-p forces.* Let

$$K_F = H_U + D_U D_U^\sharp + Q_U^\sharp a_f Q_U$$

be the actual positive field operator of the local-walk construction, before the site projection and current terms. Its local compressions retain all crossing coefficients. For a compression domain D, let I_D be its inverse and let χ be an output cutoff separated from its artificial boundary.

Lemma 3.161. For a force supported in an assigned cell z, the local output factors satisfy

$$\|\chi I_D \chi\, 1_z f\|_{\mathcal{A}_{\alpha,y}} \le C_{p,\alpha} e^{-sd(y,z)}\|f\|_{\mathcal{F}_{p,z}}. \tag{3.mclxxxiv}$$

The constants are independent of compression size, fine mesh, depth and region shape. The same estimate holds on a common smaller complex tube. ■

Proof. For $p > 2$, the normalized force cell embeds in the L^2 force cell, by the physical volume $O(\xi_z^4)$. The positive local inverse therefore has its proved exponential energy column with this source norm. On a complete nonbare box, the exact Wilson curl–divergence stencil rewrites the equation as a component covariant Laplacian with a bounded curvature multiplication and fixed neighboring shifts. The row-mass term has locally bounded point forcing: the complete average of the solution is bounded by its energy cell L^2 norm, and the actual transpose extends its bounded density. Its bound uses the physical column density, not a point evaluation of that energy function.

In a real local Coulomb frame the potential and its first derivative are bounded by the stated current regularity. In the complex tube they have the same bounds with fixed larger constants. The component covariant Laplacian is the ordinary discrete Laplacian plus first-order and zeroth-order terms with these bounded coefficients. This follows by pairing the positive and negative covariant shifts before dividing by the fine spacing. There is no derivative of curvature in that identity.

Apply the local finite-p estimates on nested complete boxes. Energy gives H^1; the first scalar estimate gives $W^{2,2}$, then strict embeddings give gradient L^3. The next estimate gives $W^{2,3}$, hence gradient L^8 and field L^∞. If $p \le 8$, apply the final p estimate there. For $p > 8$, use the $p = 8$ estimate first, then the desired finite p. The bounded row forcing and curvature terms remain controlled at every stage. The original force belongs to each lower exponent used on these fixed boxes. Morrey then gives the gradient Hölder exponent $\alpha < 1 - 4/p$.

All outer energy terms retain the exponential column weight, and neighboring box weights differ by a fixed factor. The source is present only near z. This proves the displayed column estimate with a fixed smaller rate. The output cutoff avoids the artificial boundary. At a true bare boundary the scale is η; the finite atomic stencils and the local mass bound give the same scaled estimate directly. Multiplication by the smooth output cutoff preserves the strong norm. □

The slow commutator in the positive parametrix maps this strong output into $\mathcal{F}_p$, with norm $C_{p,\alpha}/m$. Its derivative terms are $D\chi\, Dv$ and $\Delta\chi\, v$; the row commutator has the complete row difference $\chi(x) - \chi(\mathrm{row})$. The slow-cutoff bounds and the actual row moments give the same m^{-1} after rescaling. The finite-shift curvature terms also have that bound: their commutators contain one cutoff difference and a bounded curvature coefficient. No derivative of the input force is used. Choose m large after fixing p, α, κ. The weighted-overlap sum in the local-walk proof then makes this an absolute contraction on $\mathcal{F}_p$. Exactly as in eq. 3.cmlix, the resulting identity is

$$\mathbf{G}_F = \mathbf{M} \sum_{n \ge 0} (-\mathbf{T})^{\star n}, \qquad \|\mathbf{G}_F\|_{\mathcal{F}_p \to \mathcal{A}_\alpha} \le C_{p,\alpha,\kappa}. \tag{3.mclxxxv}$$

The determining geometry and background data of every coefficient are retained. This is a new strong parametrix; it need not use the same local pieces as a previously fixed energy representation.

3.40.2. *The two site adjoints without a current derivative.* For a site field u, use the normalized first-order cell norm

$$\|u\|_{\mathcal{V}_{p,y}} = \xi_y^{2-4/p} \|u\|_{L^p(B_y^+)} + \xi_y^{3-4/p} \|D_U u\|_{L^p(B_y^+)}.$$

For a site source write $\rho = D_U^\sharp f + h$, where f is a field force and h a site force. Give this source the infimum norm of

$$\|f\|_{\mathcal{F}_{p,y}} + \xi_y^{4-4/p} \|h\|_{L^p(B_y^+)}$$

over such representations on the complete source collar. The divergence is variational. Its values need not be bounded fine functions.

Lemma 3.162. The actual completed site inverse has local families from this source class into $\mathcal{V}_p$. It also has a local family with

$$\sup_y \{\xi_y^2 |G_s h|_y + \xi_y^3 |D_U G_s h|_y\} \le C \|h\|_{\infty,4} \tag{3.mclxxxvi}$$

in the corresponding weighted row/column norms. Both assertions hold on the common complex tube. ■

Proof. For the local positive site compression, first use its variational energy column with the displayed source representation. In the interior it solves

$$\Delta_U u = D_U^\sharp f + h - q^\sharp a_s q u.$$

The last term has bounded point amplitude of grade four, from the local energy norm and the actual complete row. For the divergence term, the uniform finite-p double-gradient resolvent in Prop. 3.79 gives the local first-order estimate. To see its lower-order bootstrap explicitly, put each potential-times-gradient term into a divergence of potential times u, plus a bounded first potential derivative times u. Initially $u \in H^1$, hence $u \in L^3$. The first-order estimate at 3 gives $u \in W^{1,3}$, hence $u \in L^8$. If $p \le 8$, finish at p at this stage: the outer field belongs to L^p, as do the prescribed sources. If $p > 8$, its next application at 8 gives $u \in L^\infty$. The final finite-p estimate then uses f, h at their prescribed exponent and the now bounded lower-order coefficients. All cutoffs are nested inside the artificial compression boundary.

The scalar commutator maps $\mathcal{V}_p$ to a site L^p force of grade four with norm C_p/m. Thus the same positive parametrix, now in this source class, converges after fixing m large enough. Multiplication of a variational source by a cutoff is legitimate: $\chi D^\sharp f$ is $D^\sharp(\chi f)$ plus a bounded one-step cutoff difference times f. This stays in the declared source class, without Df. This proves its exact local family assertion.

For the second assertion take $f = 0$ and bounded h. The scalar second-order bootstrap, with the same bounded row forcing, gives W^{2,p_0} for any fixed $p_0 > 4$ on the output support. Morrey gives u and its gradient bounded with the displayed scaling. The slow commutator takes that output into a bounded site force, so its positive local series converges in this class as well. True bare cells use their atomic stencils throughout. □

Let $\widehat{F} = G_s q^\sharp \Xi^{-4}$ and let $\widehat{M}$ be the actual counting site Gram matrix of eq. 3.cmxcv. Its inverse has the CCI local family. The injection $q^\sharp \Xi^{-4}$ has point density of grade four. Thus eq. 3.mclxxxvi gives local families for $\widehat{F}, D\widehat{F}$ with site amplitude grades two and three. Pairing a grade-two site field with a grade-two column costs no cell volume: $\xi^{-2}\xi^{-2}\xi^4 = 1$. Hölder's inequality gives the same statement in $\mathcal{V}_p$. Consequently the exact projection

$$P = \widehat{F}\widehat{M}^{-1}\widehat{F}^\sharp, \qquad R = 1 - P$$

has a bounded family on $\mathcal{V}_p$ and on the displayed bounded site-amplitude/gradient space. All scale ratios are absorbed once in the fixed spatial reserve, as in NCW.

The exact adjoint formulas now give the coefficient families

$$\begin{aligned} &\Lambda^\sharp = DRG_s : \{\text{site amplitude four}\} \longrightarrow \{\text{field amplitude three}\}, \\ &S^\sharp = 1 - DRG_s D^\sharp : \mathcal{F}_p \longrightarrow \mathcal{F}_p. \end{aligned} \tag{3.mclxxxvii}$$

In particular a bounded field force may be used in the second line by its cell L^p norm. The exact identity $\Lambda^\sharp D^\sharp = 1 - S^\sharp$ also gives the explicit family bound

$$\|\mathbf{\Lambda}^\sharp \mathbf{D}^\sharp f\|_{\mathcal{F}_p} \le C_{p,\kappa} \|f\|_{\infty,3}. \tag{3.mclxxxviii}$$

There is no assertion that $S^\sharp$ maps arbitrary bounded forces to bounded forces. This is the finite-p distinction required by the nonlinear adjoint factory.

3.40.3. *Woodbury before either current correction.* Use the new strong family for G_F and the actual positive coarse family for $\widehat{\Theta}^{-1}$. The Woodbury identity is

$$G_0 = G_F + G_F(D\widehat{F})\widehat{\Theta}^{-1}(D\widehat{F})^\sharp G_F.$$

The map $D\widehat{F}$ has field-force amplitude three by the preceding site lemma. Its transpose maps a strong field to counting top amplitudes: the physical pairing on a cell costs $\xi^{-3}\xi^{-1}\xi^{4}=1$. The two exponential Schur sums make these maps bounded between their cell spaces. It follows that

$$\|\mathbf{G}_0\|_{\mathcal{F}_p\to\mathcal{A}_\alpha}\le C_{p,\alpha,\kappa}. \tag{3.mclxxxix}$$

For $\lambda=\Lambda v$, the new fourth-order restoration gives a family in $\mathcal{Y}_{2,\alpha}$. Hence $S=1-D\Lambda$ has a family on $\mathcal{A}_\alpha$. The exact grouped current formula eq. 3.mii can be written as

$$B_U[J]v=W[J]\lambda+\Lambda^\sharp\Big(W[J]^\sharp v-\tfrac12 W[J]^\sharp D\lambda\Big)-\tfrac12\Lambda^\sharp D^\sharp W[J]\lambda.$$

The first term is a bounded field force of grade three. The two site forces in parentheses have amplitude four. The last term uses a bounded grade-three field force inside its variational divergence. Equation eq. 3.mclxxxvii therefore proves

$$\|\mathbf{B}_U[J]\|_{\mathcal{A}_\alpha\to\mathcal{F}_p}\le C_{p,\alpha,\kappa}\gamma,\qquad \gamma=\|J\|_{\infty,3}. \tag{3.mcxc}$$

Every product keeps the actual current bond, both matrix endpoints, and all background and geometry data read by its factors. No derivative of J is present.

Choose γ below a fixed smaller positive ceiling, after p,α and the carrier constants have been chosen. Then

$$\mathbf{G}=\mathbf{G}_0\sum_{n\ge0}(\mathbf{B}_U[J]\mathbf{G}_0)^{\star n}$$

converges normally as a family from $\mathcal{F}_p$ to $\mathcal{A}_\alpha$. Its complete sum is the first canonical inverse. The difference $G-G_0$ has the additional factor $C\gamma$.

3.40.4. *The two row inversions and the multiplier root.* The normalized field-row trace and its transpose are those in eq. 3.miv. The trace maps a strong field into counting row amplitudes, by its complete average and outward row completion. The transpose of a unit counting row has fine-force density of grade three, as in eq. 3.cmlxxxvi. The positive family for $\mathcal{T}_0^{-1}$ is already available. Since $G-G_0$ has strong family norm $C\gamma$, its normalized row-Schur difference has that same small bound. The exact Neumann formula eq. 3.mvi therefore gives the first row inverse and the first lift as strong families.

For the induced $\omega_*=H^\sharp J$, retain the original fine-current bond in each paired coefficient. The exact physical duality calculation eq. 3.mx gives its absolute rooted bound

$$\sup_c\sum_C e^{\kappa\sigma_c(C)}\xi_c^3|\omega_{c,C}|\le C\gamma.$$

The bare readout is the separately retained local term described in NCW. Its bare second constraint jet is identically zero. Thus the actual $\Delta_U^{(2)}[\omega_*]$ has a family from $\mathcal{A}_\alpha$ into bounded forces of amplitude three. This uses both absolute leg sums of the actual row coefficient, its fixed-leg fine density and the physical transpose. No individual invariant Taylor piece is used.

Compose it with S and $S^\sharp$. The second correction then has family norm

$$\|\mathbf{S}^\sharp\mathbf{\Delta}_{\mathbf{U}}^{(\mathbf{2})}[\omega_*]\mathbf{S}\|_{\mathcal{A}_\alpha\to\mathcal{F}_p}\le C\gamma.$$

A further fixed decrease of the current ceiling admits the second Neumann series for G_1. Its row matrix differs from the same positive $\mathcal{T}_0$ by $C\gamma$. The second row inverse and H_1 follow by the same exact formula. The readout in this second correction has throughout used the first lift H.

Proposition 3.163. Fix the stated α,p,κ. On a smaller common $C^{1,\alpha}$ background tube and for a sufficiently small full independent current radius, the canonical second-variant row saddle has an exact local family

$$\mathfrak{I}_{U,J}:\mathcal{F}_p\oplus\mathcal{B}\longrightarrow\mathcal{A}_\alpha\oplus\mathcal{W}. \tag{3.mcxci}$$

Its row/column carrier norm is bounded by a fixed constant. The same construction gives strong families for $G_F,G_0,G,G_1,\ H,H_1,S,\Lambda$ and the two adjoint maps in eq. 3.mclxxxvii, in their stated

spaces. Each coefficient is holomorphic in its actual local background and independent current data, with its complete determining geometry. The constants and radii are independent of depth, compatible volume and admitted region shape. ■

Proof. The preceding constructions give the displayed maps in their prescribed order. The full row saddle is obtained from the exact formulas

$$A = G_1 f + H_1(d - QG_1 f), \qquad \nu = (QG_1 Q^\sharp)^{-1}(d - QG_1 f),$$

with the physical normalizations of eq. 3.mxvi. They give precisely the datum amplitude one and multiplier amplitude three in $\mathcal{B}, \mathcal{W}$. Products use the smooth cell reconstruction and the joined-carrier algebra. Local primitive matrices, the new restoration families and all coarse inverses are holomorphic on their common smaller tube. Normal convergence preserves this property. Only finitely many strong primitive, coarse inversion and current Neumann stages are used, so the final tube and ceiling are positive.

When a cover is needed, use one common sufficiently large cover for all stages, keep full lifted carriers, and deck-average before projection. The strong local cell norms and physical measures descend with the same row/column bounds, as in NCW. No quantum-volume identity is involved. □

The current ceiling in this strong family construction may depend on the fixed p, α and carrier rate. The larger energy ceiling from the completed inverse theorems is unchanged. The proposition supplies the stated stronger local representation on its smaller domain; it makes no endpoint Riesz assertion and no history-deletion identification.

3.41. **Connected families for the selected nonlinear germ.** The strong inverse families let us expand the selected nonlinear equation itself. Each coefficient below retains the background carrier of every inverse factor, the actual row carrier of every nonlinear vertex, and all datum inputs. Their absolute connected norm is summable over every Taylor degree. This is stronger than a separate bound for each fixed derivative.

We use the auxiliary action and current convention of § 3.38. The resulting sum is that selected germ, rather than a new equation with generic local coefficients. Its physical identification is inherited from the exact scalar identity proved there.

3.41.1. *Inputs, cell slots and carrier norms.* Fix $0 < \alpha < 1$, a finite $p > 4/(1-\alpha)$, and a finite requested carrier rate κ. Choose the primitive families at a stronger fixed rate κ_+. The final rate reserve will pay fixed local stars, supported-slot collars and the base-variable Taylor expansion. All choices precede depth and volume.

Let $\mathfrak{D}$ be a smaller common domain of pairs $P = (U, J)$ supplied by Props. 3.160 and 3.163. The background is in a weighted $C^{1,\alpha}$ tube about a fixed given real current-regular U_*. The full independent-current amplitude is smaller than the strong-family ceiling. That ceiling may depend on α, p, κ_+; the larger energy ceiling is not asserted to suffice for this representation. Comparison frames, norms and the node extension are fixed at U_*. At each present base U, its restoration, constraint and fixed-for-this-germ slice are the actual $\Lambda_U, \mathfrak{q}_U$, and $R_U D_U^\sharp A = 0$.

Use the spaces

$$\mathcal{X} = \mathcal{A}_\alpha \oplus \mathcal{W}, \qquad \mathcal{Z} = \mathcal{F}_p \oplus \mathcal{B}, \qquad x = (A, \nu). \tag{3.mcxcii}$$

Here the fine strong norm, row datum amplitude one and multiplier amplitude three are those of § 3.38. The local norm is the maximum of its field and row components at the assigned cell. There are only a fixed number of row species at a top.

Local field slots are supported strong fields from a fixed smooth cell partition with complete collars. Their reconstruction has bounded overlap and is bounded from the maximum slot norm into the global strong norm. Use the corresponding bounded smooth localization for force slots. Row data and currents, which are not differentiated, can use bounded ownership slots. Multiply

block norms by the fixed reconstruction bound so their carrier product norm is submultiplicative. None of these slots counts its individual fine coordinates.

A carrier X records full tags, short joins, local determining geometry and complete coefficient read sets. Its length is $\sigma_c(X) = b_L + d_c(X)$, with the guarded joining rule used in the linear families. Every multilinear coefficient has its output tag, all input tags and its primitive coefficient carriers in X. For an m-linear family $\mathbf{V}_m$, use

$$\|\mathbf{V}_m\|_\kappa = \max\Big\{ \sup_y \sum_{z_1,\dots,z_m,X} e^{\kappa\sigma_c(X)} \|V_{m;y,\mathbf{z}}[X]\|, \max_i \sup_{z_i} \sum_{y,\mathbf{z}_{\neq i},X} e^{\kappa\sigma_c(X)} \|V_{m;y,\mathbf{z}}[X]\| \Big\}. \tag{3.mcxciii}$$

The operator norm inside the sum uses the displayed local Banach slots and is the supremum on a fixed larger common local base domain $\mathfrak{D}_X^+$. Thus the supremum is taken separately for each coefficient before the carrier sum. The final base domain has a strict margin inside these larger domains. It is a norm of divided Taylor coefficients $D^m/m!$. Ordered products and joins of such families obey the usual substitution bound: sum each internal cell index using a row sum, or the distinguished column sum along its path to a selected input. The remaining factors use row sums. The resulting norm is at most the product of the factor norms. Fixed local stars cost C_κ^m at an m-linear vertex.

Lemma 3.164 (Uniform local-data majorants)**.** The required strong linear families can be chosen with bounded coefficientwise local-data supremum norms as just defined. Their constructive bounds are positive majorants uniform on the larger common base domain. The same convention applies to every tree and nonlinear coefficient below. ■

Proof. The local Dirichlet columns and cutoff errors have bounds $Ce^{-sd(y,z)}$ and $(C/m)e^{-sd(y,z)}$, respectively, uniformly on their entire larger local coefficient tube. Taking each coefficient's local-data supremum therefore preserves those bounds. The weighted centre count and the positive word sums for the primitive walks give the sum of these suprema, rather than only a bound at one common global base point.

There is one extra count in a positive coarse inversion. A combined near power $H_<^m$ has 2-operator norm at most $(q')^m$ uniformly on the larger complex tube. Its entrywise local-data supremum is consequently at most $C(q')^m$. The declared endpoint balls have radius B_m, so the number of possible endpoints in a row or column is at most $C(1+B_m)^4$. Hence its stronger supremum family bound is

$$C(1+B_m)^4(q')^m.$$

The smaller $(1+B_m)^2(q')^m$ Hilbert-row estimate at one base point would not by itself justify moving the supremum through the endpoint sum. The larger polynomial above suffices: B_m grows polynomially in m, and the contraction is exponential. Use it in every positive coarse short-power stage, choose the long cutoff $R = Dm$ as before, and increase m until both this term and the positive long-word bound are small in the carrier norm. Reblocking still uses a bounded number of final tags for the combined entry. This only enlarges fixed carrier and separation choices.

The remaining coarse words, inverse Neumann series, rooted multiplier pairings and strong-current perturbations are bounded by products of these positive coefficient majorants. Choose the strong current radius after their constants. This proves the claim through the finitely many primitive, Gram, gauge-Schur and row-Schur stages. No exchange of a pointwise base supremum with an infinite carrier sum is presumed. All later analytic local vertex bounds hold uniformly on a larger local strong ball, so their Cauchy majorants and ordered tree bounds have the same property. □

The strong linear inputs are the exact families

$$\mathfrak{I}_P : \mathcal{Z} \longrightarrow \mathcal{X}, \quad \Lambda : \mathcal{A}_\alpha \longrightarrow Y^{2,\alpha}, \quad S : \mathcal{A}_\alpha \longrightarrow \mathcal{A}_\alpha, \tag{3.mcxciv}$$

and the adjoint families

$$\Lambda^\sharp : \{h\}_{\infty,4} \longrightarrow \{f\}_{\infty,3}, \quad S^\sharp : \mathcal{F}_p \longrightarrow \mathcal{F}_p, \quad \Lambda^\sharp D^\sharp : \{f\}_{\infty,3} \longrightarrow \mathcal{F}_p. \tag{3.mcxcv}$$

They are precisely eq. 3.mcxci, eq. 3.mclxxxvii and eq. 3.mclxxxviii, with the new strong site restoration. The first-lift readout $\omega = H^\sharp J$ has its rooted local family with multiplier amplitude $C\|J\|_{\infty,3}$. The original fine-current input stays in each such carrier. It is not replaced by a second-lift readout.

3.41.2. *The actual nonlinear vertices.* For this fixed P put

$$\Pi(A) = \Pi_U(A), \quad \Xi(A) = \Pi(A) - SA, \quad N_q(a) = \mathfrak{q}_U(a) - Qa, \quad r(A) = \mathfrak{q}_U(\Pi(A)).$$

These are the finite gauge chain and actual re-centered straightened constraint already defined. The local formula for Π is analytic in $A, \Lambda A, D\Lambda A$. Its divided fine-mesh factor is removed before taking norms. Prop. 3.160 controls the site argument through two Hölder derivatives, coefficient by coefficient. Use $S = 1 - D\Lambda$ from this same restoration family when expanding the finite chain. Its local linear jet $A - D\Lambda A$ is then removed before filing the quadratic remainder Ξ.

Lemma 3.165 (Local analytic vertices without fine counts)**.** The local Wilson, constraint, finite-gauge and adjoint remainders used below have exact multilinear carrier families with coefficients bounded by $C_0 C_1^m$ at degree m. Their coefficients are holomorphic in their actual local (U, J) data. The constants are uniform in depth and fine mesh. ■

Proof. The centered Wilson remainder $F'_U(A) - j_U - F''_U(0)A$ is a local map from the strong ball into bounded grade-three forces. Its uniform holomorphic bound is Lem. 3.146. Its constant and linear jets are subtracted before expansion. This is essential when the actual j_U at a complex base is large. Each plaquette expression reads a fixed fine stencil, hence a fixed number of complete strong cell slots. Banach-valued Cauchy and polarization give C^m, independently of the dimensions of those slots.

The actual mean and its adjoint satisfy the holomorphic bounds in Lem. 3.148. An assigned row and its complete carrier read at most a fixed number of adjacent-scale cells. Proper separation excludes a second intervening level. The fixed-leg fine density in eq. 3.mxxxvii cancels the inverse fine volume in the physical transpose. Thus the bound for $DN_q(a)^\sharp \nu$ is a bounded point-force bound before any adjoint restoration is applied. Cauchy on its uniform larger strong ball gives all higher Taylor degrees in the same point-force class. It does not count fine coordinates or postulate a new higher-leg density estimate.

The finite gauge function uses local point products of the scaled variables $\xi A, \Lambda A, \xi D\Lambda A$. Its local power series has C^m coefficients. Substitute the strong linear families in eq. 3.mcxciv; each occurrence brings its entire data carrier. A point derivative paired with a bounded fine force has exactly the factory

$$f_0 + \Lambda^\sharp h_\lambda + \Lambda^\sharp D^\sharp f_d.$$

Its local fields f_0, f_d have grade three and h_λ has site grade four. Endpoint injection uses only the fixed graph degree. The families in eq. 3.mcxcv give the required finite-p output bounds. No derivative is taken of the paired force or of J.

These local analytic maps involve a fixed number of strong cell slots. Substitution of an m-linear coefficient attaches at most a fixed multiple of $m+1$ linear factors or fixed local stars. Their family norms and the guarded joins change C^m by another fixed exponential in m. The rooted family of $\omega(P)$, where it occurs, attaches its full base-current carrier and has bounded norm. This proves the assertion in eq. 3.mcxciii. □

We next make explicit which force classes enter these adjoints. The identity $QS = Q$ gives

$$r(A) - QA = Q\Xi(A) + N_q(\Pi(A)). \tag{3.mcxcvi}$$

Use this equality before filing coefficients. It avoids a linear cancellation between different restoration carriers. Similarly,

$$\begin{aligned}(r'(A) - Q)^\sharp \nu = \Xi'(A)^\sharp Q^\sharp \nu + S^\sharp DN_q(\Pi(A))^\sharp \nu \\ + \Xi'(A)^\sharp DN_q(\Pi(A))^\sharp \nu.\end{aligned} \tag{3.mcxcvii}$$

Every input to $S^\sharp$ or the nonlinear adjoint factory on the right is a bounded grade-three force, supplied by the actual row columns. A generic $\mathcal{F}_p$ force is not passed to a factory that requires a point force.

For the constraint-current term put $C_\omega = \Delta_U^{(2)}[\omega]$, the actual second field-mean jet. Its residual has the exact expression

$$\begin{aligned}&\nabla\langle \omega, N_q(\Pi(A))\rangle - S^\sharp C_\omega SA \\ &\quad = S^\sharp\{C_\omega \Xi(A) + DN_q(\Pi(A))^\sharp \omega - C_\omega \Pi(A)\} + \Xi'(A)^\sharp DN_q(\Pi(A))^\sharp \omega.\end{aligned} \tag{3.mcxcviii}$$

The braces are bounded point forces and are quadratic in A. In the row mass use

$$r'(A)^\sharp a_f r(A) - Q^\sharp a_f QA = (r'(A) - Q)^\sharp a_f r(A) + Q^\sharp a_f (r(A) - QA). \tag{3.mcxcix}$$

The weight $a_f \asymp \xi^{-2}$ converts datum amplitude one into multiplier amplitude three. The current term is the exact finite-chain adjoint remainder after its quadratic scalar jet $\langle A, B_U[J]A\rangle/2$ is removed. Its factory inputs are again bounded forces. These formulas show both the quadratic zeros and the valid source classes coefficient by coefficient. There is no L^∞ Riesz claim.

3.41.3. *An exact tree solution of the selected equation.* Let $N_{\mathcal{L}}(A) = \mathcal{L}_P'(A) - G_1^{-1}A$ be the subtracted auxiliary gradient of eq. 3.mcli. Define

$$L_P b = \mathfrak{I}_P(0, b), \qquad \mathfrak{N}_P(A, \nu) = \mathfrak{I}_P \begin{pmatrix} -N_{\mathcal{L}}(A) + (r'(A) - Q)^\sharp \nu \\ -(r(A) - QA) \end{pmatrix}. \tag{3.mcc}$$

The actual preconditioned equation is

$$x = L_P b + \mathfrak{N}_P(x). \tag{3.mcci}$$

It is exactly eq. 3.mclv. In particular its multiplier and curvature terms have not been replaced by model vertices.

Lemma 3.166 (The nonlinear vertex family)**.** On a fixed smaller joint strong ball,

$$\mathfrak{N}_P(x) = \sum_{m \geq 2} V_{m,P}[x^m], \qquad \|\mathbf{V}_{m,P}\|_{\kappa_+} \leq C_0 C_1^m. \tag{3.mccii}$$

The series and carrier sums converge absolutely on a uniform ball. The linear family L_P has bounded row and column carrier norm. ∎

Proof. Use the explicit remainder formulas above and Lem. 3.165. The source tuple is in $\mathcal{Z}$: its first component is in finite $\mathcal{F}_p$, and its second has datum amplitude one. Apply the exact strong row-saddle family $\mathfrak{I}_P$. All constant and linear jets were removed before filing. For example eq. 3.mcxcvi has two manifestly quadratic terms; the second line of eq. 3.mcxcvii has at least one field factor and one multiplier factor. The removed finite-chain scalar quadratic jet has exactly the canonical $B_U[J]$ coefficient. Consequently no degree-zero or degree-one representative is left for cancellation between carriers.

Linear primitive family products and the local C^m coefficient bounds give the displayed bound, after enlarging C_1. Full base coefficient carriers are retained in every product. The linear assertion is the same row-saddle theorem with zero force source. □

Proposition 3.167 (All-degree connected datum families)**.** For $P \in \mathfrak{D}$ and sufficiently small $\|b\|_{\mathcal{B}} < r_b$, the selected auxiliary solution has an exact expansion

$$x(P,b) = \sum_{n\ge 1} \sum_{\mathbf{z},X} x_{n;\mathbf{z}}[X](P_X)[b_{z_1},\dots,b_{z_n}], \qquad \sum_{n\ge 1} r^n \|\mathbf{x}_n(P)\|_{\kappa_+} \le Cr, \quad 0 < r \le r_b. \tag{3.mcciii}$$

Every X is connected and contains its output, all datum inputs and all background/current read sets. Each coefficient is holomorphic in those local base data. Constants and radii are uniform in depth, compatible volume and admitted shape. ■

Proof. Expand eq. 3.mcci in ordered rooted trees. A leaf carries the exact linear family $L_P b$; an internal vertex of arity $m \ge 2$ carries $V_{m,P}$. Join every edge carrier at its shared cell, including the fixed short join when physical overlap does not mean an identical tagged vertex. The result contains every primitive base read set, not merely the geometric hull of the datum leaves. An n-leaf tree has at most $n-1$ internal vertices. All fixed stars and linear factors can therefore be paid by a fixed exponential in its degree.

To prove convergence, replace every coefficient by its family norm. The positive scalar majorant is

$$t = C_{\mathrm{lin}} r + \sum_{m\ge 2} C_0 C_1^m t^m. \tag{3.mcciv}$$

Choose r_b so this map preserves $[0, 2C_{\mathrm{lin}} r_b]$ and its derivative there is less than $1/2$. Iteration from zero gives a convergent positive series with $t(r) \le 2C_{\mathrm{lin}} r$. Its coefficients are the sums of all ordered tree weights. The substitution estimate for eq. 3.mcxciii bounds the actual coefficient families by this series. There is no extra factorial: the vertices were divided Taylor coefficients, and the ordered tree sum is precisely the expansion of the powers in eq. 3.mcciv.

Normal convergence permits substitution in the actual equation. Its sum lies in the strong uniqueness ball of Prop. 3.149, so it equals that already constructed selected solution. This establishes the claimed identity, not only a formal series solution. The local holomorphy of every primitive and normal convergence give the final assertion. □

For functions rather than multilinear kernels, group all terms with the same carrier. If $x_y(P,b) = \sum_X x_{y,X}(P_X, b_X)$, then

$$\sup_y \sum_X e^{\kappa_+ \sigma_c(X)} \sup_{\|b_X\|<r} \|x_{y,X}(P_X,b_X)\|_{\mathcal{X}_y} \le Cr. \tag{3.mccv}$$

This is an absolute connected family bound for the whole analytic function. It does not follow merely by summing separate fixed-order decay estimates.

3.41.4. *The literal datum and the field/current outputs.* The explicit inverse outward chart $b_U(B)$ in eq. 3.mxxxiii is local and analytic with uniform C_L^m Taylor bounds. Its outward factor reads only finer interior rows, which are unchanged by that chart. There is no recursive product over already corrected outward data. A one-step complete carrier therefore supplies its connected family, including its actual linear derivative $Db_U(0)$. Substitute that family in eq. 3.mcciii, and reduce the literal radius r_B so its absolute image lies in the reduced datum ball. The same tree majorant then gives eq. 3.mccv with B and a changed fixed constant.

Put $C = \Pi_U(A)$ and $\delta\omega = \nu - a_f b_U(B)$. The point-force identity for the new current can be written without cancellation of its degree-zero terms:

$$\begin{aligned} J_{\mathrm{new}} - J &= (\mathcal{E}_{\eta C}^{-\sharp} - 1)J \\ &\quad + \mathcal{E}_{\eta C}^{-\sharp}\{DN_q(C)^\sharp \omega + D\mathfrak{q}_U(C)^\sharp \delta\omega\}. \end{aligned} \tag{3.mccvi}$$

Here $\omega = H^\sharp J$ still uses the first lift. Every term on the right has positive datum degree. Its row transpose inputs have the actual fine fixed-leg density, so its output is a point force of amplitude three. No adjoint-restoration map is needed after this point-force expression. The divided exponential differential is a bounded local analytic point function.

Proposition 3.168 (Connected families for the literal update)**.** The following outputs have exact holomorphic connected families satisfying a bound Cr of the form eq. 3.mccv on $\|B\|_{\mathcal{B}} < r \le r_B$:

$$A, \quad C, \quad \nu, \quad \delta\omega, \quad J_{\mathrm{new}} - J, \quad \widehat{A}, \quad \widehat{J} - J.$$

Field outputs have the strong norm, multiplier outputs amplitude three, and current outputs point-force amplitude three. The literal potential is defined by $e^{i\eta\widehat{A}}U = \widehat{U}$, with the fixed node extension E_n. Every coefficient retains all actual datum and base read sets. ■

Proof. For $C = SA + \Xi(A)$, substitute the connected solution family in the local finite-gauge series and its strong linear factors. Its degree-one term is $SH_1 b$; higher terms are controlled by the same analytic majorant. The multiplier increment is an exact linear combination of known families. Equation eq. 3.mccvi and the point-force row bounds prove the current assertion by local analytic substitution. Multiplication of two such normalized families has its usual joined-carrier bound.

For literalization let $\zeta = E_n(i^{-1}\log v_U[C]^{-1})$, and $g = e^{i\zeta}$. The actual assigned node factor is a local analytic function of the fine strong field on its complete physical star. At an assigned scale ξ_y, its relative one-step factors at intermediate scale ξ_t have variations bounded by $C_L r\xi_t/\xi_y$ on a uniform complex strong ball. The actual path-row bounds for the group mean give this estimate before any fine coordinates are counted. Since $\sum_{t\le j_y}\xi_t/\xi_y \le L/(L-1)$, their product is uniformly analytic there. The union of its nested read sets lies in a star of radius $C_L\xi_y$, by the same geometric sum. Cauchy gives its C^m strong-cell coefficients. These are the actual relative node products, including the outward one-step factor of eq. 3.mxxxi. The fixed-reference E_n has local $Y^{2,\alpha}$ seeds. Thus ζ has a connected strong site family with norm Cr. The exact relative potential is

$$\widehat{A}_b = (i\eta)^{-1}\log\{g_- e^{i\eta C_b} U_b g_+^{-1} U_b^{-1}\}.$$

It is an analytic local function of $C, \zeta, D\zeta$; its apparent fine-mesh division cancels before expansion, as in eq. 3.mcxliii. The same local substitution proves the strong field assertion. Finally use

$$\widehat{J} - J = \mathrm{Ad}(g_-)(J_{\mathrm{new}} - J) + (\mathrm{Ad}(g_-) - 1)J.$$

This is a local point product of families already controlled and a bounded base current. Its constant datum jet is zero before filing. The bare node values are one and no boundary gauge term is added. □

3.41.5. *Joint base and datum Taylor coefficients.* The preceding coefficients are holomorphic in their local base data. We now record an absolute all-degree statement in those base variables too. The variables are supported Banach slots, not independent raw fine-bond discs.

Fix an interior pair $P_0 = (e^{i\eta E_0}U_*, J_0)$ of the smaller common domain. Let e_y be supported strong field slots and j_y bounded current ownership slots. Write

$$E = E_0 + \sum_y \mathcal{R}_y e_y, \qquad J = J_0 + \sum_y \mathcal{O}_y j_y. \tag{3.mccvii}$$

The smooth reconstruction $\mathcal{R}_y$ has complete collars and bounded overlap. The ownership $\mathcal{O}_y$ is bounded in the point-current norm and need not be smooth, since no current is differentiated. Normalize the slot radii by fixed positive fractions of their admitted tube and current margins.

Every tag and its read collar meet only their own and adjacent assigned levels when $\rho \gg LM_c$. A tag then meets at most $C_L M_c^4$ assigned strong cells. In particular, after one fixed collar enlargement, the number n_X of base slots read by a full carrier satisfies

$$n_X \le C_{L,M_c}\sigma_c(X). \tag{3.mccviii}$$

Each slot may contain arbitrarily many fine coordinates. This count does not count them. The enlargement and its canonical input tags are charged in the initial rate choice. The tag graph has bounded degree D_L. At most C_{L,M_c} assigned output cells belong to one tag. Thus a radius-j tag ball has at most $C_{L,M_c} D_L^{j+1}$ possible output cells. Reserve also a rate $a > \log D_L + 1$ for columns anchored at a base input, in addition to the supported-collar and Taylor rate costs.

Proposition 3.169 (Joint all-degree connected expansion)**.** On fixed sufficiently small reconstructed base slot and literal datum balls, all outputs in Prop. 3.168 have an exact joint Taylor expansion with absolutely summable connected coefficients at the requested final rate κ. If n is the datum degree and ℓ the combined base-slot degree, then

$$\sum_{n\ge 1,\ell\ge 0} r^n \delta^\ell \|\mathbf{F}_{n,\ell}\|_\kappa \le Cr. \tag{3.mccix}$$

Every coefficient contains its output, all datum input cells, all selected base input cells and its full determining-geometry carrier. All coefficients in this display are divided Taylor coefficients in their indicated Banach slots. ■

Proof. Begin with the datum family at a reserved rate larger than the final rate, including the one-time supported-slot collar enlargement. For a fixed carrier its coefficient function is holomorphic on a product of n_X normalized Banach slot balls of a common positive radius. Bounded-overlap reconstruction maps that product into the admitted global strong/current tube. Locality means slots outside its complete read set do not enter.

Multivariate Cauchy and dimension-free polarization bound the coefficient of total base degree ℓ, for each distribution of degrees among slots, by C^ℓ times its larger-ball bound. The polarization factor at degree j is at most $j^j/j! \le e^j$, so it is included in C^ℓ. Summing those distributions on a radius-δ_1 ball costs

$$(1 - C\delta_1)^{-n_X} \le \exp(C'\delta_1 C_{L,M_c}\sigma_c(X)), \qquad C\delta_1 < 1/2.$$

Choose δ_1 so this exponent fits the reserved Taylor rate, while leaving the additional rate a unused. Take the actual base radius $\delta \le \delta_1/2$. The coefficient of degree ℓ then gains $(\delta/\delta_1)^\ell$, so summing the degreewise supremum norms is justified by a geometric series. The original datum row and datum-column norms retain their bounds.

For a column anchored at a base slot w, every contributing carrier contains its tag. The unused rate gives $e^{-a\,\mathrm{dist}_{\mathrm{tag}}(y,w)}$ for its possible output cell y. The tag-ball count above makes the sum over those outputs finite, uniformly in volume and depth. Use the degreewise datum row bound for the remaining carrier and input sums. The same geometric factor sums the base degrees. This proves the base-column bound as well, and hence eq. 3.mccix in the row/column norm, not only its row half. All selected slots meet the declared carrier collar, which already contains their input tags and short joins. Thus the resulting joint Taylor carrier is connected. There is no fine-coordinate Cauchy count.

Every output increment under consideration vanishes at $B = 0$ for every admitted base pair. Its datum expansion was filed with that zero removed before the base expansion. Consequently every resulting joint coefficient has $n \ge 1$, as asserted. Normal convergence identifies the joint series with the same selected germ and literal update. □

3.41.6. *Physical identification and the scope retained.* At a physical pair $J = j_U = Q^\sharp \omega_{\mathrm{phys}}$, the sums are the physical PNC solution and its actual left current after the specified literal gauge. This follows from uniqueness and Props. 3.150 and 3.151; the tree construction does not impose a new physical equation. The first reduced-datum derivatives remain

$$D_b A(0) = H_1, \qquad D_b C(0) = SH_1.$$

Literal data add the actual right factor $Db_U(0)$, and the literal node gauge adds its fine gauge vector to the field derivative. Off current these jets are not equated.

For small periods construct every primitive, local vertex and tree on one common cover before projecting its carrier. Retain each lifted input and every winding join. The absolute tree norm is bounded by the same cover sums. Projection solves the actual finite periodic fixed-point equation, and strong contraction uniqueness identifies its sum. Deck averaging preserves the supported strong bounds and the original physical units. No assertion about a quantum partition function on different volumes is used.

The result supplies all-degree connected families for the selected off-current germ on its fixed strong reference chart. It does not identify a different prescribed core convention, manufacture a reference from arbitrary curvature-only coarse data, or prove history/tower admission or deletion laws. Its local background domains are the stated strong Banach domains. The auxiliary cube-Gaussian discs of a separate formation construction are not being declared independent fine-background discs.

3.42. **The decoupled response on the regular-pair domain.** The equations in eq. 2.x use a field and its first covariant differences. Their background domain is consequently the regular-pair domain of §3.12.1.1. We construct the response on that domain. The Hölder estimates below are estimates on inverse outputs; no Hölder seminorm of the complex background perturbation is assumed. The construction follows the constraint straightening and replacement of propagators in Bałaban's background and cluster arguments [B85e, B88a]. We give the first-order estimates, the independent-current completion, and the complete carrier convention needed for the present averages.

Fix the blocking factor and the separation constants of the positive local inverse construction. All its complete gauge cubes, row reads, outward completions, and local compression collars are retained. A pair is written $\mathbf{U} = e^{i\eta E}U$, $\mathbf{J}$, where U is real, its local gauge potentials and first differences have the regular-pair bounds, and

$$\sup_y\{\xi_y|E|_y + \xi_y^2|\nabla_U E|_y\} < a_*, \qquad \sup_y \xi_y^3|\mathbf{J}|_y < \gamma_*.$$

The curvature bounds in that domain are imposed as well. The positive constants a_*, γ_* are fixed after the finitely many proof carrier rates and minimal tile floors. After the auxiliary inverse construction and its proof rates have been fixed, the local column estimates are uniform in every larger admissible final tile size and separation. Enlarging those final parameters does not decrease these numerical radii: the already constructed families remain available, and reblocking into larger aligned tiles does not increase their carrier norms. At each such choice the regular-pair hypothesis is imposed on that choice's complete gauge cubes and collars. A pair admitted for smaller cubes is not thereby admitted for larger cubes. Obtaining the required local potentials from curvature alone can require a smaller curvature ceiling after the cube size has been fixed. The radii above are independent of depth, fine mesh, compatible volume, and admitted region shape on the resulting regular-pair domain. The current is an independent variable.

Use the physical fine pairing and counting measure on raw rows. A raw row is a logarithmic angle, without division by its length. If Q denotes the per-length row of the propagator construction, set $\widehat{Q} = \mathsf{m}Q$. In this subsection the letters H, H_1, Σ denote the raw-coordinate maps

$$H = \mathsf{H}\mathsf{m}^{-1}, \qquad H_1 = \mathsf{H}_1\mathsf{m}^{-1}, \qquad \Sigma = (\widehat{Q}G\widehat{Q}^\sharp)^{-1}.$$

Thus $\widehat{Q}^\sharp \mathsf{a}\widehat{Q} = Q^\sharp a_f Q$ defines the raw row mass a. A sharp denotes the transpose in these pairings, continued complex linearly. We reserve S for the fine projection $1 - D\Lambda$. Every field derivative, row, site inverse and current completion in this subsection is evaluated at the complex configuration $\mathbf{U}$. Thus an unsubscripted D means $D_{\mathbf{U}}$, and d means its covariant curl. The real factor U is used only to describe the input chart.

For a positive weight satisfying $w(y)/w(z) \le e^{\theta d(y,z)}$, put

$$\begin{aligned} \|A\|_{1,w} &= \sup_y w(y) \max\{\xi_y |A|_y, \xi_y^2 |\nabla_{\mathbf{U}} A|_y\}, \\ |f|_{3,w} &= \sup_y w(y) \xi_y^3 |f|_y, \qquad |b|_w = \sup_c w(y_c)|b(c)|. \end{aligned} \tag{3.mccx}$$

All differences and suprema use complete assigned stencils. The fixed neighborhood radius r_0 below includes these stencils and the complete nonlinear row read. Local scale ratios on this neighborhood are bounded by constants depending only on the blocking factor. The positive inverse decay leaves a fixed admissible $\theta > 0$ after these ratios have been absorbed.

3.42.1. *Strong outputs without a stronger background domain.*

Lemma 3.170. Fix $p = 8$ and $\alpha = 1/4$. The positive field inverse G_F has complete local carrier families from cell L^p forces to $\mathcal{A}_\alpha$, and from covariant divergences of cell C^α tensors to $\mathcal{A}_\alpha$. The assertions hold on the complex C^1 tube just specified. The second assertion uses the infimum norm on representations $f = D^\sharp F + g$, with F of grade two in C^α and g of grade three in cell L^p. ■

Proof. The positive field primitive and its local compressions are those of Lem. 3.161. Its proof uses the background potential and its first difference only. Indeed, after pairing the oppositely oriented covariant shifts, its equation in a local gauge is the ordinary component lattice Laplacian plus first-order and zeroth-order terms with bounded coefficients. The Wilson correction is a bounded curvature term with fixed neighboring shifts. The complete row mass is bounded point forcing from the local energy norm. None of these statements differentiates the curvature. The finite-p bootstrap in eq. 3.dcccxci therefore proves the first assertion on this C^1 tube, coefficient by coefficient.

Here is the additional divergence estimate. In unit cell coordinates let P_t be the flat lattice heat operator. The kernel of $\nabla(L_h + 1)^{-1}\nabla^\sharp$ is $\int_0^\infty e^{-t}\nabla\nabla^\sharp P_t\, dt$. The sum of each differentiated heat kernel is zero. In its action on F, subtract $F(x)$ before taking absolute values. The heat derivative bounds already proved in the discrete estimates give

$$\sum_z |\nabla^2 P_t(x,z)|\,|F(z) - F(x)| \le C t^{-1+\alpha/2}[F]_\alpha \quad (t \ge h^2).$$

For $t < h^2$, the same estimate with t replaced by h^2 and the length of that interval gives a bounded contribution. For the difference between outputs at points a distance r apart, split the integral at r^2. The near part is at most $Cr^\alpha[F]_\alpha$; the far part uses one further heat derivative and is bounded by

$$Cr[F]_\alpha \int_{r^2}^1 t^{(\alpha-3)/2}\, dt + Cr\|F\|_\infty \le Cr^\alpha \|F\|_{C^\alpha}.$$

The mass controls the integral beyond one. These estimates are uniform down to $r = h$.

Apply the finite-p divergence bootstrap eq. 3.dcccxcii first. It bounds $A, \nabla A$ in L^8, and A in the supremum norm on a smaller box. Every lower-order term is now an L^8 force. Its flat inverse has gradient in C^β for every $\beta < 1/2$. The preceding heat calculation handles the prescribed divergence. The difference between a covariant and an ordinary divergence is a bounded potential times F. Cutoff commutators involve only $F, A, \nabla A$ on the next reserved collar. This proves the interior $C^{1,\alpha}$ estimate without a derivative of F or a Hölder bound on a derivative of the background.

For completeness the estimate also gives a family, not only a bound on its complete sum. Use the same local parametrix M and commutator $T = K_F M - 1$ as in the positive field construction. For an initial divergence source, the just proved estimate bounds Mf strongly. The slow cutoff commutator maps that output to a cell L^8 force with norm C/m. Hence $G_F f = Mf - G_F T f$, where the second G_F is its already convergent L^8-force family. This is an exact normally convergent carrier formula. All collars used in the estimate are recorded in its carrier. At a true bare cell the spacing equals the cell scale and the same estimates are finite atomic estimates. The cover and deck averaging prescription of Prop. 3.112 preserves these bounds. □

Proposition 3.171. On the preceding regular-pair domain, the raw maps H, H_1, Σ, and

$$\mathcal{G} = G_1 - G_1 D R D^\sharp G_1 - H_1 \widehat{Q} G_1$$

have exact complete local carrier families with exponentially summable norms from raw row amplitudes, or bounded grade-three forces, to the first-order norm in eq. 3.mccx. The same assertion holds for H_0, $\widetilde{G} = G_0 - H_0 \widehat{Q} G_0$, and $P_1 = D(1-R)D^\sharp$, the last as a map from first-order fields to grade-three forces. The physical transpose $H^\sharp$ maps bounded grade-three forces to raw row amplitudes with the corresponding column bound. Every coefficient is holomorphic in the background and independent current on its complete local domain. ■

Proof. We specify the changes needed in the strong-family argument; the positive coarse inversions and complete current coefficients remain those of Prop. 3.112. The site inverse, its normalized columns, and the two adjoint families in eq. 3.mclxxxvii use only bounded background potentials and first differences. Their proofs through eq. 3.mclxxxix therefore apply on the present domain. The positive field factor is supplied by Lem. 3.170. Woodbury's formula gives $G_0 : \mathcal{F}_8 \to \mathcal{A}_\alpha$.

For $v \in \mathcal{A}_\alpha$, set $\lambda = \Lambda v = G_s R D^\sharp v$. The source $D^\sharp v$ is bounded of grade two. The projection $R = 1 - \widehat{F}\widehat{M}^{-1}\widehat{F}^\sharp$ preserves this bounded source class, since its column factor is bounded and its two absolute cell sums converge. The bounded-source site bootstrap gives bounded $\lambda, D\lambda$, of grades zero and one. This is the only regularity of Λv needed here. In particular $Sv = v - D\lambda$ is bounded of grade one.

The exact grouped first current correction is

$$B_{\mathbf{U}}[J]v = W[J]\lambda + \Lambda^\sharp\{W[J]^\sharp v - \tfrac{1}{2} W[J]^\sharp D\lambda\} - \tfrac{1}{2}\Lambda^\sharp D^\sharp W[J]\lambda. \tag{3.mccxi}$$

Here $W[J]\lambda(b) = \frac{i}{2}[\lambda(b_-) + \mathrm{Ad}(\mathbf{U}(b))\lambda(b_+), J(b)]$. The first term is a bounded grade-three force. The source of $\Lambda^\sharp$ in braces is bounded of grade four; the last term uses the finite-p bound eq. 3.mclxxxviii. Thus $B_{\mathbf{U}}[J] : \mathcal{A}_\alpha \to \mathcal{F}_8$ has family norm $C\gamma_*$, with no difference of J. The Neumann series for G converges in these spaces after a fixed decrease of γ_*.

The first row inverse and H now follow from eq. 3.mvi, using the actual bounded row injection. Its multiplier $H^\sharp J$ keeps the fine-current root and has eq. 3.mviii. The second row jet has both absolute leg sums and the physical fine density of eq. 3.mxi; it consequently maps a bounded grade-one field to a bounded grade-three force. Since Sv is bounded, and $S^\sharp$ is bounded on $\mathcal{F}_8$,

$$\|\mathbf{S}^\sharp \boldsymbol{\Delta}^{(\mathbf{2})}[\mathbf{H}^\sharp \mathbf{J}]\mathbf{S}\|_{\mathcal{A}_\alpha \to \mathcal{F}_8} \le C\gamma_*.$$

The second Neumann series and second row inversion give G_1, H_1. This argument does not assert that S preserves $\mathcal{A}_\alpha$ on the larger background domain.

It remains to check $G_1 D R D^\sharp G_1$. For a bounded grade-three source f, the first G_1 has $C^{1,\alpha}$ output. Therefore $D^\sharp G_1 f$ is a grade-two C^α site source. The potential in $D^\sharp$ is Lipschitz, which suffices for this conclusion. The same column formula for R, whose site columns have bounded first derivatives, preserves this C^α class. The final $G_1 D$ is bounded on it by Lem. 3.170, followed by Woodbury and the two small-current series. These are coefficientwise estimates in the joined-carrier algebra. They prove the asserted family for $\mathcal{G}$. Likewise $P_1 = D\widehat{F}\widehat{M}^{-1}\widehat{F}^\sharp D^\sharp$ uses only bounded first derivatives of the site columns and of the input field.

Finally each cell pairing for $H^\sharp f$ costs $\xi^{-1}\xi^{-3}\xi^4 = 1$. The absolute column sum proves the raw row bound. The raw-coordinate changes are precisely the physical weights in eq. 3.mxvi. All series above converge normally on the same smaller C^1 tube. They preserve their input and output collars, the read of the independent current, and the specified coarse Gram inverses. This proves both holomorphy and locality. □

3.42.2. *Cube parameters and local nonlinear coefficients.* Choose the partition P after the inverse tiles. Each coefficient is assigned its complete connected hull before intersection with Ω_0. Use the following cell convention. For a tile q at scale ξ_q, its j-enlargement has width $j\mathfrak{M}\xi_q$, $0 \le j \le 5$,

and its uncut hull has width $5\mathfrak{M}\xi_q$. A cell hull is the union of these tile hulls. Choose the fixed lower floor for $\mathfrak{M}$ so that output and input supports fit the one-enlargements and each successive nonlinear read fits the next enlargement. The local inverse compressions and their bootstrap collars are recorded within the five-enlargements; fixed reblocking, before choosing the partition, achieves this for the finitely many proof primitives. This is a choice of the common geometric hierarchy, not a deletion of rows from a previously specified sequence. All factors in a product, including output cutoffs, endpoint columns, current roots, and short joins, are retained. Let $\mathsf{P}(C)$ be the cubes meeting this hull. Use face connectivity, adding the finitely many intervening cubes at a face or corner when necessary. This convention is fixed before introducing the parameters.

Lemma 3.172. For $\bar\kappa \ge 0$, the partition side can be chosen so that each family in Prop. 3.171 defines

$$O_Y(s) = \sum_{\mathsf{P}(C)\subset Y} \Big(\prod_{\Delta\in\mathsf{P}(C)} s(\Delta)\Big) O_C, \qquad |s(\Delta)| \le e^{\bar\kappa}, \tag{3.mccxii}$$

with normally convergent row and column sums. For one constant $b = Ce^{C\bar\kappa} \ge 2$, all its weighted operator norms needed in eq. 3.mccx are at most b, including $H_s^\sharp$ and $P_{1,s}$. A fixed positive exponential decay rate remains. No algebraic inverse identity is claimed for the decorated maps at $s \ne 1$. ■

Proof. Choose a target side ℓ_*, a compatible power of L, at least $C(1+\bar\kappa)$ times the largest fixed tile size and the inverse of a reserved carrier rate. Write p for the side of the present cubic torus in the same units. First suppose $p \ge 3\ell_*$, and take $\ell_{\mathsf{P}} = \ell_*$. Cover the connected hull by balls whose radius is a fixed fraction of ℓ_{P}. Starting at an endpoint, charge a new ball to the first tree segment leaving the previous ball. Disjoint charged segments have total length at most a fixed multiple of the hull tree length $\ell(C)$. Each ball meets at most a dimension-dependent number of partition cubes, and the fixed carrier thickness is smaller than that radius. Hence

$$\#\mathsf{P}(C) \le C_0 + C_1\ell(C)/\ell_{\mathsf{P}}.$$

The factor $e^{\bar\kappa\#\mathsf{P}(C)}$ consumes at most half the reserved rate and leaves $e^{C_0\bar\kappa}$.

If $p < 3\ell_*$, use instead the coarsest compatible partition, of side $p/2$. The declared tori have equal sides that are twice a power of L, so this partition has exactly 2^4 cubes. For every carrier,

$$\#\mathsf{P}(C) \le 16, \qquad \Big|\prod_{\Delta\in\mathsf{P}(C)} s(\Delta)\Big| \le e^{16\bar\kappa}.$$

No spatial decay is spent in this case. When primitive patches require a cover, first construct and deck-average the undecorated families on one common cover, as in Prop. 3.112. Retain the full lifted carrier and its collars when projecting it. Only then assign the product of parameters, once for each distinct base cube meeting the projected complete hull. Several lifted cubes or carrier visits can therefore use the same base parameter only once in this coefficient. This prescription is squarefree in the independent base parameters; it is not substitution of tied variables into an already decorated cover monomial. The parameter factor is unchanged by a deck translation, and its absolute bound multiplies the descended row and column majorants without a sheet-count factor.

The projected complete hull still contains every projected input, output and nonlinear-read collar. It is connected, and its cube set is face connected with the fixed joins. Thus a coefficient surviving an active mask lies in one wall component. The five-enlargement stocks are formed from these complete projected hulls; a neighborhood path lifts starting at its chosen carrier lift, so their successive-read inclusions and component separation persist. This changes only the auxiliary parameter partition and supplies no identification with a separately prescribed history partition.

In either case the remaining row and column sums are the convergent carrier sums of Prop. 3.171. Increasing the fixed constant in $b = Ce^{C\bar\kappa}$ to include 16 proves the asserted weighted bounds. Normal convergence on smaller polydiscs proves holomorphy. The coefficient prescription on complete

common lifts proves transport compatibility whenever the parameter partitions and recorded geometry are carried as well. Gauge averaging and averaging with complex conjugation preserve the invariant coefficient norms and the complete sums. □

For a union Z of active cubes, define $\mathbb{Y}^j(Z)$ to be the assigned sites in the j-enlargements of tiles belonging to cells X whose complete uncut hull has $\mathsf{P}(X) \subset Z$. This is the five-enlargement convention for $j = 0, \dots, 5$, rather than erosion of $\Omega_0 \cap \bigcup Z$. The chosen floor gives $N_{r_0}(\mathbb{Y}^j(Z)) \subset \mathbb{Y}^{j+1}(Z)$ for $j \le 4$, and puts all these reads in $\Omega_0 \cap \bigcup Z$. This preserves the actual determining sequence and the indicated $\mathbb{Y}^1, \mathbb{Y}^2, \mathbb{Y}^3$ stocks. Retain nonlinear rows and the plaquette pairing at $\mathbb{Y}^2(Y)$, force values at $\mathbb{Y}^1(Y)$, and first-difference reads at $\mathbb{Y}^3(Y)$. A retained nonbare force has all six incident plaquettes. At a true bare boundary its cell scale is the fine spacing. Zero extension outside these stocks defines the local maps.

Write $\mathcal{Q}(A) = \widehat{Q}A + C(A)$ for the actual iterated straightened logarithmic average and

$$F(A) = \sum_{p \subset \Omega_0 \cap \bigcup Y} a_p(e^{i\eta A}\mathbf{U}), \qquad V(A) = F'(A) - F'(0) - F''(0)A, \qquad \Delta' = F''(0) - \mathrm{d}^\sharp \mathrm{d}.$$

Only the retained force values enter V, Δ'. The associated bilinear form is $\mathcal{E}(A, B) = (\mathrm{d}A, \mathrm{d}B)_\eta$ on the retained plaquette stock, with the same complete read convention.

Lemma 3.173. There are fixed $c, C > 0$ such that, for $\|A_i\|_1 \le r < c$, the local maps just defined obey

$$\begin{aligned} |C(A)|_y &\le C \max_{N_{r_0}(y)} |A|_{\mathrm{sc}}^2, & |C(A_1) - C(A_2)|_w &\le Cr\|A_1 - A_2\|_{1,w}, \\ |C_A'^\sharp z|_{3,w} &\le Cr|z|_w, & |(C_{A_1}' - C_{A_2}')^\sharp z|_{3,w} &\le C\|A_1 - A_2\|_{1,w}|z|, \\ |V(A)|_{3,w} &\le C\|A\|_1\|A\|_{1,w}, & |V(A_1) - V(A_2)|_{3,w} &\le Cr\|A_1 - A_2\|_{1,w}. \end{aligned} \tag{3.mccxiii}$$

The same bounds hold with the weight on the multiplier in the second line. The linear maps $\widehat{Q}, \widehat{Q}^\sharp, \Delta'$ have the corresponding fixed local bounds. All maps are holomorphic in the actual local data, covariant, real on real data, and determined by their complete reads. In particular $C(0) = C_0' = V(0) = V'(0) = 0$. ■

Proof. For the row maps use the complete iterated-average expansion in Prop. 3.6, with its absolute row and column sums and physical transpose. Iteration is in raw angles; the factors of successive row lengths form the geometric sums in that proof. The first nonlinear coefficient is quadratic. Cauchy's formula on a fixed larger amplitude ball gives the two derivative bounds; one uses the absolute fixed-leg column sum for the transpose. Local weights on a complete read differ by at most $e^{\theta r_0}$, which is incorporated in C.

We record the cancellation needed for the action bound. Rescale one assigned cell to unit size and denote its fine mesh by h. For a plaquette transport the four field values to its base, writing them as $\alpha_1, \dots, \alpha_4$, with the last two reversed. Set

$$ih^2\Theta_p = \log(e^{-ih\alpha_3}e^{-ih\alpha_4}e^{ih\alpha_1}e^{ih\alpha_2}), \qquad \Theta_p = (\mathrm{d}A)(p) + N_p.$$

The exponential and logarithm series on a fixed small ball give $|N_p| \le Cs^2$, $|N_p'| \le Cs$, where $s = \max|A|$. Also $|\Theta_p| \le C(g + s^2)$, where $g = \max|\nabla_{\mathbf{U}}A|$, and $h|\Theta_p| \le Cs$. Write the background plaquette as $c_p 1 + ih^2 F_p$. The two by two determinant identity gives $|c_p - 1| \le Ca_*^2h^4$. Expansion of its trace against $e^{ih^2\Theta_p}$ shows that the plaquette derivative is

$$h^4\langle F_p + c_p\Theta_p + M_p, \delta\Theta_p\rangle, \qquad |M_p| \le Ch^4(|\Theta_p|^3 + a_*|\Theta_p|^2).$$

At a nonbare force bond pair the opposite incident plaquettes before dividing by h. Transported differences of their N_p's are bounded by $Chsg$, by the bound on N_p'. The terms $(c_p - 1)\mathrm{d}A$ are bounded after the two differences by Ca_*s, using their h^4 factor. The terms M_p are bounded after

one difference by $Cs^2(s+a_*)$, using $h|\Theta_p| \le Cs$. The remaining differentiated N_p factor costs $Cs(a_*+g+s^2)$. Therefore

$$|F'(A)-F'(0)-\mathrm{d}^\sharp \mathrm{d}A| \le Cs(a_*+\max\{s,g\}).$$

Put $n=\max\{s,g\}$ and $w(z)=F'(zA)-F'(0)-z\mathrm{d}^\sharp \mathrm{d}A$. The preceding estimate gives $|w(z)| \le C|z|s(a_*+|z|n)$ whenever $|z|s \le c_0$, for a fixed $c_0>0$. The case $s=0$ is immediate. For $s>0$, Cauchy's formula on $|z|=R$ bounds the linear coefficient by $Cs(a_*+Rn)$. Letting $R \downarrow 0$ gives $|\Delta' A| \le Ca_* s$, without a first-difference term. To bound the higher coefficients, take $T=c_0/s \ge 2$, decreasing the field radius if necessary. Cauchy's formula gives $|[z^q]w| \le CsT^{1-q}(a_*+Tn)$, so

$$|V(A)| \le 2Cs(a_*/T+n) \le Csn.$$

The last inequality uses the fixed bound for a_* and $s \le n$. This proves the bounds on Δ' and V. At a bare cell $h=1$; direct absolute estimates on the at most six plaquettes give the same bounds. The small amplitude ball is fixed before the mesh is chosen. Polarization, or Cauchy's formula along the segment between two fields on a ball twice as large, gives the Lipschitz estimate. Rescaling supplies the factors ξ_y, ξ_y^2, ξ_y^3. All identities used are local products, convergent logarithms, and physical transposes. They prove the final assertions as well. □

3.42.3. *The two fixed points and the current.* Write $C''[a]=(\mathrm{d}C_2)_a$, where C_2 is the quadratic part of C. For $\|a\|_1 < c/b$ define

$$D_s(a)=C(a-H_sD_s(a)), \qquad T_s(a)=a-H_sD_s(a), \qquad E_s(a)=C'_{T_s(a)}{}^\sharp(1+H_s^\sharp C'_{T_s(a)}{}^\sharp)^{-1}. \tag{3.mccxiv}$$

The first equation is solved by iteration from zero. Define, for every parameter value, the following particular nonlinear force:

$$\begin{aligned} W_s(a) = &-[E_s(a)-C''[a]^\sharp]H_s^\sharp \mathbf{J} - \widehat{Q}^\sharp(\Sigma_s-\mathsf{a})D_s(a) \\ &- E_s(a)(\Sigma_s-\mathsf{a})\widehat{Q}a + E_s(a)(\Sigma_s-\mathsf{a})D_s(a) \\ &+ V(T_s(a)) - E_s(a)H_s^\sharp V(T_s(a)). \end{aligned} \tag{3.mccxv}$$

This is the force specified in eq. 3.cdxlv. Its definition uses bounds on the decorated maps, and does not use $\widehat{Q}H_s=1$ or a slice identity at general s.

Proposition 3.174. There are fixed $c, C>0$ such that the following holds with $r=cb^{-8}$, where b is the constant of Lem. 3.172. For $|B'|<r$, the equations

$$a=H_{1,s}B'+A_1, \qquad A_1=-\mathcal{G}_s W_s(a), \qquad \mathbf{H}=T_s(a) \tag{3.mccxvi}$$

and eq. 3.mccxiv have a unique solution in $\|A_1\|_1 \le br$, $|D_s| \le Cb^2r^2$. They are exactly eq. 2.x in raw coordinates. The solution is holomorphic jointly in $s, B', \mathbf{U}, \mathbf{J}$ on the indicated open domains and satisfies

$$\|\mathbf{H}\|_{1,w} \le Cb|B'|_w, \qquad \|A_1\|_{1,w} \le Cb^5|B'||B'|_w, \qquad \|\delta\mathbf{H}\|_{1,w} \le Cb|\delta B'|_w. \tag{3.mccxvii}$$

Here the difference is between two data in the same ball. The field and its datum derivative also satisfy the corresponding $\mathcal{A}_{1/4}$ output estimates, with a fixed larger power of b.

For $\|A\|_1 \le 4br$, put

$$\begin{aligned} \langle H_s^{\circledast}(A)(c), e\rangle &= \mathcal{E}(A, H_s e_c) + (\Delta' A + V(A), H_s e_c)_\eta, \\ \Psi_{s,A} &= (1+H_s^\sharp C'_A{}^\sharp)^{-1}, \qquad \omega_s(A) = \Psi_{s,A}[H_s^\sharp \mathbf{J} + H_s^{\circledast}(A)], \\ j_s(A) &= f_A^{-1}(\widehat{Q}+C'_A)^\sharp \omega_s(A) - \widehat{Q}^\sharp H_s^\sharp \mathbf{J}, \end{aligned} \tag{3.mccxviii}$$

where $f_A(b)=\sum_{n\ge 0}(-i\eta\,\mathrm{ad}_{A(b)})^n/(n+1)!$. Then the reduced response is $\mathfrak{h}_Y=(\mathbf{H}, j_s(\mathbf{H}))$. It vanishes at $B'=0$, and

$$|j_s(\mathbf{H})|_{3,w} + |P_{1,s}\mathbf{H}|_{3,w} \le Cb^4|B'|_w, \qquad |\delta j_s(\mathbf{H})|_{3,w} \le Cb^4|\delta B'|_w. \tag{3.mccxix}$$

The shifted independent current is $\mathbf{J} + j_s(\mathbf{H})$. ■

Proof. Let $\|a\|_1 \le \varepsilon < c/b$. By Lem. 3.173, the first equation of eq. 3.mccxiv maps the row ball $|D| \le C\varepsilon^2$ into itself and has Lipschitz constant $Cb\varepsilon < 1/4$. Its solution satisfies

$$|D_s(a)|_w \le C\varepsilon\|a\|_{1,w}, \quad |\delta D_s|_w \le C\varepsilon\|\delta a\|_{1,w}, \quad \|T_s(a)\|_1 \le 2\varepsilon, \quad \|\delta T_s\|_{1,w} \le 2\|\delta a\|_{1,w}.$$

Differentiation of that fixed-point equation gives the last expression in eq. 3.mccxiv. In particular $E_s(a) = C''[a]^\sharp + O(b\varepsilon^2)$ as a map from raw multipliers to bounded forces. To check the quadratic error, write $C'_{T_s(a)} - C''[a] = (C'_{T_s(a)} - C''[T_s(a)]) + C''[T_s(a) - a]$. The first term is quadratic by Cauchy's formula and the second is bounded by $Cb\varepsilon^2$; the inverse in eq. 3.mccxiv differs from one by $Cb\varepsilon$. The same decomposition gives its difference bound $Cb\varepsilon\|\delta a\|_{1,w}$.

Insert these bounds into each of the six terms of eq. 3.mccxv. The first term uses $|H_s^\sharp \mathbf{J}| \le b\gamma_*$. The result, with a fixed larger C, is

$$|W_s(a)|_{3,w} \le Cb^2\varepsilon\|a\|_{1,w}, \qquad |\delta W_s|_{3,w} \le Cb^2\varepsilon\|\delta a\|_{1,w}. \tag{3.mccxx}$$

For $\|A_1\|_1 \le br$, $|B'| \le r$, take $\varepsilon = 2br$. The outer map in eq. 3.mccxvi has norm at most Cb^5r^2 and Lipschitz constant at most $Cb^4r < 1/4$. It maps the stated ball into itself. Banach's theorem proves existence and uniqueness. Subtracting the two fixed-point equations in a weighted norm and absorbing the same constant proves eq. 3.mccxvii. The iterates are holomorphic and converge uniformly on smaller polydiscs, proving joint holomorphy. The construction remains valid on each local chart of the regular-pair domain; agreement on overlapping charts follows from the identical equations and contraction uniqueness. For the stronger output assertion, let $\|\cdot\|_{\mathcal{A}_{1/4};w}$ be the norm in eq. 3.dccclxxxvii, with each complete local-box norm multiplied by $w(y)$. The weight is not differentiated. The strong families in Prop. 3.171, with the parameter summation of Lem. 3.172, give

$$\|H_s z\|_{\mathcal{A}_{1/4};w}, \quad \|H_{1,s} z\|_{\mathcal{A}_{1/4};w} \le b_{\mathrm{str}}|z|_w, \qquad \|\mathcal{G}_s f\|_{\mathcal{A}_{1/4};w} \le b_{\mathrm{str}}|f|_{3,w}, \qquad b_{\mathrm{str}} \le Cb^q$$

for a fixed exponent q. These are first-gradient Hölder output norms on the same background domain. For two data in the indicated ball, subtract the exact equations:

$$\delta\mathbf{H} = H_{1,s}\delta B' - \mathcal{G}_s\delta W_s - H_s\delta D_s.$$

The weighted fixed-point estimates already give $\|\delta a\|_{1,w} \le Cb|\delta B'|_w$. With $\varepsilon = 2br$, the force and straightening bounds yield

$$|\delta W_s|_{3,w} \le Cb^4 r|\delta B'|_w, \qquad |\delta D_s|_w \le Cb^2 r|\delta B'|_w.$$

Consequently $\|\delta\mathbf{H}\|_{\mathcal{A}_{1/4};w} \le Cb^q|\delta B'|_w$, since $r = cb^{-8}$. Taking one datum to be zero bounds the field itself. At every datum in the open ball, divide by the size of a complex datum increment and pass to the derivative. Holomorphy and continuity of the finite-lattice norm give the same bound for the datum derivative on that whole ball.

For the current, the physical gradient pairing gives

$$|H_s^{\circledast}(A)|_w \le Cb(\|A\|_{1,w} + \|A\|_1\|A\|_{1,w}).$$

In the curl term the two first differences have grades two and two, so the cell factor is $\xi^{-2}\xi^{-2}\xi^4 = 1$. The other terms use the field/force pairing and its column sum. The same estimate holds for differences. Since $\|H_s^\sharp C'^\sharp_A\| \le Cb\|A\|_1 < 1/4$, $\Psi_{s,A}$ is uniformly bounded. It follows that

$$|\omega_s(A) - H_s^\sharp\mathbf{J}|_w \le Cb(1 + b\gamma_*)\|A\|_{1,w}.$$

The exponential series gives $\|f_A^{-1}\| \le 2$ and $\|f_A^{-1} - 1\| \le C\eta|A|$, with the corresponding difference bounds. Expand the last line of eq. 3.mccxviii around $A = 0$; its constant term cancels. The local transpose estimate and the preceding multiplier bound give $|j_s(A)|_{3,w} \le Cb^3\|A\|_{1,w}$, and the same Lipschitz estimate. Combine this with eq. 3.mccxvii and the bound on $P_{1,s}$. □

Proposition 3.175. The response of Prop. 3.174 is real on real data and real parameters, gauge covariant, and compatible with common-lift transport. If Z is a union of wall components of $\{\Delta : s(\Delta) \neq 0\}$, its restriction is the response formed using precisely those ambient carrier coefficients whose complete cube sets lie in Z. The field is supported over $\mathbb{Y}^1(Z)$; its reduced current and projected field are supported over $\mathbb{Y}^2(Z)$. All their complete native reads lie over $\mathbb{Y}^3(Z)$. A component with no retained datum has zero response.

If every cube meeting any complete cell hull has parameter one, all three fields equal their all-one fields on that same sequence. At the all-one point their complete sums are independent of the auxiliary carrier tiling and parameter partition. They commute with an identification of two regional sequences that preserves all local field, row, gauge, and geometry data in common lifts. For a general proper mask the derivative of the first response at zero is $H_{1,s}$; its linearized constraint is $\widehat{Q}H_{1,s}B'$. ■

Proof. The cube set of a surviving coefficient is face connected and contains its complete input and output read collars. It therefore lies in one active wall component. Formula eq. 3.mccxii splits into a direct sum over these components. The local maps in Lem. 3.173 cannot cross their reserved collars. Starting both iterations at zero proves the same direct-sum assertion for every iterate and hence for its limit. The transpose, curl pairing, and local row derivative in eq. 3.mccxviii use at most the next two reads; this proves the asserted support of the current. The field, current and projected field vanish on a component with zero datum because the zero iterate remains zero there. An indicator of a component consequently creates no commutator on these complete native reads.

Every coefficient and local operation is real, covariant and transported with its complete determining data. The same iteration argument proves these properties. At the specified one-valued cubes every coefficient weight is one and the local structure is the whole-sequence structure. Absolute summation gives the actual operators, independently of their expansion. Their physical formulas and local structure commute with the stated identification; uniqueness identifies the responses. Finally $D_s(0) = D_s'(0) = W_s(0) = W_s'(0) = 0$, which gives the last assertion by differentiation. Thus restriction to an active component identifies its restricted ambient solve. Identification with a different sequence's solve requires the indicated equality of determining data and operators. □

3.42.4. *Physical identification and the coupled response.*

Proposition 3.176. Let Y contain every complete cell hull of the determining sequence, let $s = 1$ there, and let U_0 be a real critical reference in the regular class, with its physical current $J(U_0) = \widehat{Q}^\sharp\lambda_0$. Use the closed noninward determining stock, including the complete preceding block at every outward row. For the response of Prop. 3.174,

$$\mathcal{Q}(\mathbf{H}) = B', \qquad RD^\sharp\mathbf{H} = 0, \qquad F'(\mathbf{H}) = (\widehat{Q} + C'_{\mathbf{H}})^\sharp\omega_1(\mathbf{H}). \tag{3.mccxxi}$$

Consequently $J(U_0) + j_1(\mathbf{H}) = J(e^{i\eta\mathbf{H}}U_0)$ and $P_{1,1}\mathbf{H} = DD^\sharp\mathbf{H}$. Every sufficiently small critical field on this slice is this response at its own reduced datum. The node factors and the change between ordinary and reduced outward data are the actual ones of eq. 3.cccxi–eq. 3.cccxiii. They depend only on the complete corresponding row or top pillar, are holomorphic on a fixed larger small ball, and commute with restriction and common-lift transport on those reads. ■

Proof. The current identification in Prop. 3.90 identifies the second precision on the Landau slice with the Hessian of the constrained action. In particular $\mathcal{G}$ is its inverse on $\mathcal{K} = \ker\widehat{Q} \cap \ker RD^\sharp$, and H, H_1 lie in the Landau slice, with $\widehat{Q}H = \widehat{Q}H_1 = 1$. The first equation of eq. 3.mccxiv therefore gives the first two equations of eq. 3.mccxxi. Differentiate the straightening map. On $\mathcal{K}$ its derivative maps bijectively onto $\ker(\widehat{Q} + C'_{\mathbf{H}}) \cap \ker RD^\sharp$, since it differs from the identity by $O(b\|a\|_1)$. Here is the exact action calculation. Write $\Delta_\pi = F''(0) - B_{U_0}[J]$, $\Delta_1 = \Delta_\pi - S^\sharp\Delta^{(2)}[H^\sharp J]S$, and $V_0(T) = F(T) - F(0) - (J,T) - \frac{1}{2}(T, F''(0)T)$. For a on the Landau slice, put

$D = D_1(a)$, $T = a - HD$, and $P = \Sigma - \mathsf{a}$. The exact identities $\Delta_\pi H = \widehat{Q}^\sharp P$, $H^\sharp \Delta_\pi H = P$, and $\frac{1}{2}(a, \Delta^{(2)}[H^\sharp J]a) = (C_2(a), H^\sharp J)$ give

$$F(T) = F(0) + (J, a) + \tfrac{1}{2}(a, \Delta_1 a) + \mathcal{R}(a),$$
$$\mathcal{R}(a) = -(D - C_2(a), H^\sharp J) - (\widehat{Q}a, PD) + \tfrac{1}{2}(D, PD) + V_0(T). \tag{3.mccxxii}$$

The pairings in each term are its physical fine or raw row pairing. The first two identities follow from $G^{-1}H = \widehat{Q}^\sharp \Sigma$ and $RD^\sharp H = 0$. The current completion vanishes bilinearly on two Landau fields, so $F''(0)$ may be replaced by Δ_π in their pairing. Differentiating eq. 3.mccxxii, using $(\mathrm{d}D)^\sharp_a = E_1(a)$, yields precisely

$$(F'(T), (\mathrm{d}T)_a \delta) = (J + \Delta_1 a + W_1(a), \delta)$$

for every slice vector δ. The six derivatives of $\mathcal{R}$ are the six terms of eq. 3.mccxv, with their displayed signs. On $\mathcal{K}$, Δ_1 is the precision inverted by $\mathcal{G}$, while $\Delta_1 H_1 B'$ and J annihilate $\mathcal{K}$. Thus the outer fixed-point equation makes $F'(\mathbf{H})$ annihilate the constrained tangent space.

Finite-dimensional annihilator duality now gives $F'(\mathbf{H}) = (\widehat{Q} + C'_{\mathbf{H}})^\sharp \lambda + DR\phi$. Pairing with H gives $\lambda = \omega_1(\mathbf{H})$, because $H^\sharp DR = 0$ and $H^\sharp F'(\mathbf{H}) = H^\sharp J + H^{\circledast}(\mathbf{H})$. The remaining gauge multiplier vanishes. Here no uniform second-derivative gauge estimate is needed: on each fixed finite lattice, the infinitesimal gauge directions with trivial reduced site averages map onto $\operatorname{ran} R$ under $RD^\sharp$ at zero, by the actual site inverse. Surjectivity persists in some neighborhood of zero. The action is invariant on those directions and their reduced constraint derivative is zero. For real data in this neighborhood, pair with a gauge direction whose $RD^\sharp$ value is $R\phi$. The result is $\|R\phi\|_2^2 = 0$. The residual is holomorphic throughout the uniform datum ball and vanishes on its real neighborhood of zero; the identity theorem extends its vanishing to that ball. This proves the last equation in eq. 3.mccxxi.

Differentiating $e^{i\eta A}$ shows directly that $F'(A) = f_A J(e^{i\eta A} U_0)$. Inserting this in eq. 3.mccxviii gives the physical current identity. The projection identity follows from $RD^\sharp \mathbf{H} = 0$. Conversely a sufficiently small critical field on this slice has a unique multiplier, since $(\widehat{Q} + C'_A)H = 1 + C'_A H$ is invertible. Reversing the straightening calculation makes it a solution of the same two contractive equations; uniqueness identifies it.

The node statements follow from the exact iterated averaging identity: each elementary node factor is the small logarithmic mean of finitely many transports in its block. Its convergent exponential and logarithm formulas read only that block. Successive factor errors have the length factors of the averaging iteration; their geometric sum gives the fixed ball and bound in eq. 3.cccxiii. At an outward row the only additional factor is the node factor of its preceding lower block. Solving the triangular near-identity change of raw data gives eq. 3.cccxii, with the same complete read. These identities also prove the covariance and transport assertions. □

Proposition 3.177. The actual coupled system eq. 3.cdxliv, using the families of Lem. 3.172, has a unique small solution when $\gamma + |B'| \le cb^{-3}$, where $\gamma = |\mathbf{J}|_3$. In the centered multiplier variable $\mu = \lambda - H_s^\sharp \mathbf{J}$, it satisfies

$$\|T\|_{1,w} + |\mu|_w \le Cb|B'|_w.$$

It has the same holomorphy, weighted locality, covariance and transport properties on its own complete reads. The component restriction and support assertions apply to T and $\mu + \mathsf{a}B'$. The centered multiplier μ itself retains the local term $-\mathsf{a}B'$ outside the active components. At $B' = 0$, $T = \mu = 0$. At the whole-sequence all-one point specified in Prop. 3.176, over a physical critical reference and on the same closed determining stock, it is the same sufficiently small constrained critical field as Prop. 3.176, after the prescribed change of raw data. Equality of the two decoupled systems away from $s = 1$ is not asserted. ■

Proof. Substitute $\lambda = H_s^\sharp \mathbf{J} + \mu$ into eq. 3.cdxliv. Its constant term is $(H_{0,s}B', (\Sigma_s - \mathsf{a})B')$. On the ball $\|T\|_1 + |\mu| \le Cbr$, the remaining terms have Lipschitz constant at most $Cb^2(\gamma + r)$, by

Lem. 3.173. Decrease c so this is below $1/4$; the ball is invariant. The weighted subtraction proof and normally convergent iterates give all the quantitative and analytic assertions. Carrier supports give transport as in Prop. 3.175. For the component assertion retain the local multiplier term. Writing $N_T = V(T) - C_T'^{\sharp}\lambda$, the second equation is

$$\mu + \mathsf{a}B' = \Sigma_s[B' - C(T)] + H_s^{\sharp}N_T + \mathsf{a}C(T).$$

The first two terms have their indicated carrier supports, and the last reads only the next complete row neighborhood of the support of T. The reserved collars separate these reads between active wall components. For a component carrier $\mathbb{Y}_i = \mathbb{Y}^1(c_i)$, the field T_i is supported over $\mathbb{Y}_i$, and $\mu_i + \mathsf{a}B'$ is supported on its first complete row neighborhood. The datum is read on that neighborhood: the local term $-\mathsf{a}B'$ also enters $C_{T_i}'^{\sharp}\lambda_i$. These reads lie in $\mathbb{Y}^2(c_i)$. If T_i, μ_i are obtained using the maps of component i, with the same full datum, the fixed-point equations and uniqueness give

$$T = \sum_i T_i, \qquad \mu = -\mathsf{a}B' + \sum_i (\mu_i + \mathsf{a}B').$$

In verifying these equations, λ and its component counterpart agree on every row read by $C_T'^{\sharp}$ in that component; their common remaining term is $-\mathsf{a}B'$. Thus the assertion also holds when no carrier survives: then $T = 0$ and $\mu = -\mathsf{a}B'$. For the physical identification start with the already constructed response of Prop. 3.176 on the common smaller datum ball. Put $K_T = \widehat{Q} + C_T'$ and $R_T = V(T) - C_T'^{\sharp}\lambda$. Its Euler equation and slice condition give

$$G_0^{-1}T = \widehat{Q}^{\sharp}[\lambda - \lambda_0 + \mathsf{a}\widehat{Q}T] - R_T.$$

The exact identities $\widetilde{G}\widehat{Q}^{\sharp} = 0$ and $\widetilde{G}G_0^{-1} = 1 - H_0\widehat{Q}$ give the first coupled equation. For the second, pair the Euler equation with H. Since H, T are Landau fields, their current-completion pairing vanishes, and

$$H^{\sharp}F''(0)T = H^{\sharp}\Delta_{\pi}T = (\Sigma - \mathsf{a})\widehat{Q}T, \qquad H^{\sharp}J = \lambda_0.$$

It follows that $\lambda = H^{\sharp}J + (\Sigma - \mathsf{a})\widehat{Q}T + H^{\sharp}R_T$, the second coupled equation. Contraction uniqueness identifies the two fields on this common ball. The coupled field's Euler, constraint, and Landau residuals are holomorphic on its entire connected datum ball and vanish on that smaller ball. The identity theorem proves their vanishing throughout the coupled ball. The smaller independent-current radius is part of this coupled-system statement and is not imposed on Prop. 3.174. □

Corollary 3.178. At the trivial reference, the Landau representative of a sufficiently small regular box minimizer is $\mathbf{H}(1; b(B))$, with its actual ordinary row logarithm B, the reduced datum $b(B)$ of eq. 3.cccxi, and its actual node factors. Suppose a common local gauge gives $|B(c)| \le C\xi_c a_0$ on the full determining stock. Then the potential has size Ca_0, and its first differences have size Ca_0/ξ_y at cell y. On complete stencils its normalized first differences have a fixed Hölder bound. The datum derivative has exponentially screened first-order and Hölder output bounds. Node factors on a complete common top pillar have a bounded holomorphic chart and the corresponding Cauchy difference bound. ■□

Proof. The trivial reference is critical and has zero current. The characterization in Prop. 3.176 applies to the small Landau representative. The outward datum change reads one preceding block only, with neighboring row lengths in a fixed ratio; it preserves the profile $\xi_c a_0$. Integrate the weighted datum derivative in eq. 3.mccxvii from zero. The ratio ξ_c/ξ_y is absorbed in the fixed reserved exponential rate of the assigned-cell kernels. This gives the two displayed sizes. The strong output conclusion following eq. 3.mccxvii gives the Hölder estimate. For the node factors use their complete-read holomorphic formula and fixed larger ball in Prop. 3.176; Cauchy's formula gives the difference bound on a smaller ball. These statements apply to the actual ordinary datum, and include its outward change of variables. □

Corollary 3.179. The response hypotheses in eq. 2.x are supplied by Props. 3.174 to 3.176 on the original first-order regular-pair domain, with the fixed small radii above. For any function F whose complete core contains $(\rho_X P) \dotplus \nu\mathfrak{h}_Y$ on its stated ν-disc, eq. 2.xi is a holomorphic interpolation with the wall splitting and rooted alternating-bracket properties stated there. A change of units multiplies its potential by L^{-m} and its current by L^{-3m}, as in eq. 2.viii. Core inclusion is checked for the particular function and its full auxiliary disc; it is separate from solving the response equations. ■□

Proof. The first assertion collects the preceding results in the specified raw-coordinate convention. The shift is the small-branch product in eq. 2.ix; its logarithm is holomorphic on the indicated core. Composition gives the interpolation. The support and splitting proof in Prop. 3.175 gives the vanishing required for the alternating brackets, and the Cauchy calculation following eq. 2.xiii applies on the complete disc. The last assertion is the physical scaling of a potential and a current. □

3.43. **A strong field–multiplier inverse at every homogeneous depth.** The energy gap of the homogeneous Landau precision can be upgraded to the strong physical norm needed for a nonlinear background equation. We prove that upgrade for the actual flat rows, uniformly in the number of fine bonds in a block. The argument uses the already proved energy gap, but assumes no supremum-norm vector inverse. In particular an order-zero singular integral is not applied at the L^∞ endpoint.

Fix the odd blocking factor $L \geq 3$ and an integer depth $k \geq 0$. The coarse spacing is one, the fine spacing is $h = L^{-k}$, and the periodic side is an integer $M \geq 2$. A real flat reference may have arbitrary commuting unitary holonomies. Work in its parallel frame on the universal cover. Fields are then quasiperiodic; all local norms and matrix products below are understood in that frame. Fine pairings use h^4 times counting measure and coarse pairings use counting measure. The transpose $\sharp$ always uses those pairings. Complexification is linear, with the analytic bilinear transpose, rather than conjugating a complex parameter.

Fix $0 < \alpha < 1$. For a fine field or site function define

$$\begin{aligned} \|u\|_{X_\alpha} &= \|u\|_\infty + \|Du\|_\infty + [Du]_{\alpha,\mathrm{loc}}, \\ \|u\|_{Y_\alpha} &= \|u\|_\infty + \|Du\|_\infty + \|D^2u\|_\infty + [D^2u]_{\alpha,\mathrm{loc}}, \\ \|u\|_{Z_\alpha} &= \|u\|_\infty + [u]_{\alpha,\mathrm{loc}}. \end{aligned} \tag{3.mccxxiii}$$

All products of forward differences of the indicated order are included. The local seminorm compares pairs at physical distance at most one, using parallel transport of the flat reference. Differences at larger distances are controlled by the supremum term. This definition is independent of a choice of fundamental cube, up to fixed constants.

Let q be the actual flat site average, Q the actual flat straightened field row, and D, d the flat gradient and curl. Thus

$$(q\lambda)(y) = h^4 \sum_{x \in B(y)} \lambda(x), \qquad (Qv)_\mu(y) = h^5 \sum_{x \in B(y)} \sum_{t=0}^{h^{-1}-1} v_\mu(x + the_\mu), \quad QD = \mathrm{d}_c q. \tag{3.mccxxiv}$$

The formula is in the parallel frame; the corresponding transports are restored on the quotient torus. The plain nonlinear group average has a different derivative before straightening.

3.43.1. *Smooth exact right inverses of the actual rows.*

Lemma 3.180 (Uniform physical row seeds)**.** There are exact right inverses E_q, E_Q with

$$qE_q = 1, \qquad QE_Q = 1, \qquad \|E_q b\|_{Y_\alpha} + \|E_Q c\|_{Y_\alpha} \leq C_\alpha(\|b\|_\infty + \|c\|_\infty). \tag{3.mccxxv}$$

Their columns have fixed physical support and bounded overlap. They also have uniformly bounded physical H^1 energy from coarse ℓ^2. These constants are independent of h, M and flat holonomy. ■

Proof. Write $h = 1/n$, with n odd. Choose an even nonnegative smooth function φ supported in $(-1/4, 1/4)$ and positive on $[-1/8, 1/8]$. Set

$$m_0 = h\sum_j \varphi(jh), \qquad m_2 = h\sum_j (jh)^2\varphi(jh). \tag{3.mccxxvi}$$

For $n \geq 9$ both have uniform positive lower bounds. Their limits are the positive integrals; the finitely many earlier values are positive, since $\pm h$ lie in the positive core. They have uniform upper bounds by the fixed support. The scalar site bump $m_0^{-4}\prod_\nu \varphi(x_\nu - y_\nu)$ is an exact column of E_q. Different pillars have disjoint supports.

For a positive coarse bond $c = (y, y + e_\mu)$ put

$$(E_Q c)_\mu(x) = (a_h + b_h(x_\mu - y_\mu))\prod_\nu \varphi(x_\nu - y_\nu), \qquad a_h = m_0^{-4}, \quad b_h = \frac{1-h}{2m_0^3 m_2}, \tag{3.mccxxvii}$$

with all other components zero, and multiply by the desired colour. Only the two rows c and $(y - e_\mu, y)$ can see this seed. At longitudinal coordinate $s = x_\mu - y_\mu$, their exact weights in eq. 3.mccxxiv are respectively $s + (1+h)/2$ and $(1-h)/2 - s$, with the common physical fine weight h^4. This follows by counting the possible starting points of a straight segment. In one dimension, at site index $j \in [-(n-1)/2, (n-1)/2]$, the two counts are $j + (n+1)/2$ and $(n-1)/2 - j$.

The transverse mean of the seed is m_0^3. Its longitudinal zeroth and first moments are $a_h m_0$ and $b_h m_2$. The two row values are therefore one and zero, exactly. The coefficients a_h, b_h are uniformly bounded, so these signed smooth seeds and all their fixed-order physical differences are uniformly bounded.

For the finitely many $n < 9$, use direct seeds. The site row has the right inverse $q^\sharp$. For a field row use its middle positive face bond, at longitudinal index $(n-1)/2$ and transverse block centres. Its coefficient in that row is h^4, and its coefficient in the preceding row is zero. Put h^{-4} times the prescribed colour there. This includes $n = 1$, when $Q = 1$. All finite-difference norms are bounded by a fixed constant in this finite range of n. On a two-cell periodic direction the two positive coarse bonds remain distinct, so the same count applies.

The columns have bounded support and overlap. Squaring their pointwise first-difference bounds and summing with physical measure proves the $\ell^2 \to H^1$ energy bounds. Their continuous smooth profiles, or the fixed coarse-mesh difference bounds, prove eq. 3.mccxxv. Unit parallel transports preserve all these estimates and give the construction for arbitrary flat holonomy. □

3.43.2. *The heat regularization used in the strong norm.* For a field u write $\|u\|_{2,\mathrm{cell},\infty} = \sup_y \|u\|_{L^2(B_y)}$. Let $L = -\sum_\mu D_\mu^- D_\mu^+$ and $P_t = e^{-tL}$. The differentiated heat kernels in the discrete Hölder estimate give, for $0 < t \leq 1$,

$$\|D^j p_t\|_1 \leq C_j (t + h^2)^{-j/2}. \tag{3.mccxxviii}$$

At $t = 1$ their physical L^2 norms on successive unit cells have summable tails. The differentiated fixed-time Fourier bound gives a uniform pointwise bound, and the proved heat-tail estimate gives arbitrarily fast decreasing cell L^1 tails. Apply $\|k\|_{L^2(C)}^2 \leq \|k\|_\infty \|k\|_{L^1(C)}$ with a sufficiently high tail power. Equivalently use the pointwise estimate eq. 3.dclxxxv directly. Consequently $D^j P_1$ maps the cell-L^2 supremum norm to L^∞, uniformly in the mesh. Twisted torus kernels are periodizations with unitary phases; their absolute bounds are dominated by the same infinite-lattice sums.

Lemma 3.181 (Strong estimates from a bounded scalar Laplacian)**.** If $Lu = g$, then

$$\|u\|_{X_\alpha} \leq C_\alpha(\|u\|_{2,\mathrm{cell},\infty} + \|g\|_\infty). \tag{3.mccxxix}$$

If $g \in Z_\alpha$, then

$$\|u\|_{Y_\alpha} \leq C_\alpha(\|u\|_{2,\mathrm{cell},\infty} + \|g\|_{Z_\alpha}). \tag{3.mccxxx}$$

The same estimates hold with a fixed small exponential spatial weight, using local cell seminorms for the weighted norms. ■

Proof. The exact finite-time identity is

$$u = P_1 u + \int_0^1 P_t g \, dt. \tag{3.mccxxxi}$$

The first term and all its fixed derivatives are controlled by the cell-L^2 norm. The zeroth and first derivatives of the integral are controlled by eq. 3.mccxxviii, since the power $1/2$ is integrable. For a grid translation of length $a \le 1$, the first-derivative kernel difference is bounded in L^1 by

$$C \min\{(t+h^2)^{-1/2},\ a(t+h^2)^{-1}\}. \tag{3.mccxxxii}$$

Use the first estimate directly and the second by telescoping one more difference. Splitting the time integral at $t = a^2$ gives $Ca(1+\log(1/a)) \le C_\alpha a^\alpha$. This proves eq. 3.mccxxix.

For two derivatives use the cancellation of $D^2 p_t$ against a constant. Subtract $g(x)$ inside its convolution. The spatial α moment of the differentiated heat bound gives

$$\|D^2 P_t g\|_\infty \le C_\alpha (t+h^2)^{\alpha/2-1} \|g\|_{Z_\alpha}. \tag{3.mccxxxiii}$$

This is integrable because $\alpha > 0$. A translated difference is bounded by twice that expression. When $a \le \sqrt{t+h^2}$ one can instead use $Ca(t+h^2)^{(\alpha-3)/2}\|g\|_{Z_\alpha}$: telescope an extra kernel difference and use its cancellation, subtracting the forcing at a fixed endpoint. The translation is within the diffusion length, so its moment has the same scale. Thus the minimum of these two bounds is valid. Splitting again at a^2 gives $C_\alpha a^\alpha$. This proves the last seminorm in eq. 3.mccxxx. The other terms were already bounded.

We specify why a small exponential weight causes no mesh loss. For a constant vector s, conjugation by $e^{s\cdot x}$ replaces the symbol of L by its value at $\xi + is$. Its real part is bounded below by $c|\xi|^2 - C|s|^2$ on the Brillouin cube. The same differentiated Fourier calculation as for the heat tails, now on the shifted contour, gives

$$\|e^{s\cdot x} D^j p_t(x)\|_1 \le C_j (t+h^2)^{-j/2} \quad (0 < t \le 1,\ |s| \le s_0), \tag{3.mccxxxiv}$$

with the analogous fixed-time cell-L^2 and increment bounds. One can see the uniformity directly from $\mathrm{Re}\,\lambda_h(\xi+is) = 2h^{-2}\sum_\mu\{1-\cosh(hs_\mu)\cos(h\xi_\mu)\}$: the negative part is at most $C|s|^2$, and every derivative of the remaining multiplier has the same scaled Gaussian bound. The estimate for $e^{s|x|_1}$ follows by summing the sixteen sign choices. A one-Lipschitz spatial weight has ratio at two points at most $e^{s|x-y|_1}$, so the same convolution estimates apply. Local Hölder differences read weights at neighboring cells, whose ratios are bounded. This proves the weighted assertion. □

3.43.3. *Strong smoothing by the actual site projector.* Put

$$G_s = (L + q^\sharp q)^{-1}, \quad F = G_s q^\sharp, \quad M_s = F^\sharp F, \quad P = F M_s^{-1} F^\sharp, \quad R = 1 - P. \tag{3.mccxxxv}$$

The proved site/Gram energy package gives exponential physical cell-L^2 entries of G_s, F, DF, M_s^{-1}. These statements are applicable here before any vector inverse is constructed.

For coarse $b \in \ell^\infty$, weighted cell summation gives $\|Fb\|_{2,\mathrm{cell},\infty} + \|qFb\|_\infty \le C\|b\|_\infty$. The actual scalar equation is

$$L(Fb) = q^\sharp (b - qFb). \tag{3.mccxxxvi}$$

Here $q^\sharp$ extends a coarse colour as a constant in its cell in the parallel frame, so its supremum norm is unchanged. Thus Lem. 3.181 proves

$$\|Fb\|_{X_\alpha} \le C_\alpha \|b\|_\infty, \qquad \|DFb\|_{Z_\alpha} \le C_\alpha \|b\|_\infty. \tag{3.mccxxxvii}$$

The weighted forms follow from the same scalar equation and eq. 3.mccxxxiv.

The adjoints $F^\sharp, (DF)^\sharp$ map fine cell-L^2 supremum norms to coarse ℓ^∞: sum their exponentially decreasing cell operator entries. Composing these estimates gives

$$\begin{aligned} \|Pu\|_{X_\alpha} &\le C_\alpha \|u\|_{2,\mathrm{cell},\infty}, \\ \|DPD^\sharp u\|_\infty &\le C \|u\|_{2,\mathrm{cell},\infty}. \end{aligned} \tag{3.mccxxxviii}$$

In the second line use the exact factorization $DPD^\sharp = (DF)M_s^{-1}(DF)^\sharp$. No absolute pointwise kernel bound was inferred from a cell-L^2 bound. Strong estimates were obtained only after the scalar heat regularization. In particular R is bounded on Z_α.

If $\rho \in \operatorname{ran} R \cap Z_\alpha$, the exact range identities give $qG_s\rho = 0$ and $LG_s\rho = \rho$. Using the site energy bound and eq. 3.mccxxx,

$$\|G_s\rho\|_{Y_\alpha} \le C_\alpha \|\rho\|_{Z_\alpha}. \tag{3.mccxxxix}$$

This estimate will be used for gauge restoration, rather than an unbounded point-evaluation map on an energy space.

3.43.4. *The full vector inverse and its multiplier.* Define the actual flat penalized operator

$$H_0 = \mathrm{d}^\sharp \mathrm{d} + DRD^\sharp, \qquad K_0 = H_0 + Q^\sharp Q. \tag{3.mccxl}$$

The uniform flat Landau gap proves $\langle v, K_0 v\rangle \ge c(\|Dv\|_2^2 + \|v\|_2^2)$. Conjugating by a small physical exponential weight changes this form by at most $C|s|$ times its two H^1 norms. For the nonlocal part use the weighted factorization in eq. 3.mccxxxviii; for Q use its fixed carrier and physical row/column bounds. The normalized Neumann series in H^1, H^{-1} therefore gives exponential cell-L^2 bounds for K_0^{-1}, uniformly in h and the torus. In particular, for $u = K_0^{-1} f$,

$$\|u\|_{2,\mathrm{cell},\infty} \le C\|f\|_\infty. \tag{3.mccxli}$$

Flat Hodge theory is the exact operator identity $\mathrm{d}^\sharp \mathrm{d} + DD^\sharp = LI$. Hence

$$Lu = f + DPD^\sharp u - Q^\sharp Q u. \tag{3.mccxlii}$$

The second term is bounded by eq. 3.mccxxxviii. The row Q maps the cell-L^2 supremum norm to coarse ℓ^∞. Its transpose maps coarse ℓ^∞ to fine ℓ^∞: in eq. 3.mccxxiv each fine coefficient is at most h^4 and each fine bond occurs in a fixed number of coarse rows. The physical transpose divides by h^4, giving a bounded density, not h^{-4} growth. Therefore the right side of eq. 3.mccxlii is bounded by $C\|f\|_\infty$. Apply Lem. 3.181 to obtain the actual strong inverse

$$\|K_0^{-1} f\|_{X_\alpha} \le C_\alpha \|f\|_\infty. \tag{3.mccxliii}$$

The argument with spatial weights gives its exponentially weighted version as well.

Proposition 3.182 (Uniform strong joint inverse)**.** For every bounded fine f and coarse b, the system

$$H_0 A - Q^\sharp \omega = f, \qquad QA = b \tag{3.mccxliv}$$

has a unique solution, and

$$\|A\|_{X_\alpha} + \|\omega\|_\infty \le C_\alpha(\|f\|_\infty + \|b\|_\infty). \tag{3.mccxlv}$$

It satisfies the corresponding small exponentially weighted estimate. The constants are uniform in homogeneous depth, volume and flat holonomy. This is an inverse for the penalized equations; removing their gauge penalty in a nonlinear solution requires a separate Ward argument. ∎

Proof. Put $S = QK_0^{-1}Q^\sharp$. It has a uniform positive lower bound. Indeed the actual lift E_Q from Lem. 3.180 has bounded K_0 energy, and

$$\|b\|_2^2 = \langle K_0 K_0^{-1} Q^\sharp b, E_Q b\rangle \le C\langle b, Sb\rangle^{1/2}\|b\|_2. \tag{3.mccxlvi}$$

The upper bound follows from the full gap and the bounded row norm. The weighted vector inverse and the fixed row carrier show that the conjugate of S differs from S by $O(|s|)$ in operator norm. Its inverse is therefore exponentially decreasing on the coarse lattice, and S^{-1} is bounded on coarse ℓ^∞ and its small weighted variants.

Set

$$\sigma = S^{-1}(b - QK_0^{-1} f), \qquad A = K_0^{-1}(f + Q^\sharp \sigma), \qquad \omega = \sigma - b. \tag{3.mccxlvii}$$

Direct substitution gives eq. 3.mccxliv. The coarse bound on σ and eq. 3.mccxliii give eq. 3.mccxlv. Uniqueness follows from positivity of S and K_0. Every step retains the full multiplier; no supremum bound for a field-only inverse is used in its place. □

There is one more strong inverse needed for the nonlinear gauge argument. On site functions the map

$$\lambda \longmapsto (q\lambda, RL\lambda) : Y_\alpha \longrightarrow \ell^\infty(\text{coarse sites}) \oplus (\operatorname{ran} R \cap Z_\alpha) \tag{3.mccxlviii}$$

has the explicit inverse

$$\lambda = E_q c + G_s\{\rho - RLE_q c\}. \tag{3.mccxlix}$$

The braces belong to $\operatorname{ran} R$; $qG_sR = 0$ and $LG_sR = R$ prove both equations. The bounds for E_q, R and eq. 3.mccxxxix prove a uniform Y_α bound. If both outputs vanish, $\lambda \in \ker q$ implies $L\lambda \in \operatorname{ran} R$, so $L\lambda = 0$ and the site gap gives $\lambda = 0$. This establishes uniqueness in the stated strong space, including nontrivial flat holonomy.

3.44. **An actual homogeneous Wilson background on a fixed coarse ball.** The strong inverse just proved permits a construction of the nonlinear background itself. The data are arbitrary small coarse bond logarithms relative to a flat connection. Their smallness is measured in the physical coarse supremum norm; neither volume nor fine depth reduces the radius. This class includes spatially varying noncommuting coarse connections. It is smaller than the class of all small-curvature coarse fields on arbitrarily large tori. Proper regions and hereditary decoupling domains are separate questions.

Keep the setting of § 3.43. Let V_0 be a real flat coarse connection and choose a flat fine extension W_0 with $M^k W_0 = V_0$. To obtain one, choose commuting logarithms of its four holonomies, use their constant fine representatives, and extend the coarse node gauge to the fine nodes. Gauge covariance of the actual mean, and its value on identical transported paths, give the equality. Use the parallel frame of W_0 and put

$$U_A = e^{ihA}W_0, \qquad V_B = e^{iB}V_0, \qquad \mathscr{A}_h(A) = \sum_{p>0} \left(1 - \tfrac{1}{2}\operatorname{tr} U_A(p)\right). \tag{3.mccl}$$

The sum uses each positive unoriented plaquette once. The colour pairing is $\langle X, Y\rangle = \frac{1}{2}\operatorname{tr}(XY)$. Thus the flat quadratic action is $\frac{1}{2}\|\mathrm{d}A\|_2^2$ with fine measure h^4. Complex parameters mean holomorphic continuation to $\mathrm{SL}(2,\mathbb{C})$, without inserting a real-part operation.

Proposition 3.183 (A depth-uniform homogeneous critical orbit)**.** Fix L and $0 < \alpha < 1$. There are $r, \rho, \delta, C > 0$, independent of depth, volume and flat holonomies, such that for $\|B\|_\infty < \rho$ there is a holomorphic pair $(A(B), \omega(B))$ with

$$\begin{aligned} q_h(A(B)) &= B, \qquad RD^\sharp A(B) = 0, \\ \mathscr{A}_h'(A(B)) &= q_h'(A(B))^\sharp \omega(B), \\ \|A(B)\|_{X_\alpha} + \|\omega(B)\|_\infty &\le C\|B\|_\infty. \end{aligned} \tag{3.mccli}$$

The actual straightened nonlinear average q_h is defined below; R, D are the fixed flat site projector and gradient. The pair is real for real B. A specified holomorphic fine gauge converts U_A into $\widehat{U}(B)$ satisfying the literal constraint $M^k\widehat{U}(B) = V_B$. For real data this is a critical point of the actual Wilson action on that constraint manifold.

Among node-fixed gauge orbits possessing a representative $U = e^{ihA}W_0$ with $\|A\|_{X_\alpha} < \delta$, its orbit is the only constrained-critical orbit. The representative with $q_h(A) = B$ and $RD^\sharp A = 0$ has a strict local action minimum on that simultaneous slice. The literal representative is a local minimum modulo node-fixed gauges. All maps have fixed absolute complex radii inside the actual logarithm charts and exponentially localized response bounds. ■

The fixed reference gauge distinguishes the orbit during construction. It is not identified with a background-dependent Landau gauge. Its penalty will be removed by the exact nonlinear Ward identity.

3.44.1. *The actual nonlinear row and its physical transpose.* On a one-step lattice with spacing set to one, let $T_{yx}(W)$ be the specified internal mean transport and put

$$\begin{aligned} u_W(a)(y) &= \exp\left[L^{-4}\sum_{x\in B_L(y)}\log\{T_{yx}(e^{ia}W)T_{yx}(W)^{-1}\}\right], \\ F_W(a)(c) &= \frac{1}{i}\log\left[u_W(a)(c_-)^{-1}M(e^{ia}W)(c)u_W(a)(c_+)M(W)(c)^{-1}\right]. \end{aligned} \tag{3.mcclii}$$

The transports use the actual Federbush mean. The auxiliary u_W is the explicit exponential of averaged relative logarithms. Set $a_0 = hA$, $v_0 = 1$, $W_s = M^s W_0$, and define

$$a_{s+1} = F_{W_s}(a_s), \qquad v_{s+1} = v_s|_{\mathrm{next}} u_{W_s}(a_s), \qquad q_h(A) = a_k, \qquad v_h(A) = v_k. \tag{3.mccliii}$$

At depth zero $q_1(A) = A$ and $v_1 = 1$. Solving the second line of eq. 3.mcclii for the plain mean, and applying its gauge covariance inductively, proves

$$M^k(U_A) = \left(e^{iq_h(A)}V_0\right)^{v_h(A)}, \qquad U^g(c) = g(c_-)U(c)g(c_+)^{-1}. \tag{3.mccliv}$$

In particular the order of the two factors $v_s u_s$ is fixed.

All W_s are one in the parallel frame. The finite analytic coefficient estimates proved for this actual recursion give

$$\|D_a F_1(a)\|_{\mathrm{row}} \le L(1 + C_L\|a\|_\infty), \qquad \|D_a F_1(a)\|_{\mathrm{col}} \le L^{-3}(1 + C_L\|a\|_\infty). \tag{3.mcclv}$$

These are counting-coordinate sums of colour matrix norms. At zero they are the exact straight-row values. The analytic chart is $\|a\|_\infty < c_L/L$. Put $\xi_s = hL^s$. A first-exit argument gives

$$\|a_s\|_\infty \le 2r\xi_s \quad (0 \le s \le k), \qquad \sum_{s<k}\xi_s \le (L-1)^{-1}. \tag{3.mcclvi}$$

Indeed $p_s = \|a_s\|_\infty/\xi_s \le 2r$ implies $p_{s+1} \le p_s(1 + C_L\xi_s p_s)$. Choose $2C_L r/(L-1) < \log 2$ and multiply. The first exit contradicts this product. Decrease r to keep every raw input strictly inside its chart. Since $\|u_{W_s}(a_s) - 1\| \le C_L\|a_s\|_\infty$, also

$$\|v_h(A) - 1\|_\infty \le C_L r, \qquad \sup_y \|v_h(A)(y)\|\|v_h(A)(y)^{-1}\| \le e^{C_L r}. \tag{3.mcclvii}$$

These are complex-ball bounds; unitary reference twists preserve them.

The actual row calculation and its fixed-input-leg Hessian bound give on this entire fine supremum ball

$$\begin{aligned} q_h(0) = 0, \qquad q_h'(0) = Q, \\ \|q_h'(A) - Q\|_{\mathrm{row}} \le C_L\|A\|_\infty, \qquad \|q_h'(A) - Q\|_{\mathrm{col}} \le C_L h^4\|A\|_\infty, \\ \sup_b \sum_{b'} \|\partial_b\partial_{b'} q_{h,c}(A)\| \le C_L h^4. \end{aligned} \tag{3.mcclviii}$$

Every fine input affects a fixed number of coarse row carriers. The last line is eq. 3.dcii at output scale one. Its fine density follows from one inner column sum, one inner row sum and the geometric sum over the differentiated scale. Integrate that bound from zero to A for the column error; sum over the $O(h^{-4})$ row inputs for the row error. A bound on second directional derivatives alone would not justify this step.

Writing $C_h(A) = q_h(A) - QA$, one obtains

$$\|C_h(A)\|_\infty \le C_L\|A\|_\infty^2, \qquad \|(q_h'(A) - Q)^\sharp\omega\|_\infty \le C_L\|A\|_\infty\|\omega\|_\infty. \tag{3.mcclix}$$

The fine component of the transpose is $h^{-4}\sum_c (q_h'(A)-Q)^{\mathsf{T}}_{c,b}\omega(c)$. The column density in eq. 3.mcclviii cancels this h^{-4}. The same moment gives, on the joint radius-r ball,

$$\begin{aligned}\|C_h(A)-C_h(\widetilde{A})\|_\infty &\le C_L r\|A-\widetilde{A}\|_\infty,\\ \|(q_h'(A)-Q)^\sharp\omega-(q_h'(\widetilde{A})-Q)^\sharp\widetilde{\omega}\|_\infty &\le C_L r(\|A-\widetilde{A}\|_\infty+\|\omega-\widetilde{\omega}\|_\infty).\end{aligned} \tag{3.mcclx}$$

These estimates use the full finite-lattice constraint.

3.44.2. *The complete Wilson residual.* Let $J_h(A)$ be the normal-coordinate physical gradient: $\mathscr{A}_h'(A)[a] = h^4\sum_b\langle J_h(A)(b),a(b)\rangle$. The field equation needs this entire gradient, including its coordinate differential, rather than an action remainder alone.

Lemma 3.184 (Uniform quadratic Wilson residual)**.** The map $N_h(A)=J_h(A)-\mathrm{d}^\sharp\mathrm{d}A$ is holomorphic from a fixed X_α ball to fine ℓ^∞. On a smaller ball,

$$\|N_h(A)\|_\infty \le C\|A\|_{X_\alpha}^2, \qquad \|N_h(A)-N_h(\widetilde{A})\|_\infty \le Cr\|A-\widetilde{A}\|_{X_\alpha} \tag{3.mcclxi}$$

when both arguments have norm at most r. The constants are uniform in mesh and volume. ■

Proof. For $U_A(p)=e^{ih^2F_p(A)}$, the exact four-factor logarithm gives

$$F(A)=\mathrm{d}A+E_h(A), \qquad \|E_h(A)\|_\infty\le C\|A\|_\infty^2, \qquad \|DE_h(A)\|_\infty\le C\|A\|_\infty\|DA\|_\infty. \tag{3.mcclxii}$$

The linear logarithm is $h^2\mathrm{d}A$. Each remaining monomial contains at least two factors hA, so division by h^2 leaves a uniformly analytic function of the four neighbouring A values. Its derivative is bounded by $C\max|A|$. Subtract the same function at neighbouring plaquettes to prove the last bound. No D^2A is used.

The exact physical left current is eq. 3.dcci. Its covariant difference differs from the ordinary difference by at most $C\|A\|_\infty\|F\|_\infty$. Its sine factor obeys

$$W_h(F)=h^{-2}\sin(h^2F)=F+S_h(F), \quad |S_h(F)|\le Ch^4|F|^3, \quad |D^-S_h(F)|\le Ch^3\|F\|_\infty^3. \tag{3.mcclxiii}$$

The last estimate uses two bounded values, not a derivative of F. It follows that

$$J_h^{\mathrm{left}}(A)=\mathrm{d}^\sharp\mathrm{d}A+R_h(A), \qquad \|R_h(A)\|_\infty\le C(\|A\|_\infty\|DA\|_\infty+\|A\|_\infty^3+h^3\|F\|_\infty^3)\le C\|A\|_{X_\alpha}^2. \tag{3.mcclxiv}$$

No zero-divergence assumption is required: the ordinary divergence of the linear plaquette curl is $\mathrm{d}^\sharp\mathrm{d}A$ itself.

The exact change from normal to left coordinates is

$$\mathcal{E}_{hA}a=\int_0^1 \mathrm{Ad}(e^{ithA})a\,dt, \quad J_h(A)=\mathcal{E}_{hA}^\sharp J_h^{\mathrm{left}}(A), \quad \|\mathcal{E}_{hA}-1\|\le Ch\|A\|_\infty. \tag{3.mcclxv}$$

Although $\mathrm{d}^\sharp\mathrm{d}$ is not uniformly bounded from X_α to ℓ^∞, the elementary fine difference bound gives $\|\mathrm{d}^\sharp\mathrm{d}A\|_\infty\le Ch^{-1}\|DA\|_\infty$. The explicit h in the coordinate differential cancels that loss. This proves the first bound in eq. 3.mcclxi for the complete gradient. The same holomorphic estimates hold on a larger fixed complex ball. Banach-valued Cauchy estimates bound its second derivative uniformly on a smaller ball. Integrating that derivative, using $N_h(0)=DN_h(0)=0$, proves the stated Cr Lipschitz estimate. No coordinate-count factor enters this operator-norm argument. □

3.44.3. *The actual joint field–multiplier contraction.* Let $\mathcal{L}_0^{-1}(f,b)$ be the inverse in Prop. 3.182, with norm at most C_0. The actual penalized system

$$J_h(A)+DRD^\sharp A-q_h'(A)^\sharp\omega=0, \qquad q_h(A)=B \tag{3.mcclxvi}$$

is exactly equivalent to

$$(A,\omega)=\mathcal{T}_B(A,\omega):=\mathcal{L}_0^{-1}\big(-N_h(A)+(q_h'(A)-Q)^\sharp\omega,\,B-C_h(A)\big). \tag{3.mcclxvii}$$

For $\|(A,\omega)\| = \|A\|_{X_\alpha} + \|\omega\|_\infty \le r$, the preceding estimates imply

$$\|\mathcal{T}_B(x) - \mathcal{T}_B(\widetilde{x})\| \le C_1 r \|x - \widetilde{x}\|, \qquad \|\mathcal{T}_B(0)\| \le C_0 \|B\|_\infty. \tag{3.mcclxviii}$$

Choose r below all primitive ceilings and $C_1 r \le 1/4$, and $\rho \le r/(4C_0)$. The radius-$r/2$ ball is invariant and contractive. Iteration from zero gives a unique pair there. The same Lipschitz inequality identifies it with any solution in the radius-r ball, and

$$\|A(B)\|_{X_\alpha} + \|\omega(B)\|_\infty \le 2C_0 \|B\|_\infty. \tag{3.mcclxix}$$

The holomorphic iterations converge locally uniformly on the fixed complex polydisc. Their limit is holomorphic; reality and uniqueness give reality for real B. An unknown orbit or inverse is not a hypothesis of this construction.

3.44.4. *The effective coarse gauge and removal of the penalty.* The nonlinear straightened average has its own effective coarse gauge. One cannot obtain its Ward identity by replacing the flat site map by a convenient average. For $g = e^{-it\lambda}$ define

$$h_A(g) = v_h(A^g)^{-1} g|_{\mathrm{coarse}} v_h(A), \qquad h_A(e^{-it\lambda}) = 1 - it\tau_A\lambda + O(t^2), \tag{3.mcclxx}$$

where $U_{A^g} = U_A^g$. The exact factorization proves

$$e^{iq_h(A^g)} V_0 = (e^{iq_h(A)} V_0)^{h_A(g)}, \qquad q_h'(A)\Gamma_A\lambda = \Gamma^c_{q_h(A)}\tau_A\lambda. \tag{3.mcclxxi}$$

The symbols Γ_A, Γ^c_B are normal-coordinate infinitesimal fine and coarse gauge generators, with the same sign convention.

We derive estimates for these actual maps. Write $\mathcal{E}_z v = \int_0^1 \mathrm{Ad}(e^{itz}) v\, dt$. At one step in the flat frame put $T_{yx}(e^{ia}) = e^{iz_x}$, $m = L^{-4}\sum_x z_x$ and $u = e^{im}$. Direct differentiation gives

$$\tau_a^{(1)}\lambda(y) = \mathrm{Ad}(u(y)^{-1})\Big[\lambda(y) + \mathcal{E}_m L^{-4} \sum_{x \in B_L(y)} \mathcal{E}_{z_x}^{-1}\{-\lambda(y) + \mathrm{Ad}(T_{yx}(e^{ia}))\lambda(x)\}\Big]. \tag{3.mcclxxii}$$

Indeed the left logarithmic derivative of $T_{yx}(U^g) = g(y)T_{yx}(U)g(x)^{-1}$ is $i[-\lambda(y) + \mathrm{Ad}(T_{yx}(U))\lambda(x)]$. Convert it by $\mathcal{E}_{z_x}^{-1}$, average, and differentiate $u(A^g)^{-1}g(y)u(A)$. This gives the formula, including its sign. At zero it is exactly the one-step site average $q^{(1)}\lambda$. The finite one-step logarithm domain therefore gives

$$\|\tau_a^{(1)} - q^{(1)}\|_{\infty\to\infty} \le C_L \|a\|_\infty, \qquad \|\tau_a^{(1)}\|_{\infty\to\infty} \le 1 + C_L\|a\|_\infty. \tag{3.mcclxxiii}$$

The effective gauge parameters compose through successive scales. Telescoping that product and using eq. 3.mcclvi yields

$$\|\tau_A - q\|_{\infty\to\infty} \le C_L \|A\|_\infty. \tag{3.mcclxxiv}$$

This retains the node evaluation terms in eq. 3.mcclxxii; no fine L^2 point-evaluation bound is inferred from it.

The fine generator has the exact expression

$$\begin{aligned} \Gamma_A\lambda &= \mathcal{E}_{hA}^{-1} D_{U_A}\lambda, \\ (D_{U_A}\lambda)_\mu(x) &= h^{-1}\{\mathrm{Ad}(U_A(x,\mu))\lambda(x + he_\mu) - \lambda(x)\}. \end{aligned} \tag{3.mcclxxv}$$

It implies

$$\|(\Gamma_A - D)\lambda\|_{X_\alpha} \le C\|A\|_{X_\alpha}\|\lambda\|_{Y_\alpha}. \tag{3.mcclxxvi}$$

Its zeroth-order difference consists of $A\lambda$ and $hAD\lambda$ terms. One fine difference gives terms of the forms $DA\lambda$ and $AD\lambda$, together with $hDAD\lambda$ and $hAD^2\lambda$. Their analytic coefficients are uniformly bounded. The discrete product rule for the local Hölder seminorm proves the stated last seminorm as well. The inverse of $\mathcal{E}_{hA}$ is uniformly analytic on the chosen chart.

For $\rho \in \operatorname{ran} R \cap Z_\alpha$ put $\lambda_0 = G_s\rho$. The strong site inverse gives $q\lambda_0 = 0$, $RL\lambda_0 = \rho$ and $\|\lambda_0\|_{Y_\alpha} \le C\|\rho\|_{Z_\alpha}$. Since $\tau_A E_q = 1 + O(r)$, define

$$\lambda_A(\rho) = \lambda_0 - E_q(\tau_A E_q)^{-1}\tau_A\lambda_0. \tag{3.mcclxxvii}$$

Then $\tau_A\lambda_A = 0$ and $\|\lambda_A - \lambda_0\|_{Y_\alpha} \le Cr\|\rho\|_{Z_\alpha}$. Boundedness of R on Z_α and eq. 3.mcclxxvi show that

$$\mathscr{R}_A\rho = RD^\sharp\Gamma_A\lambda_A(\rho), \qquad \|\mathscr{R}_A - 1\|_{\operatorname{ran} R\cap Z_\alpha} \le Cr. \tag{3.mcclxxviii}$$

After decreasing r this is invertible by a Neumann series. Consequently for every such ρ there is a site function with

$$\tau_A\lambda = 0, \qquad RD^\sharp\Gamma_A\lambda = \rho. \tag{3.mcclxxix}$$

For the real fixed point choose $\rho = RD^\sharp A$. Test eq. 3.mcclxvi against the actual gauge vector $\Gamma_A\lambda$ from eq. 3.mcclxxix. Wilson gauge invariance annihilates its current term. The constraint term vanishes by eq. 3.mcclxxi and $\tau_A\lambda = 0$. The remaining equality is

$$0 = \langle\rho,\rho\rangle_{2,h}. \tag{3.mcclxxx}$$

Thus $RD^\sharp A = 0$ and the full unpenalized stationarity equation holds. The identity extends to the complex data ball by holomorphy from its real open part. This proves the equations in eq. 3.mccli.

The same argument with arbitrary λ gives

$$(\Gamma^c_B)^\sharp\omega = 0. \tag{3.mcclxxxi}$$

Indeed τ_A is onto with right inverse $E_q(\tau_A E_q)^{-1}$. The coarse frame term arising on differentiation of eq. 3.mccliv therefore contributes no extra physical force.

3.44.5. *A literal trial lift and admission of its fine gauge.* There is an explicit bounded extension of coarse node values to fine site functions. Choose fixed scalar smooth bumps supported inside the pillars and equal to one at their centers, transporting colours in the flat frame. Their supports are disjoint. Sample them on the fine lattice. At the finitely many coarse meshes use center Kronecker bumps, whose physical derivatives have a fixed bound. This gives

$$\mathrm{ev}_{\mathrm{coarse}}\, E_n = 1, \qquad \|E_n\nu\|_{Y_\alpha} \le C\|\nu\|_\infty. \tag{3.mcclxxxii}$$

For $w = e^{i\nu}$ close to one define $\mathfrak{E}(w) = e^{iE_n\nu}$. It is unitary for real ν, holomorphic for complex ν, and has exactly the prescribed node values.

The finite fine gauge transformation satisfies

$$\begin{aligned} A^{e^{-i\lambda}} &= A + D\lambda + \mathcal{B}_h(A,\lambda),\\ \|\mathcal{B}_h(A,\lambda)\|_{X_\alpha} &\le C(\|A\|_{X_\alpha} + \|\lambda\|_{Y_\alpha})\|\lambda\|_{Y_\alpha}. \end{aligned} \tag{3.mcclxxxiii}$$

The dependence is uniformly analytic. To check the apparent h^{-1}, write $\lambda(x + he_\mu) = \lambda(x) + hD_\mu\lambda(x)$ before taking the product and logarithm. At $h = 0$ the numerator is exactly one. Its logarithm divided by h therefore extends analytically to $h = 0$. Differences of this finite formula use only $A, DA, \lambda, D\lambda, D^2\lambda$ and their stated local seminorms. Its first-order terms are $A + D\lambda$. Taylor's formula proves eq. 3.mcclxxxiii and the corresponding local Lipschitz bound, uniformly in the mesh.

For any small A put

$$\widehat{U}_A = U_A^{\mathfrak{E}(v_h(A)^{-1})}. \tag{3.mcclxxxiv}$$

Its literal mean is $e^{iq_h(A)}V_0$. Its normal coordinate has X_α norm at most $C\|A\|_{X_\alpha}$ by eq. 3.mcclvii, eq. 3.mcclxxxii and eq. 3.mcclxxxiii. Choose the fixed-point radius below the primitive admission ceiling divided by this fixed constant. Then the original field, its literal representative, the specified fine gauges and all intermediate raw logarithms stay inside the actual complex charts. This proves admission for this gauge without assuming arbitrary complex gauge saturation of the domain.

A literal section can also be constructed independently of the action. On the range of the actual smooth seed E_Q, solve

$$A_{\mathrm{tr}} = E_Q\{B - C_h(A_{\mathrm{tr}})\}. \tag{3.mcclxxxv}$$

The seed bound and eq. 3.mcclx make this a supremum-norm contraction. Its solution has $q_h(A_{\mathrm{tr}}) = B$. Since it is E_Q applied to a bounded coarse vector, its whole Y_α norm is at most $C\|B\|_\infty$. Equation eq. 3.mcclxxxiv gives an actual literal trial lift. Its physical curvature is at most $C\|B\|_\infty$. Before the last gauge its physical current has the same bound by the exact current formula and the Y_α estimate. Gauge covariance preserves this bound for real data; the bounded condition number of the specified complex gauge gives it in the complex case. This supplies a genuine deep trial field with physical derivative bounds, rather than assuming the required trial lift.

3.44.6. *The mean-gauge slice and physical criticality.* For λ small in Y_α define

$$\mathscr{S}_A(\lambda) = \big(i\log h_A(e^{-i\lambda}),\ RD^\sharp A^{e^{-i\lambda}}\big). \tag{3.mcclxxxvi}$$

At $(A,\lambda) = (0,0)$ its derivative is $(q\lambda, RL\lambda)$, with explicit bounded inverse eq. 3.mccxlix. On a small $X_\alpha \times Y_\alpha$ ball that derivative differs from this fixed map by at most $C(\|A\|_{X_\alpha} + \|\lambda\|_{Y_\alpha})$. For the first component differentiate the exact h_A at the current point: its derivative is τ_{A^g} composed with the bounded near-identity exponential gauge differential and a near-identity conjugation. Use eq. 3.mcclxxiv. For the second use $RD^\sharp : X_\alpha \to Z_\alpha$ and eq. 3.mcclxxxiii. These bounds give the claimed operator norm between the precise strong spaces.

The contraction with linear part eq. 3.mccxlix therefore solves

$$h_A(e^{-i\lambda}) = v_h(A), \qquad RD^\sharp A^{e^{-i\lambda}} = 0, \qquad \|\lambda\|_{Y_\alpha} \le C\|A\|_{X_\alpha}. \tag{3.mcclxxxvii}$$

Explicitly subtract $\mathscr{S}_A(0)$ and move the quadratic remainder to the right after applying that inverse. The Lipschitz constant is $C(\|A\|_{X_\alpha} + \|\lambda\|_{Y_\alpha})$. A ball of radius $C'\|A\|_{X_\alpha}$ is invariant and contractive for a fixed smaller input radius. This proves existence, analytic dependence and uniqueness in this gauge chart.

If $M^k U_A = V_B$, write $g = e^{-i\lambda}$ for this solution and $\overline{A} = A^g$. Exact factorization gives

$$q_h(\overline{A}) = B, \qquad RD^\sharp \overline{A} = 0, \qquad v_h(\overline{A}) = g|_{\mathrm{coarse}}. \tag{3.mcclxxxviii}$$

The last equality follows from $v_h(\overline{A})^{-1} g|_{\mathrm{coarse}} v_h(A) = v_h(A)$. No coarse stabilizer is divided out. Consequently $\widehat{U}_{\overline{A}}$ differs from U_A by a gauge exactly equal to one at every coarse node.

These maps establish the critical-point correspondence with all tangent directions included. The map $A \mapsto \widehat{U}_A$ sends the entire local $q_h = B$ manifold into the literal fibre and preserves the action. Conversely eq. 3.mcclxxxvii sends the local literal fibre into $q_h = B$ and preserves the action. At a mean-slice point the two maps compose to the identity up to a node-fixed gauge: the inverse of its specified extension gauge solves eq. 3.mcclxxxvii, and uniqueness in the small gauge chart identifies it. Differentiating these action identities proves both directions of the critical-point correspondence. In particular the constructed fixed point is a literal constrained-critical orbit.

3.44.7. *Competing multipliers and orbit uniqueness.* Let A be any small mean-slice critical point. Its actual derivative is onto, with the exact right inverse

$$T_A = q_h'(A)E_Q = 1 + O(r), \qquad E_A = E_Q T_A^{-1}, \qquad q_h'(A)E_A = 1. \tag{3.mcclxxxix}$$

The error has coarse row and column sums at most Cr, by eq. 3.mcclviii and the seed carriers. Thus its Neumann inverse is bounded in both Schur norms. Columns of E_A have uniformly bounded physical $W^{1,1}$ norms and H^1 energy: sum the column ℓ^1 bound of T_A^{-1} against the corresponding fixed seed-column bounds.

Since $q_h'(A)$ is onto, constrained criticality gives a unique ω with $J_h(A) = q_h'(A)^\sharp\omega$. To bound it without an assumed D^2A estimate, evaluate the first variation on $E_A e_c$. The exact current identity, summed by parts once, gives

$$|\mathscr{A}_h'(A)[a]| \le C\|F(A)\|_\infty(\|D(\mathcal{E}_{hA}a)\|_{1,h} + \|A\|_\infty\|\mathcal{E}_{hA}a\|_{1,h}). \tag{3.mccxc}$$

The measure is h^4. This is summation by parts of the covariant difference of $W_h(F)$, whose supremum is at most $C\|F\|_\infty$. Its transport differs from the flat one by $Ch\|A\|_\infty$. Moreover $\|\mathcal{E}_{hA}\| \le C$ and $\|D\mathcal{E}_{hA}\| \le Ch\|DA\|_\infty$. The seed column bounds and eq. 3.mcclxii therefore imply

$$\|\omega\|_\infty \le C\|A\|_{X_\alpha}. \tag{3.mccxci}$$

There is no fine point-mass readout or hidden h^{-1} here.

A literal critical connection in the radius-δ chart maps to a mean-slice critical point of norm at most $C\delta$. Choose δ so that its field and the multiplier in eq. 3.mccxci have joint norm less than r. Decrease ρ further so that the literal constructed representative has strong norm below $\delta/2$. They solve eq. 3.mcclxvii, since the fixed gauge penalty vanishes. Contraction uniqueness identifies them with $(A(B), \omega(B))$. Equation eq. 3.mcclxxxviii then identifies the original connection with $\widehat{U}(B)$ modulo a node-fixed gauge. This proves the stated orbit uniqueness.

3.44.8. *A real minimum and the effective coarse action.* Keep $\omega = \omega(B)$ fixed and set $\mathscr{L}(A) = \mathscr{A}_h(A) - \langle\omega, q_h(A) - B\rangle$. On a fixed small strong ball,

$$\mathscr{L}''(A)[a,a] + \|RD^\sharp a\|_2^2 + \|q_h'(A)a\|_2^2 \ge c(\|Da\|_2^2 + \|a\|_2^2). \tag{3.mccxcii}$$

Here is the comparison with the proved flat gap. The exact twice-varied plaquette estimate eq. 3.dccxxxvi uses physical left variations. Normal variations are $\mathcal{E}_{hA}a$; their difference from a has coefficient $O(h\|A\|_\infty)$ and first-difference coefficients $O(h\|DA\|_\infty)$ and $O(h\|A\|_\infty)D$. The change in the curl form is at most $Cr\|a\|_{H^1}^2$. The second coordinate differential contributes a local coefficient $O(h)J_h^{\mathrm{left}}(A)$, bounded by Cr: the exact current formula gives $h\|J_h^{\mathrm{left}}(A)\|_\infty \le C\|DA\|_\infty + Ch\|A\|_{X_\alpha}^2$. The two-leg moment bounds the constraint curvature by $C\|\omega\|_\infty\|a\|_2^2$. Finally physical Schur applied to eq. 3.mcclviii gives $\|q_h'(A) - Q\|_{2\to 2} \le Cr$. Thus the entire left side differs from $\langle a, K_0 a\rangle$ by at most $C(r + \|\omega\|_\infty)\|a\|_{H^1}^2$, proving eq. 3.mccxcii after a fixed decrease.

Let $A_* = A(B)$ and let $A_* + a$ be another real mean-slice point with the same $q_h = B$. Then $RD^\sharp a = 0$. The equality of the two constraints and the two-leg moment imply, for $A_t = A_* + ta$,

$$\|q_h'(A_t)a\|_2 \le C\|a\|_\infty\|a\|_2. \tag{3.mccxciii}$$

Indeed $D^2q_h(A)[a,\cdot]$ has physical L^2 operator norm at most $C\|a\|_\infty$: the fixed-leg moment supplies its column density $Ch^4\|a\|_\infty$, and summing over a row's inputs supplies row sum $C\|a\|_\infty$. Apply physical Schur, then integrate in t. Since $\mathscr{L}'(A_*) = 0$, Taylor's formula gives

$$\mathscr{A}_h(A_* + a) - \mathscr{A}_h(A_*) \ge c'(\|Da\|_2^2 + \|a\|_2^2) \tag{3.mccxciv}$$

on a smaller fixed ball. The mean-gauge slice preserves action and is a local node-fixed orbit section of the literal fibre. This proves the minimum assertion.

Define $S_c(V_B) = \mathscr{A}_h(A(B))$ and continue holomorphically. It is locally coarse-gauge invariant. A sufficiently small coarse gauge has the fine extension eq. 3.mcclxxxii. The transformed critical field remains in the strong chart and is critical for the transformed literal coarse data. Orbit uniqueness identifies it with the new critical orbit, and fine gauge invariance identifies their actions. Thus the coarse invariance required when subtracting $S_c \circ M^k$ is a conclusion of this construction.

3.44.9. *Localized analytic response and the exact domain supplied.* Every carrier in the depth-k recursion has bounded physical diameter: the radii grow by a fixed multiple of ξ_s, and $\sum_{s<k}\xi_s \le (L-1)^{-1}$. The nonlinear Wilson term is local on the fine stencil. Therefore all the residual and transpose Lipschitz bounds above remain valid with a small fixed exponential weight, with constants multiplied by at most $e^{C_L s}$. For the Wilson residual use its local stencil and the same product estimates; for q_h and its transpose use their actual finite carriers and eq. 3.mcclviii. Write $w_z(x) = e^{sd(x,z)}$, where d is physical periodic distance and $s > 0$ is small enough for the weighted inverse of Prop. 3.182. Here $\|w_z u\|_{X_\alpha}$ denotes the cellwise weighted norm of u and its indicated local derivatives and seminorms; it does not mean differentiating the product $w_z u$.

Decrease r so that the derivative of the nonlinear fixed-point map has norm below $1/2$ in these weighted spaces as well. Differentiating eq. 3.mcclxvii gives the explicit Neumann inverse of $1 - D\mathcal{T}_B$. Thus

$$\|w_z DA(B)b\|_{X_\alpha} + \|w_z D\omega(B)b\|_\infty \le C\|w_z b\|_\infty. \tag{3.mccxcv}$$

The constant is uniform on a smaller unweighted complex data ball, and in z, k, M. The same proof shows analytic dependence on the unweighted parameter B with values in the weighted operator space. Banach-valued Cauchy differentiation in the remaining $m-1$ directions consequently gives

$$\begin{aligned}\|w_z D^m A(B)[b_1,\dots,b_m]\|_{X_\alpha} + \|w_z D^m\omega(B)[b_1,\dots,b_m]\|_\infty \\ \le C_m\|w_z b_1\|_\infty \prod_{j=2}^m \|b_j\|_\infty.\end{aligned} \tag{3.mccxcvi}$$

Any input can occupy the first slot by symmetry. For unit inputs at coarse bonds $y_1,\dots,y_m$, choosing $z = y_j$ for each j gives decay $C_m e^{-s\max_j d(x,y_j)}$. Since $\max_j d(x,y_j) \ge m^{-1}\sum_j d(x,y_j)$, every fixed jet has all spatial moments, with constants uniform in depth and volume. The literal representative has the same property: v_h has uniformly bounded analytic derivatives and bounded carriers by its explicit formula; E_n is local; and the gauge change is uniformly analytic in the stated strong norms.

These estimates provide an actual fixed-radius homogeneous background, its multiplier, a literal trial lift, a local minimum, local coarse gauge invariance and localized analytic response. They do not provide independent fine decoupling domains, a hereditary tower, mixed-scale proper-region inversion, or extension to every curvature-only regular coarse field. Those are separate model estimates, not conclusions hidden in the domain of this proposition.

3.45. **The second jet and fixed-leg density of the actual hierarchy.** The straightened nonlinear row in eq. 3.mccliii is obtained by composing the actual one-step rows. This fact is essential for its fixed-fine-leg moment. We compute the one-step second jet before estimating the composition. A single mean over a block of side L^k would be a different nonlinear map and does not replace this computation.

For Hermitian logarithms write $[X,Y]_{\mathrm{H}} = i[X,Y]$; thus the quadratic term in $i^{-1}\log(e^{iX}e^{iY})$ is $\frac{1}{2}[X,Y]_{\mathrm{H}}$. At one output row let t_x, t'_x, ℓ_x denote the degree-one logarithms of its source internal transport, target internal transport, and straight length-L line. A bar denotes the normalized average over the L^4 starting sites. Subscripts two denote homogeneous degree-two terms. Define

$$\mathrm{Cov}_{\mathrm{H}}(a,b) = \overline{[a_x, b_x]_{\mathrm{H}}} - [\bar a, \bar b]_{\mathrm{H}}.$$

Lemma 3.185 (The actual one-step quadratic coefficient)**.** The quadratic coefficient of the literal plain mean is

$$\begin{aligned}(M_{\log})_2 = \bar t_2 + \bar\ell_2 - \bar t'_2 \\ + \frac{1}{2}\overline{[t,\ell]_{\mathrm{H}} - [t,t']_{\mathrm{H}} - [\ell,t']_{\mathrm{H}}}.\end{aligned} \tag{3.mccxcvii}$$

For the actual straightened map F_1 in eq. 3.mcclii, its linear coefficient is the straight row $Q_1 = \bar{\ell}$, and

$$(F_1)_2 = \bar{\ell}_2 + \frac{1}{2}\{\mathrm{Cov}_{\mathrm{H}}(t,\ell) - \mathrm{Cov}_{\mathrm{H}}(t,t') - \mathrm{Cov}_{\mathrm{H}}(\ell,t')\}. \tag{3.mccxcviii}$$

In particular all second jets of the internal transports cancel from the straightened row. ■

Proof. For a normalized group mean, the logarithm of its output through degree two is the average of the input logarithms. Indeed its defining equation is the average of $\log(e^{iz_x}e^{-im}) = 0$; the degree-two commutator containing $m_1 = \bar{z}_1$ averages to $[\bar{z}_1, \bar{z}_1] = 0$. This proves the assertion for the internal implicit mean. The outer operation is explicitly the exponential of the average of closed logarithms, so its logarithm is that arithmetic average exactly. Its second jet has the same property without replacing it by an implicit mean.

Let c be the logarithm of the central straight reference path. The actual closed inputs of the outer mean are $T_x e^{i\ell_x}(T'_x)^{-1}e^{-ic}$. Expand their logarithms and then multiply the output by e^{ic}, as in the actual definition of M. The terms containing c_1 cancel: the averaged commutator with $-c_1$ is cancelled by the final product with e^{ic_1}. The linear result is $\bar{t}+\bar{\ell}-\bar{t}'$, and its quadratic coefficient is eq. 3.mccxcvii. This also checks that the central reference path has not been silently discarded before taking a jet.

The straightening is $e^{-i\bar{t}_{\log}}M(e^{ia})e^{i\bar{t}'_{\log}}$, where the barred logarithms include their second coefficients. Its first coefficient is $\bar{\ell}$. The two endpoint exponentials cancel $\bar{t}_2 - \bar{t}'_2$ exactly. Their additional quadratic commutators are

$$\frac{1}{2}\{-[\bar{t},\bar{\ell}]_{\mathrm{H}} + [\bar{t},\bar{t}']_{\mathrm{H}} + [\bar{\ell},\bar{t}']_{\mathrm{H}}\}.$$

Combining them with the averaged commutators gives eq. 3.mccxcviii. □

Lemma 3.186 (One-step rows and one fixed input leg)**.** On a raw fine-angle ball $\|a\|_\infty < c/L$, with $c > 0$ universal, the actual one-step map has

$$\begin{aligned} \|DF_1(a)\|_{\mathrm{row}} &\le L + CL^2\|a\|_\infty, \\ \|DF_1(a)\|_{\mathrm{col}} &\le L^{-3} + CL\|a\|_\infty, \\ \sup_b \sum_{c,b'} \|D^2F_1(a)_{c;b,b'}\| &\le CL. \end{aligned} \tag{3.mccxcix}$$

The constants are independent of $L \ge 3$, compatible volume and the number of path-mean inputs. ■

Proof. Every coordinate-order path has length at most CL and contains a fixed fine bond at most once. Its first derivative therefore has absolute row sum CL; with one input bond fixed its norm is bounded by a constant. Its second derivative with one fixed leg and the other leg summed is at most CL. These statements remain valid on the indicated complex ball, since products of complex transports have norm at most $e^{CL\|a\|_\infty}$.

All averaging weights are normalized. The inverse in the implicit group-mean equation is within a fixed neighborhood of the identity on this ball. Implicit differentiation once and twice preserves the preceding bounds: terms have either one second path derivative or two first derivatives, with the fixed leg in one of them. Products of separate normalized averages obey the same bounds. Only a fixed number of coarse rows can use a given internal bond or a given crossing bond. This proves the last line of eq. 3.mccxcix. Without a fixed leg, the same calculation gives the absolute row Hessian bound CL^2.

At zero the exact derivative is Q_1, with row norm L and column norm L^{-3}. Integrate the two Hessian bounds on the segment from zero to a. This gives the first two lines. The column estimate can be written

$$L^{-3}(1 + CL^4\|a\|_\infty).$$

Thus uniform path-row bounds do not assert a uniform nonlinear column constant after factoring out L^{-3}. □

Proposition 3.187 (Hierarchical fixed-fine-leg density)**.** Let $h = L^{-k}$, and let q_h be the actual straightened hierarchy of eq. 3.mccliii, with physical fine potential as input. There are universal $c, C > 0$ such that, for $\|A\|_\infty < cL^{-3}$,

$$\sup_b \sum_{c,b'} \|D^2 q_h(A)_{c;b,b'}\| \le CL^3 h^4. \tag{3.mccc}$$

Consequently

$$\|q_h'(A) - Q_h\|_{\mathrm{col}} \le CL^3 h^4 \|A\|_\infty. \tag{3.mccci}$$

For each fixed L these bounds are uniform in depth. They require no projection of the multiplier onto a divergence-free subspace. ■

Proof. At zero the chain rule is the exact identity

$$D^2 q_h(0)[u,v] = h^2 \sum_{t=0}^{k-1} Q_1^{k-1-t} D^2 F_1(0)[Q_1^t u, Q_1^t v]. \tag{3.mcccii}$$

The powers denote the actual linear row at its successive grids. The factor h^2 comes from the two physical inputs $a_0 = hA$. Write $B_L = \sup_b \sum_{c,b'} \|D^2 F_1(0)_{c;b,b'}\|$. Propagate the fixed inner leg by the column bound L^{-3t}, the other inner leg by the row bound L^t, and the output by the remaining column bound $L^{-3(k-1-t)}$. The resulting bound is

$$\begin{aligned} h^2 B_L \sum_{t=0}^{k-1} L^{-3(k-1-t)} L^{-3t} L^t &= h^4 \frac{B_L L^3}{L-1}(1-h) \\ &\le CL^3 h^4. \end{aligned} \tag{3.mcccciii}$$

For $k = 0$ the Hessian is zero. The central-edge contribution in the one-step row is included in B_L; it is not estimated as a density of order L^{-4}.

At a nonzero field, the second-order chain rule has the same sum with the actual Jacobian products on its three branches and $D^2 F_1(a_t)$ at its vertex. The row majorant gives $\|a_t\|_\infty \le 2\xi_t \|A\|_\infty$, where $\xi_t = hL^t$. The row products, divided by their powers of L, are bounded by $\exp(C\|A\|_\infty \sum_t L\xi_t) \le e^{C\|A\|_\infty}$. The analogous column products are bounded by

$$\exp\left(CL^4 \|A\|_\infty \sum_{t<k} \xi_t \right) \le e^{CL^3 \|A\|_\infty}.$$

This is a fixed constant on the stated ball. The same estimate applies to every subproduct, and the one-step fixed-leg Hessian remains CL. Thus eq. 3.mcccciii, multiplied by fixed constants, proves eq. 3.mccc. Integration in A proves eq. 3.mccci. □

The factor L^3 in this absolute estimate can be necessary. For the symmetric coordinate-order contours, choose different axes μ, ν and a background, on the two relevant blocks, of the form

$$A_\mu(X) = rX_\nu \sigma_2, \qquad A_\lambda = 0 \quad (\lambda \ne \mu).$$

Extend it periodically with supremum at most Cr; the extension can be smooth with uniformly bounded physical derivatives. Vary only the positive fine ν-bond from the source block center, with physical variation $\delta A = \sigma_1$. Put $x \in \{-(L-1)/2, \dots, (L-1)/2\}^4$ and $u = x/L$. The first internal-transport variation at that bond has weight

$$w_x = \frac{\mathbf{1}_{\{x_\nu > 0\}}}{d(x)}, \qquad d(x) = \#\{\lambda : x_\lambda \ne 0\}.$$

Indeed the ν-segment must be first among the nonzero coordinate segments. The target transport does not contain this fine bond. The background has $\ell_x = r u_\nu \sigma_2$ and $t'_x = (r/2) u_\mu u_\nu \sigma_2$. Their averages vanish. The covariance formula eq. 3.mccxcviii gives

$$D^2 q_{1/L}(0)[\delta A, A]_\mu(0) = -\frac{r}{L} a_L \sigma_3, \qquad a_L = L^{-4} \sum_x w_x \frac{x_\nu}{L} = \frac{(L+1)(L^4-1)}{32L^5}. \tag{3.mccciv}$$

The $u_\mu u_\nu$ term cancels by reflection in x_μ. In the remaining sum there are $\binom{3}{j}(L-1)^j$ choices with exactly j nonzero other coordinates. Use

$$\sum_{j=0}^{3} \frac{\binom{3}{j}(L-1)^j}{j+1} = \frac{L^4-1}{4(L-1)}$$

and sum $x_\nu = 1, \dots, (L-1)/2$ to obtain eq. 3.mccciv. Since $a_L \to 1/32$, a bound written as $C_L h^4 \|A\|_\infty$ cannot in general have C_L bounded as L grows. This example does not contradict its uniformity in k for fixed L.

3.45.1. *Uniform row amplitudes and a radius that may depend on L.* For completeness the row majorant has a different dependence on L. Normalized path and mean expansions give higher absolute row coefficients $(CL)^m$ at one step. Their proof uses products of at most CL edge factors and normalized averages, and has no factor equal to the number of sites in the block. The combined linear row is exactly L. Thus the positive majorant is

$$b_{t+1} \le L b_t + \frac{C(L b_t)^2}{1 - C L b_t}.$$

For a partial output spacing $\xi = h L^s$, $\sum_{t<s} L\xi_t \le L\xi/(L-1) \le 3\xi/2$. The first-exit product, the node-frame product and the final plain logarithm therefore give the following bound for the divided degree-m Taylor row coefficients $T^{(m)} = D^m/m!$:

$$\sum_{b_1,\dots,b_m} \|T^{(m)}_{h,s;b;b_1\dots b_m}\| \le C^m \xi^m, \tag{3.mcccv}$$

with C independent of $L \ge 3$. The physical row support has radius $C\xi$, by the same sum. This statement applies to the literal mean as well as to the straightened row and its node correction.

The free inverse and its smooth seeds in § 3.43 use the direct rows eq. 3.mccxxiv at $h = 1/N$. Their constants are uniform over odd N; they do not depend on a factorization $N = L^k$. The Wilson residual and the smooth node extension also have such mesh-uniform constants. The nonlinear transpose constant in eq. 3.mccci may instead grow as L^3. Decrease the nonlinear ball after fixing L, so that its contribution to the fixed-point Lipschitz bound is at most one half. The solution estimate is still

$$\|A(B)\|_{X_\alpha} + \|\omega(B)\|_\infty \le 2\|\mathcal{L}_0^{-1}\|\,\|B\|_\infty.$$

Its amplitude constant is uniform in L; its allowed radius need not be. The actual node product, its local extension and finite-gauge formula preserve this uniform amplitude estimate for the literal field. Equation eq. 3.mcccv, stopped one level before the output, consequently gives

$$\|\log p_j^{\mathrm{lit}}(e^{iB})\|_\infty \le \frac{C}{L}\|B\|_\infty. \tag{3.mcccvi}$$

Here $p_j^{\mathrm{lit}} = M^{j-1} U_j$ is the literal partial mean, before the one-step axial gauge, and B lies in the smaller ball just specified. The axial representative need not have this raw angle bound: a flat constant Abelian input can become a field with identity internal links and full output angle on the face-crossing links. For a complete gauge-invariant physical function, the two representatives give the same value on their admitted overlap. Apply that complete identity before composing any noninvariant local representatives with p_j^{lit}. A fixed analytic-radius shrink in these literal coordinates can be paid by choosing a sufficiently large blocking integer once. A full iteration still

requires the representative identity and the local analytic-family and source-domain bounds at its buffered radii.

3.46. **Descent between real flat reference charts.** The homogeneous background was constructed on a fixed complex bond ball about each real flat connection. We now show that these physical background orbits agree wherever the balls overlap. A comparison of coarse flat connections must retain their holonomies. A globally periodic pure gauge is generally unavailable; the construction below uses a smooth gauge on the universal cover with its exact two-sided deck law. It selects no logarithm or root of a global holonomy.

The physical coarse torus has integer side $M \geq 2$, and the fine spacing is $h = L^{-k}$, $k \geq 0$. Coarse links have unit length. All connections in the first geometric construction are real SU(2) connections. Complexification will be used only after a uniformly close real flat fine extension has been produced. Constants depend on L, $0 < \alpha < 1$ and a fixed scalar bump, but not on depth, volume or holonomy. Bond-ball distances use a unitary-invariant matrix operator norm; it is equivalent to the Pauli norm in the strong background estimates.

3.46.1. *Parallel frames with their based holonomies.* For a flat connection on a periodic lattice, choose its parallel frame on the universal cover, based at the coarse node zero. It is convenient to write the links as

$$W(x, x') = p(x)p(x')^{-1}, \qquad p(0) = 1. \tag{3.mcccvii}$$

Thus $p(x)$ is the inverse of the path transport from zero to x. Let H_ν denote the actual positively oriented holonomy from zero to Me_ν. Periodicity and flatness give

$$p(x + Me_\nu) = p(x)H_\nu^{-1}. \tag{3.mcccviii}$$

Indeed the two parallel potentials for the translated connection differ by a constant right factor, determined at zero. The four H_ν commute, since the fundamental cycles commute and the connection is flat. They need not be close to the identity.

Let V_0, V_1 be real flat coarse connections, and let W_0 be any real flat fine extension of V_0. On coarse nodes the potential p_0 of W_0 also represents V_0: every path in a flat averaging row has the same endpoint transport, so $M^k W_0 = V_0$ is that transport. Choose the coarse parallel potential p_1 for V_1. In the parallel frame of W_0, put

$$g_z = p_0(z)^{-1}p_1(z), \qquad \widetilde{V}_1(z, z + e_\mu) = g_z g_{z+e_\mu}^{-1}. \tag{3.mcccix}$$

Here a tilde denotes the frame change p_0^{-1}, which makes W_0 the identity on the cover. With the actual based holonomies $H_{i,\nu}$, equations eq. 3.mcccviii give exactly

$$g_{z+Me_\nu} = H_{0,\nu} g_z H_{1,\nu}^{-1}. \tag{3.mcccx}$$

The order of these factors matters. In particular g_z need not be periodic or globally close to one.

Suppose

$$\sup_c \|V_1(c) - V_0(c)\| \leq \varepsilon. \tag{3.mcccxi}$$

The two parallel-frame factors are unitary, so $\|\widetilde{V}_1(c) - 1\| \leq \varepsilon$. Consequently $\|g_z - g_{z+e_\mu}\| \leq \varepsilon$. Any fixed-radius unit star of nodes has

$$\|g_z - g_{z'}\| \leq C_* \varepsilon \tag{3.mcccxii}$$

by a coordinate path with a fixed number of edges. This estimate uses no path going around the torus. In particular it does not bound $H_{1,\nu} - H_{0,\nu}$ by a volume-independent multiple of ε.

3.46.2. *A smooth quaternion interpolation respecting both deck factors.* Choose a nonnegative smooth product bump ρ, supported in $(-1,1)^4$ and positive on $[-3/4,3/4]^4$. On $\mathbb{R}^4$ set

$$\eta_z(X)=\frac{\rho(X-z)}{\sum_{w\in\mathbb{Z}^4}\rho(X-w)},\qquad M_g(X)=\sum_z \eta_z(X)g_z. \tag{3.mcccxiii}$$

Only a fixed number of terms are nonzero. The denominator has uniform positive lower and finite upper bounds. Thus $\sum_z \eta_z = 1$, $|\partial^r \eta_z| \le C_r$ and $\eta_z(y)=\delta_{zy}$ at the integer nodes. The last assertion uses the open support: every other bump and all its derivatives vanish at that boundary point. Also $\eta_{z+Mn}(X+Mn)=\eta_z(X)$.

Lemma 3.188 (Normalized quaternion interpolation)**.** For a fixed small ε, the formula

$$g(X)=\frac{M_g(X)}{\sqrt{\det M_g(X)}} \tag{3.mcccxiv}$$

defines a smooth SU(2) function, using the positive real scalar square root. It has $g(z)=g_z$ and the exact deck law

$$g(X+Me_\nu)=H_{0,\nu}g(X)H_{1,\nu}^{-1}. \tag{3.mcccxv}$$

For $1\le r\le 3$,

$$\|\partial^r g\|_\infty \le C_r\varepsilon. \tag{3.mcccxvi}$$

These bounds also hold for the right-translated derivatives. ■

Proof. Every g_z has real quaternion form $a_zI+ib_z\cdot\sigma$, with $a_z^2+|b_z|^2=1$. Real scalar averaging preserves that form. For a matrix $M=aI+ib\cdot\sigma$ with real coefficients, $M^*M=(a^2+|b|^2)I$ and $\det M=a^2+|b|^2$. At a given X fix one active node z_0. All other active nodes belong to a fixed star, so $\|M_g(X)g_{z_0}^{-1}-1\|\le C\varepsilon$ by eq. 3.mcccxii. Hence $\det M_g\ge(1-C\varepsilon)^2>0$. Formula eq. 3.mcccxiv is therefore globally smooth and lies in SU(2).

For $r\ge 1$, subtract g_{z_0} in the differentiated partition sum, since $\sum_z \partial^r\eta_z=0$. It follows that $\|\partial^r M_g\|\le C_r\varepsilon$ for $r\le 3$. Differentiating the determinant and its positive scalar square root gives the same bounds for their derivatives. Their uniform positive lower bound proves eq. 3.mcccxvi. No derivative of a globally selected root node is taken: on each star z_0 is fixed, and the resulting uniform estimates cover the whole space.

Normalization by this determinant is equivariant under constant left and right SU(2) multiplication. Both determinant factors are one, and the positive square root is unchanged. Reindexing eq. 3.mcccxiii by a deck shift and using eq. 3.mcccx proves eq. 3.mcccxv. Cardinality gives $g(z)=g_z$. Finally right translation by the unitary $g(X)^{-1}$ preserves the derivative norms. □

Only a positive real number is square-rooted in this argument. There is no choice of a continuous matrix logarithm of a holonomy, including at a central holonomy, and no choice of an h-dependent group root.

Proposition 3.189 (A uniformly close flat fine extension)**.** There is a real flat fine extension W_1' of V_1 such that

$$W_1'=e^{ihC_h}W_0,\qquad \|C_h\|_{X_\alpha(W_0)}\le C_\alpha\varepsilon. \tag{3.mcccxvii}$$

It is periodic in the original frame, has the actual holonomies of V_1, and has $M^kW_1'=V_1$ exactly. ■

Proof. In the W_0 parallel frame define $\widetilde{W}_1'(x,x+he_\mu)=g(x)g(x+he_\mu)^{-1}$. Its plaquettes are one by telescoping. The deck law is conjugation by $H_{0,\nu}$, so undoing the p_0^{-1} frame gives an ordinary periodic fine connection.

Every flat path from a coarse node y to $y+e_\mu$ has transport $g_yg_{y+e_\mu}^{-1}$ in this frame. Its actual contour means therefore give that same matrix. Identical transported inputs have their exact common mean even when that common value is far from one: the defining relative products are

one, and unitary covariance translates their regular branch. Thus the full average is exactly V_1. Its coarse cycle products are the fine cycle products, so the based fine holonomies are $H_{1,\nu}$.

Set $F_{h,\mu}(X) = g(X)g(X + he_\mu)^{-1}$. The integral difference formula and eq. 3.mcccxvi imply $\|\partial^r(F_{h,\mu} - 1)\| \le Ch\varepsilon$ for $r = 0, 1, 2$. For $r = 2$ this uses the third derivative of g; products of lower derivatives are also bounded by $C\varepsilon$. The logarithm near one consequently satisfies

$$\left\| \partial^r \frac{1}{ih} \log F_{h,\mu} \right\|_\infty \le C\varepsilon, \qquad r = 0, 1, 2.$$

Sampling this continuous expression on fine sites bounds its physical first differences and their local α seminorm, for every $\alpha < 1$. The frame change is unitary and converts ordinary differences into the flat covariant differences of W_0. This proves eq. 3.mcccxvii. The logarithm is traceless anti-Hermitian, so C_h is real. □

3.46.3. *Independence of the chosen real flat fine extension.*

Lemma 3.190 (Node-fixed equivalence of flat extensions)**.** If W_1 is any other real flat fine extension of the same literal coarse connection V_1, then there is a periodic unitary fine gauge f, equal to one at every coarse node, with $W_1^f = W_1'$. Applying f simultaneously to a field and its reference preserves its reference-covariant strong norm. ■

Proof. Let $T_1(0, x)$ and $T'(0, x)$ be their path transports on the cover and set $f(x) = T'(0, x)^{-1}T_1(0, x)$. Flatness shows directly on every edge that $W_1^f = W_1'$. On a coarse path both transports are the same product of the links of V_1. Hence f is one at all coarse nodes. Equality of the based holonomies makes f periodic: their left deck factors cancel in its displayed formula. The argument uses equality of every coarse link. Four equal holonomies alone would not force the gauge to be one at all coarse nodes.

For $U = e^{iha}W_1$, one has $U^f = e^{ih\,\mathrm{Ad}(f)a}W_1^f$. The unitary frame change intertwines every reference-covariant difference and parallel comparison. Thus its supremum and local Hölder norms are preserved. No ordinary fine derivative of this possibly large gauge is estimated or required. Unitary covariance also preserves the admitted complex mean branches. □

3.46.4. *Complex uniqueness inside a flat-reference strong chart.* We record the complex uniqueness statement needed on overlaps. It is stronger than equality obtained by analytic continuation from a possibly empty real overlap.

Lemma 3.191 (Complex critical-orbit uniqueness)**.** There are fixed $\delta_c, \rho_c > 0$, uniform in depth, volume and real flat reference, with the following property. Let $V = e^{iB}V_0$, $\|B\|_\infty < \rho_c$. A complex literal constrained-critical connection with a representative $U = e^{ihA}W_0$, $\|A\|_{X_\alpha(W_0)} < \delta_c$, is in the node-fixed complex gauge orbit of the constructed background. The comparison gauge is holomorphic in any holomorphic family of such representatives. ■

Proof. The canonical local branch is holomorphically critical: its real stationarity identities, written using the analytic right inverse, extend to its complex parameter ball. This is continuation inside one chart about a real center, not a claim about a real overlap.

The actual mean-slice contraction eq. 3.mcclxxxvii is an analytic contraction between the displayed complex Banach spaces. It sends U to $\overline{A}$ with $q_h(\overline{A}) = B$ and $RD^\sharp\overline{A} = 0$. Its group equation fixes the complete effective coarse gauge, so the subsequent literal correction differs from U by an exactly node-fixed gauge, including at reducible coarse connections.

The two analytic fibre maps in the proof of eq. 3.mcclxxxviii identify all tangent directions and preserve the action. Thus holomorphic constrained criticality implies $J_h(\overline{A}) = q_h'(\overline{A})^\sharp\omega$. The actual derivative is onto with right inverse eq. 3.mcclxxxix. The multiplier readout eq. 3.mccxc uses absolute values and the physical $W^{1,1}$ seed-column bound, so it remains valid for complex fields and gives $\|\omega\|_\infty \le C\|\overline{A}\|_{X_\alpha}$. This estimate uses no positivity.

Choose δ_c so the resulting pair lies in the joint contraction ball of eq. 3.mcclxvii. Its reference Landau penalty is zero by the imposed slice. It therefore solves that actual fixed-point equation and equals its unique complex solution. The explicit mean-slice gauge and literal node extension give the claimed comparison. They depend holomorphically on the representative. Real positivity was used to prove a minimum, but is not used in this uniqueness argument. □

3.46.5. *Changing the reference in a strong complex neighbourhood.* In the smooth relative frame of Prop. 3.189, an increment a measured relative to W_1' has the same strong norm as $\mathrm{Ad}(g^{-1})a$ in the trivial frame. Product differences and eq. 3.mcccxvi give

$$\|a\|_{X_\alpha(W_0)} \le C_\alpha \|a\|_{X_\alpha(W_1')}. \tag{3.mcccxviii}$$

Only the first two bounded derivatives of g enter. Its values may range throughout the unitary group. Locally its variation is $O(\varepsilon)$, and unitary conjugation does not change the zeroth-order size.

The pointwise matrix map

$$Z_h(a,C) = \frac{1}{ih}\log(e^{iha}e^{ihC}) \tag{3.mcccxix}$$

extends analytically to $h=0$ with value $a+C$. Its nonlinear part is h times a uniformly analytic quadratic expression. The discrete product rule and the Banach algebra estimate for X_α give, on a fixed small ball,

$$\|Z_h(a,C_h)\|_{X_\alpha(W_0)} \le C_\alpha(\|a\|_{X_\alpha(W_1')} + \varepsilon). \tag{3.mcccxx}$$

There is no h^{-1} loss: the logarithm in eq. 3.mcccxix vanishes to first order in h.

Let $\mathcal{B}_\rho(V_f)$ be the coarse complex ball $V = e^{iB}V_f$, $\|B\|_\infty < \rho$, about a real flat V_f. If two such balls intersect, their real centers satisfy

$$\|V_1 - V_0\|_\infty \le 2e^\rho \rho \le 3\rho \tag{3.mcccxxi}$$

for a fixed small ρ. Choose ρ below the homogeneous existence radius, the real interpolation threshold, and the complex uniqueness radius divided by the constants in eq. 3.mcccxx. All these choices are uniform.

Take the V_1-based background and use the real unitary node-fixed gauge of Lem. 3.190 to put its flat fine reference at W_1'. Its increment has $X_\alpha(W_1')$ norm at most $C\rho$. Equations eq. 3.mcccxx and eq. 3.mcccxxi put that actual connection inside the W_0 complex uniqueness chart, with strong norm at most $C'\rho < \delta_c$. Its coarse mean is still V, and it remains holomorphically constrained critical. Lem. 3.191 identifies it with the V_0-based background orbit.

3.46.6. *Holomorphic orbit and action descent.*

Proposition 3.192 (Uniform descent over real flat centers)**.** For a fixed $\rho > 0$ independent of M, k, the physical homogeneous background orbits and their total actions descend to the open set

$$\mathcal{D}_\rho^{\mathbb{C}} = \bigcup_{V_f \text{ real flat}} \mathcal{B}_\rho(V_f). \tag{3.mcccxxii}$$

The total action is a single holomorphic function there. The local background representatives have holomorphic node-fixed transition gauges, with the cocycle identity on triple overlaps. On real data these gauges are unitary. The descended orbit is covariant under all real coarse gauge transformations, and its total action is invariant under them. ■

Proof. The preceding argument gives equality of the physical orbits on each complex overlap directly, without a real-overlap identity theorem. The transition gauge is explicit: apply the fixed real comparison gauge f, then the actual holomorphic mean-slice gauge for the resulting W_0 representative, then the canonical literal extension at its mean-slice solution. Their product has value one at every coarse node. The exact group equations in the mean-slice construction prove this, not merely a first-order calculation. After factoring out the fixed real comparison gauge, the remaining site gauge has a logarithm of $Y_\alpha(W_0)$ norm at most $C\rho$. The comparison formula is analytic on a fixed

larger neighborhood of the inner overlap: choose an intermediate coarse radius so its background and BCH image still lie inside δ_c, and then choose the atlas radius much smaller. Cauchy's formula on that intermediate ball gives uniform parameter jets of the transition in these relative norms. The possible thinness of the final overlap therefore introduces no volume- or depth-dependent constant.

The node-fixed gauge action is free on a connected fine graph. Indeed a stabilizing gauge is transported from its value at one coarse node along every fine edge; that value is one. Consequently the transition gauge between two given literal representatives is unique. If $U_i = U_j^{t_{ij}}$, this implies $t_{02} = t_{01}t_{12}$ on triple overlaps. This argument does not require irreducibility of the coarse holonomies. Local representatives and these holomorphic transitions give the asserted holomorphic orbit descent. Fine Wilson trace invariance gives equality of their holomorphic total actions, so ordinary function gluing gives a single holomorphic action. Only its local strong representatives are asserted; a globally chosen gauge with the same strong bound is not needed.

For a real coarse gauge u, the center V_f^u is again real flat, and $V^u(V_f^u)^{-1} = u(VV_f^{-1})u^{-1}$ at each initial node. Thus the ball is carried isometrically to the ball about V_f^u. Extend u by any unitary fine site values with the prescribed coarse values, and transform a field and its flat reference together. Their reference-covariant strong norms are preserved exactly. Their literal means transform by u and their actions are unchanged. Complex critical-orbit uniqueness at the transformed reference identifies the transformed branch with the descended branch. Two choices of the fine extension differ by a node-fixed gauge, so the orbit statement is independent of that choice. This proves the last assertions, including arbitrary real coarse gauges. □

The domain eq. 3.mcccxxii is a union of small complex balls about real flat connections. It is not asserted to contain all curvature-only regular data or to be saturated under arbitrary complex gauges. On an overlap the equality is the nonlinear total identity $S_0(B_0(V)) = S_1(B_1(V))$. Taylor polynomials about the two centers need not agree term by term. This descent therefore does not identify local fixed-reference Taylor pieces, their filing, their contour cutoffs, or older fine-core activity transports. Those require their own coordinate and domain comparisons.

3.47. **A homogeneous critical atlas from coarse curvature alone.** We construct the regular trial which was an input to Prop. 3.120. The coarse connection need not be close to a flat connection in a global bond gauge. Its plaquettes are small, but its holonomies and topological sector are unrestricted. A smooth quaternionic line bundle interpolates the coarse connection. Sampling its connection gives fine trials with bounded physical curvature and current at every depth.

The setting is homogeneous. Coarse spacing is one, the fixed blocking integer is the odd number L, and $h = L^{-k}$ is the fine spacing. The coarse torus has compatible integer periods at least two. Write V_{ij} for transport from the head j to the tail i, and $V_{ji} = V_{ij}^{-1}$. Assume

$$\|V(\partial p) - 1\| \le \kappa \quad \text{for every coarse plaquette } p. \tag{3.mcccxxiii}$$

For small angles this norm and the admitted plaquette logarithm are equivalent. All smallness choices below are independent of h, the periods and the number of coarse cells. Constants may depend on L and on the fixed regularity exponents and collars.

3.47.1. *Local transports without logarithms of coarse links.* We work first on the universal covering lattice $\mathbb{Z}^4$. Lift V periodically. Distinct lifted vertices remain distinct indices, even if they have the same image on a small torus. This convention is important on a two-cell period: its two oppositely placed crossing edges can have different holonomy.

A bounded closed edge word in a box of fixed diameter can be reduced by interchanging adjacent coordinate steps and canceling inverse pairs. An interchange inserts a conjugate of one plaquette. A word of bounded length requires a bounded number of such interchanges. Since all transports are unitary,

$$\|V(\gamma) - 1\| \le C_R\kappa \tag{3.mcccxxiv}$$

for every contractible edge word of length and diameter at most R. This is a finite word estimate on the covering lattice. It is not a bound for a noncontractible torus loop.

One may fix short paths with reverse paths paired. We specify a symmetric choice to retain lattice covariance. For two vertices in a fixed bounded box, take the at most 4! coordinate-order paths, traversing each nonzero coordinate displacement in one block. Let their backward transports be W_γ and set

$$M_{ij} = \frac{1}{n_{ij}} \sum_\gamma W_\gamma, \qquad U_{ij} = M_{ij} (\det M_{ij})^{-1/2}, \qquad U_{ii} = 1. \tag{3.mcccxxv}$$

An average of real quaternion matrices is quaternionic and $M_{ij}^\sharp M_{ij} = (\det M_{ij}) I_2$. Here $\sharp$ on a 2 by 2 matrix means its quaternionic adjugate; on real quaternion matrices it is the Hermitian transpose. The paths differ by bounded contractible loops. Thus M_{ij} is within $C_R\kappa$ of any one W_γ, and its determinant is positive and close to one. The square root in eq. 3.mcccxxv is the positive scalar root. It is not a root or logarithm of a coarse group element. Only overlapping partition indices are used in the projection below. Auxiliary paths to an anchor are used only on the fixed read boxes. Fix their maximum radius after the required mean and regularity collars, and choose κ afterward. No estimate for unbounded-length paths is asserted.

This construction is equivariant under left and right unitary multiplication, and under reversal. Indeed the reversed path average is $M_{ij}^\sharp$, its determinant is unchanged, and $U_{ji} = U_{ij}^\sharp = U_{ij}^{-1}$. For adjacent vertices there is one path, so U_{ij} is exactly the given coarse link. Coordinate isometries permute the path multiset. In particular the choice is translation and hypercubic covariant. The short loop bound also gives, for three vertices in a fixed box,

$$\|U_{ij} - U_{iy} U_{yj}\| \le C_R \kappa. \tag{3.mcccxxvi}$$

To see this for the normalized averages, first use eq. 3.mcccxxiv for one chosen path in each factor, then use their $C_R\kappa$ difference from the averages.

3.47.2. *A smooth rank-one projection.* Choose an even nonnegative smooth function φ, supported in $(-1, 1)$, positive on $[-1/2, 1/2]$, with $\varphi(0) = 1$. For $i \in \mathbb{Z}^4$ put

$$f_i(x) = \prod_{\mu=1}^4 \varphi(x_\mu - i_\mu), \qquad s_i(x) = \frac{f_i(x)}{(\sum_j f_j(x)^2)^{1/2}}, \qquad \psi_i = s_i^2. \tag{3.mcccxxvii}$$

The denominator is uniformly bounded below. The s_i are smooth, including at their support boundaries; all their fixed derivatives are uniformly bounded. At most sixteen indices are active at any point, $\sum_i s_i^2 = 1$, and $s_i(j) = \delta_{ij}$. Along a coarse edge only its two endpoints can be active.

Use these indices as quaternionic coordinates and form

$$P_{ij}(x) = s_i(x) s_j(x) U_{ij}. \tag{3.mcccxxviii}$$

This is a bounded self-adjoint quaternionic operator on $\ell^2(\mathbb{Z}^4; \mathbb{H})$, but every calculation below is finite: its nonzero block at a point has at most sixteen quaternionic rows. Derivatives on a fixed small neighborhood use a fixed finite union of those indices. No infinite determinant or infinite-dimensional Gaussian is introduced.

Fix an anchor y and a physical box of fixed radius R about it. Define, throughout that box,

$$u_y(x)_i = s_i(x) U_{iy}. \tag{3.mcccxxix}$$

The anchor need not be active. Its transports have bounded length in a fixed larger box. The exact identities are $u_y^\sharp u_y = I_2$ and $u_y^\sharp \mathrm{d} u_y = 0$; the latter follows from $\sum_i s_i \, \mathrm{d} s_i = 0$, since each U_{iy} is independent of x. By eq. 3.mcccxxvi,

$$\|P - u_y u_y^\sharp\|_{C^m} \le C_{m,R} \kappa \tag{3.mcccxxx}$$

for every fixed m. The matrix norm has no volume factor, because the active block is bounded in size.

Choose κ below the finitely many margins used below. At each point the spectrum of P lies in disjoint small neighborhoods of zero and one. Define

$$\Pi(x) = \frac{1}{2\pi i} \int_{|z-1|=1/4} (z - P(x))^{-1}\, dz. \tag{3.mcccxxxi}$$

The contour resolvent is computed on the finite active block; the integral on its zero complement is zero. The resolvent identity, or its Neumann expansion about $u_y u_y^\sharp$, proves

$$\Pi^2 = \Pi = \Pi^\sharp, \quad \operatorname{rank}_{\mathbb{H}} \Pi = 1, \quad \|\Pi - u_y u_y^\sharp\|_{C^m} \le C_{m,R}\kappa. \tag{3.mcccxxxii}$$

For example every differentiated resolvent is a finite sum of products of bounded resolvents and derivatives of P; a difference from the comparison projector contains at least one $O(\kappa)$ difference. This proves the derivative estimate without a spectral-eigenvector choice. The quaternionic rank is one, equivalently its complex rank is two.

The ranges $E_x = \operatorname{ran} \Pi(x)$ form a smooth quaternionic line bundle on the cover. Put on it the connection $\nabla = \Pi \mathrm{d}$. A normalized local frame on the whole fixed box is

$$v_y = \Pi u_y \, (u_y^\sharp \Pi u_y)^{-1/2}. \tag{3.mcccxxxiii}$$

The middle 2 by 2 matrix is a positive scalar multiple of I_2: it is a self-adjoint quaternion of size one. It differs from I_2 by $O(\kappa)$. Thus $v_y^\sharp v_y = I_2$, $v_y v_y^\sharp = \Pi$, and $v_y - u_y = O(\kappa)$ in every fixed local C^m norm. Its connection matrix and its curvature satisfy

$$A_y = v_y^\sharp \mathrm{d} v_y, \qquad \|A_y\|_{C^m} + \|\mathrm{d}A_y + A_y \wedge A_y\|_{C^{m-1}} \le C_{m,R}\kappa. \tag{3.mcccxxxiv}$$

Indeed $u_y^\sharp \mathrm{d} u_y = 0$ cancels the order-one terms from the partition. The remaining terms have a factor $v_y - u_y$ or its derivative. The matrices A_y are traceless anti-Hermitian. Local frames have exact unitary transition functions $v_z^\sharp v_y$. We have not chosen a global smooth frame, which need not exist.

3.47.3. *Exact edge interpolation and periodic descent.* On a coarse edge (y, z) the two-index block of P is exactly a projection. Its unit frame is

$$u = (s_y I_2,\ s_z U_{zy})^{\mathsf{T}}.$$

Its connection $u^\sharp \mathrm{d} u$ is zero along that edge. At the endpoints this frame is e_y and $e_z U_{zy}$, respectively. Backward connection transport therefore sends $e_z \zeta$ to $e_y U_{yz} \zeta$. Consequently

$$\text{backward transport in } (E, \nabla) \text{ along } (y, z) \text{ in canonical endpoint frames} = V_{yz}. \tag{3.mcccxxxv}$$

This checks the orientation against the lattice convention. It also explains why a potentially large V_{yz} requires neither a logarithm nor a fractional power.

For each coarse-period translation t, let S_t shift the ambient vertex indices. The construction is exactly equivariant:

$$P(x + t) = S_t P(x) S_t^{-1}, \qquad \Pi(x + t) = S_t \Pi(x) S_t^{-1}. \tag{3.mcccxxxvi}$$

Thus the bundle and connection descend under $(x, w) \sim (x + t, S_t w)$. At every coarse vertex their canonical frame e_y descends as well. This gives an ordinary rank-one quaternionic bundle over the coarse torus. The use of a covering-coordinate Hilbert space is only a uniform way to retain distinct local indices; all its bundle charts and connection computations are finite-dimensional.

Equivalently, any fixed finite collection of read stars can first be placed in a sufficiently large compatible finite cover. The finite active-block formulas are the same there. One descends the equivariant bundle and connection. One does not average projections or compare partition functions on different volumes. In particular no short torus loop is silently declared contractible: the loop filling in eq. 3.mcccxxiv always occurs between distinct lifted indices.

3.47.4. *Fine trials and the actual Wilson-current cancellation.* At the fine vertices choose arbitrary unit quaternionic frames of E, with frame e_y at the coarse vertices. A choice is possible on this finite set even when the bundle is nontrivial. Define W_h on a fine edge by backward parallel transport of ∇ between those frames. This is a real SU(2) lattice connection. Changing the fine frames changes it by a fine gauge equal to one at coarse vertices.

On every fixed physical read box use the smooth frame v_y. In this frame $A_y = ia_y$, where a_y is Hermitian and has all fixed C^m norms bounded by $C_m\kappa$. The parallel transport equation and its integral iteration give fine links $W_h(x,\mu) = e^{iha_{h,\mu}(x)}$ with

$$\|a_h\|_{C^m} \le C_m\kappa. \tag{3.mcccxxxvii}$$

Here differences or derivatives of the sampled function have physical units. To justify division by h, the transport matrix is $1 + \int_0^h A_y(x + te_\mu)\,dt + O(h^2\kappa^2)$. Its admitted logarithm vanishes at $h = 0$, so its logarithm divided by h is smooth with these bounds. Differentiating the integral equation proves every fixed spatial derivative estimate. This is a local frame statement, not a global small potential for the lattice connection.

The same equation applied to a square gives, uniformly in the local box,

$$\|W_h(\partial p) - 1\| \le C\kappa h^2, \qquad \|\partial_x^m(W_h(\partial p) - 1)\| \le C_m\kappa h^2. \tag{3.mcccxxxviii}$$

The missing linear term follows either by multiplying the four integral expansions or by cancellation of the two oppositely oriented segments in each direction. Their second-order coefficient is the connection curvature. The integral remainder and all its fixed derivatives are bounded by $C_m\kappa h^3$. These estimates follow from eq. 3.mcccxxxiv; no field equation is assumed.

It is essential to pair the plaquettes in the current. Put $\mathcal{S}(P) = (P - P^{-1})/(2i)$. For the positive bond $b = (x, x + he_\mu)$, the two plaquettes in the $\mu\nu$ plane contribute, in the tail frame,

$$h^{-3}\left\{\mathcal{S}(P_{\mu\nu}(x)) - \mathrm{Ad}(W_h(x - he_\nu, \nu)^{-1})\mathcal{S}(P_{\mu\nu}(x - he_\nu))\right\}. \tag{3.mcccxxxix}$$

This follows by varying the first link in the upper plaquette and the inverse third link in the lower one, then using cyclicity of the trace. It is the actual physical left Wilson current normalization. The translated difference of the two $\mathcal{S}$ terms is $O(\kappa h^3)$ by eq. 3.mcccxxxviii. The transporting link in this smooth frame is $1 + O(\kappa h)$; its additional commutator is $O(\kappa^2 h^3)$. Summing the three planes proves

$$\|F(W_h)\|_\infty + \|j(W_h)\|_\infty \le C\kappa, \tag{3.mcccxl}$$

with physical fine spacing h. The statement is gauge covariant, so arbitrary vertex frames cause no loss. Bounding each summand before this pairing would instead give the false bound $C\kappa/h$ for this purpose.

3.47.5. *The complete hierarchical mean has a uniform error.* The actual k-fold mean of a coarse edge reads a fixed physical star of radius R_L, independent of k: the successive stencil radii sum as a geometric series. Choose the preceding local boxes larger than that star, including every internal contour and a fixed collar. Use its tail vertex y as anchor. The local smooth frame at its head is $e_z U_{zy}$, so the central coarse edge is 1 in this frame, by eq. 3.mcccxxxv.

Extend a_h from the read star by a fixed smooth cutoff on a larger box. Its supremum and fixed physical derivatives remain $C_L\kappa$. On a small period one can do this on a large compatible cover; the mean's read set is kept before descent. The actual mean is local and gauge covariant, so this extension does not alter the edge under consideration.

Apply the absolute plain-mean row majorant eq. 4.cccxlv, with physical output length $\xi_s = hL^s$. It gives

$$\|\log M^s(e^{iha_h})\|_\infty \le C_L\kappa\xi_s, \qquad 0 \le s \le k \tag{3.mcccxli}$$

on every intermediate read edge needed for this final edge. The majorant also controls the actual internal node factors and closed logarithms. Choose κ below its fixed raw input ceilings; thus every

actual mean operation is on its intended analytic branch. At $s = k$ the local output is $1 + O(\kappa)$, while its central original edge was exactly 1. Transforming the endpoints back gives

$$\sup_c \left\| \frac{1}{i} \log\{M^k(W_h)(c)V(c)^{-1}\} \right\| \le C_L \kappa. \tag{3.mcccxlii}$$

No factor C_L^k has been iterated. This estimate uses the full actual plain mean, not a straight-line linear replacement. Its gauge covariance also shows that the answer is independent of the arbitrary fine vertex frames with canonical coarse endpoints.

Proposition 3.193 (Actual smooth homogeneous trials)**.** For sufficiently small coarse curvature in eq. 3.mcccxxiii, every $h = L^{-k}$ has a real fine trial $W_h(V)$, defined up to a gauge one at coarse nodes, with eq. 3.mcccxl and eq. 3.mcccxlii. Its local smooth-frame potentials have all fixed C^m bounds $C_m\kappa$. Its connection has exactly the original coarse-edge transports before hierarchical averaging. All actual hierarchical mean charts are admitted. The constants are uniform in depth and compatible volume. ∎

3.47.6. *A holomorphic comparison which has no fine-frame jump.* Fix a real coarse centre V_*. Write nearby coarse data as $V_B = e^{iB}V_*$, with the raw coarse bond supremum norm of B small. Products along every fixed short path are holomorphic in B. In complex formulas $\sharp$ is the analytic quaternionic adjugate, followed by block transpose; it does not conjugate a parameter. The normalized averages in eq. 3.mcccxxv use the scalar branch near determinant one. Reversal and $P^\sharp = P$ remain algebraic identities. The fixed contour in eq. 3.mcccxxxi therefore defines a holomorphic idempotent Π_B, with

$$\|\Pi_B - \Pi_*\|_{C^m} \le C_m \|B\|_\infty. \tag{3.mcccxliii}$$

All these norms are local finite-block norms and their supremum over physical boxes. The constants do not count the coarse volume. In particular $\Pi_B(y) = \Pi_*(y) = e_y e_y^\sharp$ at coarse vertices.

For two close idempotents put

$$T_B = \{\Pi_B\Pi_* + (1-\Pi_B)(1-\Pi_*)\}\{1 - (\Pi_B - \Pi_*)^2\}^{-1/2}. \tag{3.mcccxliv}$$

The inverse square root is its norm-convergent binomial series. Direct multiplication of the two idempotents shows

$$T_B^\sharp T_B = 1, \qquad T_B\Pi_* = \Pi_B T_B, \qquad T_B(y) = 1, \qquad \|T_B - 1\|_{C^m} \le C_m\|B\|_\infty. \tag{3.mcccxlv}$$

For the first equality, if $S = \Pi_B\Pi_* + (1-\Pi_B)(1-\Pi_*)$, then $S^\sharp S = 1 - (\Pi_B - \Pi_*)^2$; the latter commutes with both idempotents and with S. Real data make T_B unitary. These formulas remain valid on the smaller complex ball by the same algebra and series.

Choose the fine frames of the deformed trial to be $T_B(x)e_x^*$, where e_x^* are the fixed frames of $W_h(V_*)$. Pulling its connection back to E_* gives

$$\nabla_B^{\mathrm{al}} = \nabla_* + C_B, \qquad C_B = \Pi_* T_B^\sharp(\mathrm{d}T_B)\Pi_*\big|_{E_*}, \qquad \|C_B\|_{C^m} \le C_m\|B\|_\infty. \tag{3.mcccxlvi}$$

This follows by applying $T_B^\sharp \Pi_B \mathrm{d}$ to $T_B s$ for a section s of E_*. It compares connections, not discontinuously chosen vertex frames.

The relative edge transport of these two smooth connections is $1 + O(h\|B\|)$ in the tail reference frame. The integral transport equation and its differentiated equations give an admitted logarithm

$$W_h(V_B)(b)W_h(V_*)(b)^{-1} = e^{ihE_h(B)(b)}, \qquad \|E_h(B)\|_{\mathrm{str},\alpha;W_h(V_*)} \le C_\alpha\|B\|_\infty. \tag{3.mcccxlvii}$$

The local reference connection has its uniform C^m bounds, so ordinary derivatives of the relative transport give the stated covariant differences and Hölder seminorm. Division by h is removable in this relative equation, just as in eq. 3.mcccxxxvii. Both the map and its fixed-order derivatives are holomorphic uniformly in h. A new arbitrary anchor choice at each B would not justify this

estimate: it could create a jump of order B/h in relative coordinates. The prescribed aligned frames avoid that jump.

The construction is local in the coarse data on each fixed physical box: P reads finitely many short paths, and the functional calculus and T_B act pointwise on its finite active block. Thus its parameter estimates do not hide a volume-dependent global gauge choice.

3.47.7. *Critical correction at every curvature-small datum.* Fix the real trial $W_h(V_*)$, with approximate multiplier zero. By eq. 3.mcccxl it satisfies the actual regularity and defect hypotheses of Prop. 3.120, with defect at most $C\kappa$. The homogeneous determining region has no artificial inner boundary; the actual site and field rows are admitted by eq. 3.mcccxli. All fixed inverse and regularity collars can be chosen before decreasing κ.

Let $V_*^{\mathrm{tr}} = M^k W_h(V_*)$. For target $V_B = e^{iB}V_*$, its literal datum relative to the trial is

$$B^{\mathrm{tr}}(B) = \frac{1}{i}\log(V_B(V_*^{\mathrm{tr}})^{-1}), \qquad \|B^{\mathrm{tr}}(B)\|_\infty \le C(\kappa + \|B\|_\infty). \tag{3.mcccxlviii}$$

This logarithm is close to the identity even when the individual coarse links are not. Apply the actual forced fixed point of RTC to this datum. It retains the source $-j(W_h(V_*))$, removes its gauge penalty by the exact gauge tests, and uses the actual mean slice and literal correction. It gives a holomorphic critical orbit with mean exactly V_B. In its trial chart its field and multiplier are bounded by $C(\kappa + \|B\|_\infty)$. In particular a critical orbit at V_* has actual physical curvature and current at most $C\kappa$. No critical reference or globally small coarse potential was assumed in obtaining it.

3.47.8. *Identification on overlaps and the resulting atlas.* Consider two real centres $V_*, \widetilde{V}_*$ whose sufficiently small complex datum balls overlap. Their raw relative coarse distance is at most $C\rho$, where ρ is the common radius. The real unitary map in eq. 3.mcccxliv aligns their trial bundles. It is the identity at coarse nodes. Fine frames chosen differently from this alignment are related by a real fine gauge one at those nodes. After that fixed gauge, their real trials differ by at most $C\rho$ in the covariant strong norm of eq. 3.mcccxlvii.

Both complex critical germs on the overlap differ from their respective trials by at most $C(\kappa+\rho)$. Reference strong norms are equivalent under the above small real connection change. Choose ρ and then κ so that their combined bound lies inside the larger RTC uniqueness chart of the first trial. They have the same literal coarse datum. The actual complex mean-slice and competing-multiplier uniqueness of RTC therefore identify their orbits modulo fine gauges one at coarse nodes. No positivity of a complex square is needed in this step.

These orbit identifications are holomorphic. Indeed the fixed-reference mean-slice maps and the specified literal correction used in RTC are holomorphic. They send the two germs to the same unique slice solution; composing their admitted gauges gives the transition gauge, with identity coarse-node values. On a triple overlap this describes the same orbit, irrespective of which sequence of Kato maps was used. Kato maps themselves need not obey a multiplicative cocycle. Alternatively both local trial frames can be placed in the common bundle $E(V)$ by $T(\Pi(V), \Pi(V_*))$; ordinary frame changes there obey the exact cocycle. The node-fixed fine gauge action is free: an element fixing the fine connection is propagated from its identity value at a coarse node along every fine edge. Thus the transition gauges for specified local representatives also obey that cocycle. The total Wilson action is unchanged by all these gauges.

Changing the bounded short-path policy does not change this orbit. Its used transports differ by $O(\kappa)$ by eq. 3.mcccxxiv; hence the two projections differ by $O(\kappa)$ in every fixed local derivative norm. Their Kato identification is the identity at coarse nodes and their trial connections differ by $O(\kappa)$ in the strong norm. The same RTC uniqueness argument identifies the two critical corrections. The partition and all finite read collars remain fixed in this comparison.

The interpolating construction is equivariant under real coarse gauge transformations. For $g = (g_i)$, the ambient constant diagonal map $G = \mathrm{diag}(g_i)$ gives $P(V^g) = GP(V)G^{-1}$, and similarly for Π and its connection. At coarse nodes $Ge_i = e_i g_i$, exactly the required coarse gauge. Coordinate isometries likewise permute the chosen path averages and partition. Arbitrary fine frame choices only introduce the gauges already factored out. RTC uniqueness thus gives real coarse gauge and lattice covariance of the total critical orbit and action.

Proposition 3.194 (A physical homogeneous curvature atlas)**.** For sufficiently small κ, every real homogeneous coarse field satisfying eq. 3.mcccxxiii has an actual constrained-critical fine orbit at every $h = L^{-k}$. Its literal mean is the given coarse field, and its physical fine curvature and current are bounded by $C\kappa$, uniformly in depth and volume. Large holonomies and nontrivial bundle topology are allowed.

There is a fixed positive datum radius about every such real field on which the orbit has a holomorphic germ. These germs identify on overlaps as above. The total action therefore defines a holomorphic function on their union, with real coarse gauge and lattice covariance. On real curvature-small data,

$$|S_h(V)| \le C\kappa^2 \mathcal{V}. \tag{3.mcccxlix}$$

Local fixed-order analytic responses have the uniform localized bounds of RTC in each chosen real trial chart. ■

Proof. The trial proposition supplies all the real reference hypotheses of RTC and the small literal datum error. Its actual forced fixed point gives the critical orbit and its physical bounds. The overlap argument identifies the germs, so at any real curvature-small datum the estimate obtained by using that datum itself as centre is the estimate for the glued orbit. Its fine plaquette action is at most $Ch^4\kappa^2$; summing $O(h^{-4}\mathcal{V})$ plaquettes proves eq. 3.mcccxlix. Localized responses follow from the RTC fixed point on the same reference, composed with the pointwise analytic datum eq. 3.mcccxlviii. The deck-equivariant geometric construction gives the same statements at small periods without any quantum-cover comparison. □

The uniqueness asserted here is the controlled trial-atlas uniqueness. It does not classify arbitrary disconnected fine critical sectors. The result removes the need to assume a regular trial for homogeneous curvature-small data; it does not construct a mixed-scale proper trial, an independent-current history core, or a positive conditional measure.

3.48. **Constant diagonal weights on the curvature atlas.** The curvature atlas supplies smooth fine trials without a global small-potential assumption. We keep those trials and change the six plaquette coefficients. The change of principal part is bounded from $W^{2,p}$ to L^p. We first retain that stronger field norm in the joint inverse, and then solve the weighted equation about the given trial.

Coarse spacing is one, $h = L^{-k}$, and the homogeneous periods are compatible with the fixed odd L. Let

$$\mathcal{A}_h^a(U) = \sum_{\mu<\nu} a_\mu a_\nu \sum_x \left(1 - \tfrac{1}{2}\operatorname{tr} U_{\mu\nu}(x)\right), \qquad a = (a_1, \dots, a_4). \tag{3.mcccl}$$

The parameter a is constant in space. Its complex domain is a polydisc about 1; the real weights in that disc are positive. The group mean, its straightening, the site restoration and the literal node correction do not change.

3.48.1. *A joint inverse with two L^p derivatives.* Fix $0 < \alpha < 1$ and a finite $p > 4/(1-\alpha)$. Use complete enlarged unit cells C_y^+, with all stencils and averaging collars. In the fixed comparison

frames of a real regular reference put

$$\begin{aligned}\|f\|_{\mathcal{F}_p} &= \sup_y \|f\|_{L^p(C_y^+)},\\ \|A\|_{\mathcal{W}_p} &= \sup_y \sum_{r=0}^{2} \|D^r A\|_{L^p(C_y^+)}.\end{aligned} \tag{3.mcccli}$$

The fine measure is h^4, and all mixed covariant second differences are included. The fixed enlargement can accommodate the finitely many nested cutoffs used below. Discrete Morrey gives

$$\|A\|_{\mathcal{A}_\alpha} \le C_{p,\alpha}\|A\|_{\mathcal{W}_p}. \tag{3.mccclii}$$

These are cell Banach norms, not sums over fine coordinates. On a sufficiently small $C^{1,\alpha}$ tube the second-difference norms at the present base and at the fixed real reference are equivalent: their difference contains only the connection difference, its first difference, and at most one difference of the field.

Lemma 3.195 (The strong row saddle in $W^{2,p}$)**.** On the homogeneous restriction of the domain of Prop. 3.163, the field output of the full row saddle satisfies

$$\|A\|_{\mathcal{W}_p} + \|\mu\|_\infty \le C_{p,\alpha}(\|f\|_{\mathcal{F}_p} + \|b\|_\infty). \tag{3.mcccliii}$$

It retains a sufficiently small exponential weight on the cell norms. The constants are uniform in depth and compatible volume. The present base may have a rough unweighted Wilson current; it must be in the stated strong tube, and the independent current has the smaller strong-family bound. ■

Proof. We give the second-derivative step in the strong column proof, rather than inferring it from $C^{1,\alpha}$ regularity. For the positive field primitive, its local energy columns and coarse row bounds first control the local H^1 norm and the multiplier. A localized $\mathcal{F}_p$ force is in the physical L^2 force class because $p > 2$ and these cells have bounded physical volume.

After adding the full divergence term, the exact Wilson curl–divergence stencil is a component covariant Laplacian plus bounded curvature multiplications and fixed neighboring shifts, as in Lem. 3.161. The row-mass forcing is bounded pointwise by the energy cell norm of the complete average. The physical transpose has its actual fine density, so no energy field is evaluated at a point. In the local real comparison frame the scalar equation has bounded first-order and zeroth-order coefficients. On the complex tube the same coefficient bounds hold. Pairing opposite shifts before dividing by h gives these bounds without differentiating curvature. Possible normal-coordinate current coefficients carry h; the plaquette bound controls them. No pointwise estimate for the present unweighted current is used.

Apply the local scalar estimates on nested complete boxes. Energy gives H^1. The 2 estimate gives $W^{2,2}$, hence gradient L^3 by a strict four-dimensional embedding. The 3 estimate then gives $W^{2,3}$, hence gradient L^8 and bounded field. If $p \le 8$, apply the final p estimate. If $p > 8$, first apply the 8 estimate, obtaining bounded gradient, and then the desired finite p estimate. Retain the D^2A term in that last estimate, before the Morrey step in the strong-field proof. Each prescribed force belongs to the lower exponents used in this finite bootstrap. The cutoff commutators contain only the controlled outer field and first differences.

The slow positive parametrix has the same C_p/m force error when its output slot is supplied with this additional $W^{2,p}$ norm. Its local output factors have just been bounded in that norm. Thus its positive series still converges after increasing the fixed m. In the Woodbury correction the field output again has a positive field inverse on the left. The current corrections map strong fields to $\mathcal{F}_p$, by eq. 3.mcxc and the subsequent second-constraint estimate. Their physical adjoints use the finite-p force classes of eq. 3.mclxxxvii. Consequently the current Neumann series retains the $W^{2,p}$ output: apply this improved leftmost field factor, and use the already proved strong bounds for

its remaining factors. There is no assertion that the restoration projection by itself preserves three derivatives.

The row lift has the same leftmost field factor. The normalized coarse row inverse bounds its multiplier in ℓ^∞, while $Q^\sharp$ sends a bounded row multiplier to the bounded fine force supplied by its physical column density. The full row-saddle formula in eq. 3.mcxci therefore gives eq. 3.mcccliii.

For a spatial weight use the energy columns first and apply the finite sequence of scalar estimates on each output cell. Weights on neighboring enlarged cells have bounded ratio. No artificial weight is differentiated. The other primitive and coarse factors have their two exponential Schur sums. This proves the weighted assertion. □

We shall use this lemma at a smooth trial U_0, with independent current zero. Write

$$H_0 = F_0''(0), \qquad F_0(A) = \mathcal{A}_h^1(e^{ihA}U_0).$$

Remove the artificial row mass from the saddle by its exact multiplier shift. If the mass-added saddle returns (A,μ) with $QA = b$, put $\nu = \mu - a_f b$. Then the inverse of

$$\mathcal{L}_0\begin{pmatrix} A \\ \nu \end{pmatrix} = \begin{pmatrix} (H_0 + DRD^\sharp)A - Q^\sharp\nu \\ QA \end{pmatrix} \tag{3.mcccliv}$$

has the same bound eq. 3.mcccliii. Here a_f is bounded above and below, since coarse spacing is one. This is the full saddle; no horizontality of its trial lift is assumed.

3.48.2. *The principal perturbation and the weighted trial force.* Let V_* be real with $\|V_*(\partial p)-1\| \le \kappa$. Choose the smooth trial

$$U_0 = W_h(V_*) \tag{3.mcccclv}$$

of Prop. 3.193. Its local potentials have all fixed C^m bounds $C_m\kappa$, and its ordinary Wilson current and curvature are bounded by $C\kappa$. All finite read collars are chosen before κ is decreased. Holonomies and bundle topology are not restricted.

Put

$$F_0^a(A) = \mathcal{A}_h^a(e^{ihA}U_0), \qquad j_0^a = (F_0^a)'(0), \qquad H_{0,a} = (F_0^a)''(0).$$

Lemma 3.196 (Bounds at the unchanged trial)**.** On a fixed complex weight polydisc,

$$\begin{aligned} \|j_0^a\|_\infty &\le C\kappa, \\ \|(H_{0,a} - H_0)A\|_{\mathcal{F}_p} &\le C|a-1|\|A\|_{\mathcal{W}_p}, \\ \|(F_0^a)'(A) - j_0^a - H_{0,a}A\|_{\mathcal{F}_p} &\le C\|A\|_{\mathcal{W}_p}^2. \end{aligned} \tag{3.mcccclvi}$$

The last remainder has Lipschitz constant Cr on a radius-r ball. The maps are holomorphic on fixed larger product domains, uniformly in h and volume. ■

Proof. For each plane multiply the exact paired-current formula eq. 3.mcccxxxix by $a_\mu a_\nu$. The two plaquettes retain the same constant coefficient. Their transported difference is $O(\kappa h^3)$, including the commutator from the connecting link. Division by h^3 and summation over the three planes incident to a bond give the first bound. A bound on separate unpaired plaquettes would lose a factor h^{-1}.

Each plane Hessian at this smooth trial is a second-difference operator with bounded principal coefficients and bounded lower-order coefficients in the fixed local frames. This also follows directly by differentiating its paired plaquette expression: covariant second differences act on the variation, and differences of trial coefficients have the bounds eq. 3.mcccxxxvii. Thus its L^p output is bounded by the three terms in eq. 3.mcccli. The difference of the weights is $a_\mu a_\nu - 1$. There are six planes, which proves the second bound. It is not a bounded perturbation on $C^{1,\alpha}$ alone.

For the final bound apply the centered Wilson residual calculation Lem. 3.146 separately to those six planes. Constant coefficients $a_\mu a_\nu$ change only its constants. Subtract both the constant

and the full linear jet before estimating. The remainder is bounded pointwise by $C\|A\|^2_{\mathcal{A}_\alpha}$. Use eq. 3.mccclii and the cell volume to obtain its $\mathcal{F}_p$ bound. Cauchy on the larger strong ball gives the Lipschitz estimate. □

Define $\mathcal{L}_{0,a}$ by eq. 3.mcccliv with $H_{0,a}$ in place of H_0. The perturbation affects only its first component. By the second bound in eq. 3.mccclvi,

$$\|\mathcal{L}_0^{-1}(\mathcal{L}_{0,a}-\mathcal{L}_0)\|_{\mathcal{W}_p\oplus\ell^\infty\to\mathcal{W}_p\oplus\ell^\infty}\le C|a-1|. \tag{3.mccclvii}$$

Choose the weight disc so that this quantity is at most $1/4$. Its Neumann series gives the actual $\mathcal{L}_{0,a}^{-1}$, with uniform bound and a sufficiently small exponential cell weight. This choice is independent of depth and volume.

3.48.3. *The forced weighted equation.* Let $V_*^{\mathrm{tr}} = M^k U_0$. For target $V_B = e^{iB}V_*$, use the actual literal offset and its reduced datum

$$\beta_*(B) = i^{-1}\log\{V_B(V_*^{\mathrm{tr}})^{-1}\},\qquad \mathsf{b}_*(B) = b_{U_0}(\beta_*(B)),\qquad \|\mathsf{b}_*(B)\|_\infty \le C_L(\kappa+\|B\|_\infty). \tag{3.mccclviii}$$

Here β_* is eq. 3.mcccxlviii, and b_{U_0} is the actual datum map eq. 3.mxxxiii. The relative product inside the logarithm is near one. Neither individual coarse transport needs a small logarithm.

Write $\mathfrak{q}_0(A)$ for the actual re-centered straightened constraint at U_0, and put

$$C_q(A) = \mathfrak{q}_0(A) - QA,\qquad N_a(A) = (F_0^a)'(A) - j_0^a - H_{0,a}A.$$

The weighted counterpart of the forced RTC equation, with approximate multiplier zero, is

$$\begin{pmatrix} A \\ \nu \end{pmatrix} = \mathcal{L}_{0,a}^{-1}\begin{pmatrix} -j_0^a - N_a(A) + (\mathfrak{q}_0'(A)-Q)^\sharp\nu \\ \mathsf{b}_*(B) - C_q(A)\end{pmatrix}. \tag{3.mccclix}$$

Its affine source is the weighted trial current. It has not been removed by a centering convention.

Lemma 3.197 (A weighted correction of the smooth trial)**.** After fixed reductions of the weight disc, the curvature ceiling and a datum radius ρ, eq. 3.mccclix has a unique solution in a fixed $\mathcal{W}_p\oplus\ell^\infty$ ball. It is holomorphic in a, B, real at real data, and

$$\|A(a,B)\|_{\mathcal{W}_p} + \|\nu(a,B)\|_\infty \le C(\kappa+\|B\|_\infty). \tag{3.mccclx}$$

It solves the full weighted critical equation after the gauge penalty is removed. The specified literal correction gives mean exactly V_B. ■

Proof. The actual constraint estimates give

$$\|C_q(A)\|_\infty \le C\|A\|^2_{\mathcal{A}_\alpha},\qquad \|(\mathfrak{q}_0'(A)-Q)^\sharp\nu\|_\infty \le C\|A\|_{\mathcal{A}_\alpha}\|\nu\|_\infty.$$

These are the physical column-density bounds in Lem. 3.148, before any restoration adjoint. The fixed-L hierarchical density, not a single direct large-block contour, supplies their uniformity in depth. Use eq. 3.mccclii for the field arguments and the cell volume for the force. Together with eq. 3.mccclvi, the nonlinear tuple in eq. 3.mccclix has size Cr^2 and Lipschitz constant Cr on a joint radius-r ball.

Choose r inside the strong mean, site and gauge-chart margins so that the inverse bound times this Lipschitz constant is below $1/4$. Include the SCF background tube among these margins. The trial qualifies by its unweighted bounds from CTA. Choose ρ, κ afterward so the inverse times the two affine sources has norm below $r/8$. Require also $C(\kappa+\rho)$ below the smaller independent-current ceiling of that strong-family tube. Iteration from zero is invariant and contractive. Normal convergence on the larger product domain proves holomorphy and eq. 3.mccclx. The construction used the inverse at the given trial; no inverse at the desired critical field was assumed.

The equation before penalty removal is exactly

$$(F_0^a)'(A) + DRD^\sharp A = \mathfrak{q}_0'(A)^\sharp\nu,\qquad \mathfrak{q}_0(A) = \mathsf{b}_*(B).$$

The actual gauge cocycle, site extensions and gauge-test surjectivity in RTC depend on the trial geometry and its strong regularity. They do not depend on the plaquette coefficients. The trial already has the needed unweighted regularity. Test this equation on the actual fine gauge directions in the kernel of its effective coarse gauge. The first term vanishes by gauge invariance of $\mathcal{A}_h^a$, and the constraint term vanishes by the exact intertwining. The site surjectivity used in eq. 3.mliii therefore annihilates the penalty. For complex parameters use the same range and bilinear nondegeneracy argument as RTC, not positivity of a complex square. Thus $RD^\sharp A = 0$, and the full equation is

$$(F_0^a)'(A) = \mathfrak{q}_0'(A)^\sharp \nu.$$

The actual mean slice and literal node extension are unchanged. They convert the reduced datum in eq. 3.mccclviii to the prescribed literal mean V_B. The extension has its fixed strong site bound and gives a strong literal field of size $C(\kappa + \|B\|)$. No $W^{2,p}$ claim for an arbitrary choice of literal extension is needed. □

At the literal output, denote by j_a the weighted left current and by ω_a its physical row multiplier in the declared coarse coordinates. The row-coordinate conversion is the actual derivative of the datum map and the normal-to-left conversion of eq. 3.mlxv; the trial multiplier ν is not silently identified with this covector. The actual transpose density and bounded divided exponential differential give

$$j_a(U_h^a(V_B)) = Q^\sharp \omega_a, \qquad \|\omega_a\|_\infty + \|j_a(U_h^a(V_B))\|_\infty + \|F(U_h^a(V_B))\|_\infty \le C(\kappa + \|B\|_\infty). \tag{3.mccclxi}$$

Here Q is re-centered at the output and the physical fine units are retained. The first equality follows from actual weighted stationarity and the admitted coordinate conversions. The current estimate uses that equality, not an estimate of a second difference of the corrected potential. Its unweighted Wilson current is not asserted pointwise bounded.

Lemma 3.198 (Uniqueness on a strong trial neighborhood)**.** For the same fixed smaller domains, the weighted critical orbit is unique among orbits with a sufficiently small $C^{1,\alpha}$ representative relative to the trial and with the same literal datum. No $W^{2,p}$ assumption on a competing representative or point bound on its unweighted current is required. ■

Proof. Put a competing orbit into the actual trial mean slice by the unchanged site construction. Its relative potential has strong norm at most $C\varepsilon$. Let $\mathcal{H}_{0,a}$ be the full row lift of $\mathcal{L}_{0,a}$. It satisfies $Q\mathcal{H}_{0,a} = 1$. The inverse

$$\mathscr{H}_A = \mathcal{H}_{0,a}(\mathfrak{q}_0'(A)\mathcal{H}_{0,a})^{-1}$$

exists on a small strong ball, by the actual row estimates. Its normalized columns have the exponential energy bounds of the full trial lift.

Pair stationarity with $\mathscr{H}_A b_{c,e}$. The trial term j_0^a gives $C\kappa$. For the remaining term use the weak Wilson readout in eq. 3.mlxii, separately in each weighted plane. Its integration by parts pairs the first field difference with the energy column. Thus it is bounded by $C\|A\|_{\mathcal{A}_\alpha}$; no derivative of the actual current is evaluated pointwise. Consequently

$$\|\nu\|_\infty \le C(\kappa + \|A\|_{\mathcal{A}_\alpha}).$$

This is the weighted version of eq. 3.mlxxiii.

Every finite-array competing field has a finite $W^{2,p}$ norm, though it has not yet been uniformly bounded. Apply the exact inverse $\mathcal{L}_{0,a}^{-1}$ to its equation. The nonlinear forces are bounded in $\mathcal{F}_p$ by its strong norm and the multiplier bound just obtained. It follows that

$$\|A\|_{\mathcal{W}_p} + \|\nu\|_\infty \le C\{\kappa + \|B\|_\infty + \varepsilon^2 + \kappa\varepsilon\}.$$

Choose the strong uniqueness neighborhood and then the working ρ, κ so this lies inside the larger contraction ball. The competing field is therefore the same slice solution. The slice and literal extension identify precisely the top-fixed gauge orbit. All these norm estimates and inverses hold on the smaller complex domains, so the same uniqueness applies there. □

3.48.4. *The weighted physical atlas.*

Proposition 3.199 (A diagonal deformation of the curvature atlas)**.** There are a curvature ceiling $\kappa_* > 0$, a weight polydisc $\mathcal{A}_+$ about 1, and a datum radius $\rho > 0$, independent of depth and compatible volume, with the following properties. Every real coarse V with $\|V(\partial p) - 1\| \le \kappa \le \kappa_*$ has an actual weighted constrained-critical fine orbit $U_h^a(V)$. For real positive a in a fixed smaller cube, its literal mean is V, and

$$\|F(U_h^a(V))\|_\infty + \|j_a(U_h^a(V))\|_\infty + \|\omega_a(V)\|_\infty \le C\kappa. \tag{3.mccclxii}$$

It has a jointly holomorphic germ in a and $\|B\|_\infty < \rho$ about each real coarse centre $V_B = e^{iB}V$. The germs identify as physical orbits on controlled overlaps and define a holomorphic total action

$$S_h^a(V) = \mathcal{A}_h^a(U_h^a(V)).$$

For real data,

$$0 \le S_h^a(V) \le C\kappa^2\mathcal{V}. \tag{3.mccclxiii}$$

Large holonomies and nontrivial bundle topology are allowed. At fixed a there is real coarse gauge, translation and reflection covariance; axis permutations also permute a. ■

Proof. The smooth trial of CTA is independent of a. Lem. 3.196 supplies its weighted force, and Lem. 3.197 corrects the actual datum error. At the real centre $B = 0$, both errors are $O(\kappa)$. Equation eq. 3.mccclxi gives eq. 3.mccclxii.

For overlaps use the same Kato alignment of the trial bundles as CTA. The aligned trial connections differ by $C\rho$ in every fixed local derivative norm, by eq. 3.mcccxlvi and eq. 3.mcccxlvii. The two weighted corrections have strong size $C(\kappa + \rho)$. Choose these constants inside the common strong uniqueness neighborhood of Lem. 3.198. The two solutions have the same literal datum and weighted equation, so their orbits coincide. The actual mean slices and literal gauges are holomorphic, giving holomorphic transitions. Their top-fixed cocycle follows from the free top-fixed gauge action, exactly as in CTA. No multiplicative cocycle for the Kato map itself is being assumed.

Real fine-frame changes and coarse gauge changes conjugate the full equations. The CTA short-path and partition policy is equivariant under coordinate isometries. The weighted action has the stated joint permutation covariance, and the other constructions are unchanged. Uniqueness therefore proves all the covariance claims.

Finally a fine plaquette has $1 - \frac{1}{2}\,\mathrm{tr}\,U_p \le Ch^4\kappa^2$. The weights are bounded and positive, and there are $O(h^{-4}\mathcal{V})$ plaquettes. This proves eq. 3.mccclxiii. Use the datum itself as real centre for this estimate. No global bond gauge close to a flat connection enters the proof. □

The corrected orbit remains in a fixed smaller $C^{1,\alpha}$ tube of its smooth trial. Thus the existing off-current families may be evaluated there with a sufficiently small independent current, in particular with j_a. They are the operators of their stated convention. This observation does not identify an unweighted canonical precision with the weighted physical Hessian. The latter is treated next.

3.48.5. *The physical weighted Hessian and its row mass.* Fix a real point of the atlas, put $U = U_h^a(V)$, and re-center the actual rows and derivatives there. Let $\mathscr{D}_a$ be the full normal Hessian of $\mathcal{A}_h^a$, and write $\Delta^{(2)}[\omega_a]$ for the actual second constraint jet paired with its physical multiplier. Define

$$\mathscr{H}_{L,a} = \mathscr{D}_a - \Delta^{(2)}[\omega_a]. \tag{3.mccclxiv}$$

All these derivatives are in the declared straightened normal coordinates. Gauge invariance identifies the scalar action with the literal coarse action, as in NEG.

We record the gauge-current term as well. Let $B_U[j_a]$ be the finite-gauge curvature operator of the canonical convention. The first inverse and its first row lift are

$$G_a = \{\mathscr{D}_a - B_U[j_a] + DRD^\sharp + Q^\sharp a_f Q\}^{-1}, \qquad H_a = G_a Q^\sharp (QG_aQ^\sharp)^{-1}. \tag{3.mccclxv}$$

The second inverse is formed afterward:

$$\mathscr{G}_a^{-1} = \mathscr{D}_a - B_U[j_a] + DRD^\sharp + Q^\sharp a_f Q - S^\sharp \Delta^{(2)}[H_a^\sharp j_a] S. \tag{3.mccclxvi}$$

The lift in the multiplier readout is the first lift. The row covariance in the effective Hessian below will use the second inverse.

Lemma 3.200 (The physical identity and energy gap)**.** For the real atlas points and the fixed real weight cube, the two inverses in eq. 3.mccclxv–eq. 3.mccclxvi exist with uniform energy bounds. Moreover

$$\mathscr{G}_a^{-1} = \mathscr{H}_{L,a} + DRD^\sharp + Q^\sharp a_f Q, \qquad c\|v\|_{\mathcal{E}}^2 \le \langle v, \mathscr{G}_a^{-1} v\rangle \le C\|v\|_{\mathcal{E}}^2. \tag{3.mccclxvii}$$

Here the physical homogeneous unit-scale norm is

$$\|v\|_{\mathcal{E}}^2 = \|D_U v\|_{2,h}^2 + \|v\|_{2,h}^2,$$

equivalent to the energy norm in the nonflat row-saddle theorem. The fine Lagrangian form also satisfies

$$\langle v, \mathscr{H}_{L,a} v\rangle \ge c\|\mathrm{d}_U v\|_{2,h}^2 - C\kappa\|v\|_{\mathcal{E}}^2, \qquad |\langle v, \mathscr{H}_{L,a} w\rangle| \le C\|v\|_{\mathcal{E}}\|w\|_{\mathcal{E}}. \tag{3.mccclxviii}$$

■

Proof. The Wilson form calculation is applied plane by plane. The real coefficients $a_\mu a_\nu$ lie between fixed positive constants. Its leading curl form is therefore comparable to $\|\mathrm{d}_U v\|_2^2$. The actual curvature terms have bound $C\|F(U)\|_\infty\|v\|_{\mathcal{E}}^2$. They are retained in $\mathscr{D}_a$. The finite-gauge current operator has bound $C\|j_a\|_\infty\|v\|_{\mathcal{E}}^2$. The constraint-curvature form has bound $C\|\omega_a\|_\infty\|v\|_{\mathcal{E}}^2$, by the actual two-leg estimate. All three small quantities are $O(\kappa)$ by eq. 3.mccclxii.

The geometric curl, restoration and row estimate underlying eq. 3.dcccxxviii is unchanged. Combining it with these plane estimates proves the gap for the first variant. The actual coarse row lift and its physical energy seeds give an invertible row Schur matrix. Since $QH_a = 1$ and $j_a = Q^\sharp \omega_a$, its readout is exactly

$$H_a^\sharp j_a = \omega_a.$$

The small second correction therefore preserves the energy gap.

For its exact form use weighted gauge invariance before simplifying any term. If Π is the finite gauge chain, then $\mathcal{A}_h^a(e^{ih\Pi(A)}U) = \mathcal{A}_h^a(e^{ihA}U)$. Twice differentiating gives the same finite-chain identity as in ACC, with the weighted physical current:

$$\mathscr{D}_a - B_U[j_a] = S^\sharp \mathscr{D}_a S.$$

The physical stationarity and the exact mean gauge cocycle give the Lagrangian Ward identity used in eq. 3.cmxxi. Its algebra is unchanged by constant plaquette weights: its first gradient is $Q^\sharp \omega_a$, and the coarse Ward covector annihilates the induced coarse gauge. Consequently

$$S^\sharp\{\mathscr{D}_a - \Delta^{(2)}[\omega_a]\}S = \mathscr{H}_{L,a}.$$

Substitution in eq. 3.mccclxvi proves the equality in eq. 3.mccclxvii. Thus the gauge-current term was used in the identity; it was not discarded on the ground that the background is nearly flat.

The plane form estimate and the actual multiplier bound now give eq. 3.mccclxviii. The same geometric curl–restoration–row estimate, with κ decreased, proves the two energy inequalities in eq. 3.mccclxvii. They concern the actual full constrained precision. No positive fine Dirichlet compression has been identified with it. □

Let

$$\mathcal{H}_a = \mathscr{G}_a Q^\sharp (Q\mathscr{G}_a Q^\sharp)^{-1}. \tag{3.mccclxix}$$

The actual row seeds, their energy bound and eq. 3.mccclxvii imply

$$Q\mathcal{H}_a = 1, \qquad RD^\sharp \mathcal{H}_a = 0, \qquad \|\mathcal{H}_a z\|_{\mathcal{E}} \le C\|z\|_{2,c}.$$

For completeness, the row-seed identity $QE_Q = 1$ gives an inf-sup lower bound for $Q^\sharp$ from coarse L^2 to $\mathcal{E}^*$. The bounded row map gives its upper bound. The energy inverse then makes $Q\mathscr{G}_a Q^\sharp$ comparable to the coarse identity, with no fine rank factor. The middle identity follows from the physical gauge test, as in NEG.

Twice differentiate the actual constrained graph. Its first derivative in the fixed horizontal slice is $\mathcal{H}_a$, and its second derivative satisfies the differentiated constraint. The first fine action derivative is $Q^\sharp\omega_a$. The chain rule therefore gives

$$\Gamma_{h,a} := D^2 S_h^a(V) = \mathcal{H}_a^\sharp \mathscr{H}_{L,a} \mathcal{H}_a = (Q\mathscr{G}_a Q^\sharp)^{-1} - a_f. \tag{3.mccclxx}$$

The second equality follows by adding the artificial row mass to the differentiated stationarity equation and using $Q\mathcal{H}_a = 1$ and horizontality. Subtracting a_f is essential. Positivity of the mass-added Schur matrix alone would not give the next estimate.

3.48.6. *The effective curl and the outer Gaussian.* The covariant flux comparison Lem. 5.38 is independent of the action coefficients:

$$\|\mathrm{d}_V Q v\|_{2,c} \le C_L\{\|\mathrm{d}_U v\|_{2,h} + \kappa\|v\|_{2,h}\}. \tag{3.mccclxxi}$$

The local gauge proof there needs curvature, the actual normalized row moments and complete carriers, not an unweighted current bound. Alternatively the constructed trial frames and the strong correction provide the same small local potential for this atlas. The comparison retains the flat positive flux-row norm before its $O(\kappa)$ error. It does not count fine plaquettes.

Insert $v = \mathcal{H}_a z$ in eq. 3.mccclxviii and use eq. 3.mccclxxi. The lift energy bound absorbs the error. Together with the upper form bound this gives

$$\Gamma_{h,a}[z,z] \ge c\|\mathrm{d}_V z\|_{2,c}^2 - C\kappa\|z\|_{2,c}^2, \qquad |\Gamma_{h,a}[z,w]| \le C\|z\|_{2,c}\|w\|_{2,c}. \tag{3.mccclxxii}$$

This is a bound on the mass-removed physical Hessian.

Use the actual one-step outer graph

$$V(u) = e^{i\Phi_V(u)}V, \qquad \mathsf{C}_V = D\Phi_V(0), \qquad \Phi_V(u)|_{\mathrm{free}} = u.$$

Let $K_G(V)$ be its relative contour-gauge Hessian. Define the complete composed action and outer precision by

$$K_{A,h,a}(V) = \mathsf{C}_V^\sharp \Gamma_{h,a}\mathsf{C}_V + \langle \omega_a, D^2\Phi_V(0)\rangle, \qquad K_{h,a,\tau}(V) = \tau K_{A,h,a}(V) + K_G(V). \tag{3.mccclxxiii}$$

The second term is the outer nonlinear constraint contribution. It is separate from the inner $\Delta^{(2)}[\omega_a]$ in eq. 3.mccclxiv. Centering the outer action by its linear free-coordinate jet changes neither term.

Proposition 3.201 (A gap throughout the weighted real atlas)**.** On a fixed smaller real weight cube and for sufficiently small κ, the actual outer precision obeys

$$c_L I \le K_{h,a,\tau}(V) \le C_L I \tag{3.mccclxxiv}$$

for real τ in a fixed interval about one. Constants are independent of the inner depth and compatible volume. ∎

Proof. The finite outer chart has $\|\mathsf{C}_V\|_{2\to 2} \le C_L$, $\|\mathsf{C}_V u\|_2 \ge \|u\|_2$, and its second derivative paired with a bounded covector has norm at most $C_L\|\omega_a\|_\infty$, by eq. 5.cclv. Thus eq. 3.mccclxxii gives

$$K_{A,h,a}(V)[u,u] \ge c\|\mathrm{d}_V\mathsf{C}_V u\|_2^2 - C_L\kappa\|u\|_2^2, \qquad \|K_{A,h,a}(V)\| \le C_L.$$

The geometric outer curl–gauge inequality eq. 5.cclvii has no action coefficient in it. Combine it with this estimate. The positive real coefficients and τ in a compact positive interval retain a fixed multiple of that geometric gap. Decrease κ to absorb its negative mass error. This proves the lower bound. The finite chart, gauge and effective Hessian bounds give the upper bound.

For a nonaxial real V, the exact node-fixed block gauge is a real orthogonal change of free coordinates, and it carries the relative contour gauge to the axial one. Thus the estimate holds in the literal frame as well. No global trivialization of the coarse bundle is used. □

3.48.7. *Complex sectors and the response retained.*

Proposition 3.202 (A uniform sector near every real centre)**.** Fix a real atlas centre (a_0, V_0, τ_0) in smaller weight and τ intervals. There are positive radii, uniform in that centre, depth and compatible volume, such that the physical analytic continuation satisfies

$$K_{h,a,\tau}(e^{iB}V_0) = K_0^{1/2}(I+E)K_0^{1/2}, \qquad K_0 = K_{h,a_0,\tau_0}(V_0), \qquad \|E\| \le \tfrac{1}{2}, \tag{3.mccclxxv}$$

when $|a-a_0|, \|B\|_\infty, |\tau-\tau_0|$ lie in those radii. The matrices are complex symmetric; the inverse and the determinant branch are holomorphic. ■

Proof. Use the common trial chart at V_0. The weighted fixed point and multiplier are holomorphic on larger uniform product domains. Their Cauchy estimates give uniform first variations in the strong field and row norms. The actual row column moments and restoration comparisons then bound their fine energy-operator variations. In particular, after identifying the fixed real comparison spaces, the change of $\mathscr{H}_{L,a} + DRD^\sharp + Q^\sharp a_f Q$ as an operator $\mathcal{E} \to \mathcal{E}^*$ is at most

$$C\{|a-a_0| + \|B\|_\infty\}.$$

The Wilson estimate here is a derivative form estimate with bounded coefficient variations; it does not estimate a rough unweighted current. The multiplier term uses its actual point-small analytic ω_a. The unchanged row and gauge families have their uniform complete-column bounds on the same strong tube.

The real gap in eq. 3.mccclxvii therefore gives a complex energy inverse by a Neumann series. Its row Schur inverse has the uniform inf-sup margin proved above. The exact resolvent identity and eq. 3.mccclxx give

$$\|\Gamma_{h,a}(e^{iB}V_0) - \Gamma_{h,a_0}(V_0)\|_{2,c\to 2,c} \le C\{|a-a_0| + \|B\|_\infty\}.$$

Subtracting the fixed artificial mass does not alter this variation bound. The finite outer chart, its second derivative, the physical covector and the relative gauge have uniform analytic bounds as well. Consequently the difference of the two matrices in eq. 3.mccclxxv is bounded by $C_L(|a-a_0| + \|B\| + |\tau-\tau_0|)$. Choose the radii below half the real lower gap. This proves eq. 3.mccclxxv.

It follows, for example, that the Hermitian real part of this matrix is at least $K_0/2$. This is a sector estimate, not positivity of an analytic bilinear square. The finite-dimensional log branch of $I+E$ is its convergent power series, fixing the determinant and normalized Gaussian branches. The radii came from operator norms, so they do not shrink with volume. □

The construction also retains the following fixed-order response. For a small exponential cell weight $w = e^{s\psi}$, with ψ one-Lipschitz, its trial-chart first variation satisfies

$$\|D_B A[b]\|_{\mathcal{W}_p;w} + \|D_B \nu[b]\|_{\infty;w} \le C\|b\|_{\infty;w}. \tag{3.mccclxxvi}$$

Differentiate eq. 3.mccclix. Its weighted linear inverse is bounded, and its weighted nonlinear derivative is a contraction after a fixed further reduction of the working ball. The actual mean vertices have fixed physical carriers, so the weight ratios within them are bounded. The same fixed-order Cauchy argument as RTC bounds mixed derivatives with one weighted datum slot and the other slots unweighted, by constants C_n. The literal node extension and physical weighted current inherit their strong and point-force versions. The geometric sum of the intermediate physical path lengths keeps their read stars uniform in depth.

The parameter a is global. Cauchy on its larger fixed polydisc controls its derivatives and their mixed datum responses; no spatial location is assigned to a weight derivative. In particular at a real curvature centre the first weight variation of the trial-chart field and the physical multiplier is

$O(\kappa)$. These are fixed-order localized responses. An all-degree connected carrier expansion for this weighted nonflat atlas is not inferred from them.

The results concern the homogeneous curvature atlas and its actual physical Gaussian. They construct neither a mixed-scale trial from arbitrary proper data nor independent background cube discs, a history tower, or a quantum identity between covers.

3.49. **Constant diagonal weights in the selected connected germ.** We deform the selected off-current equation, including its actual row inversions, by constant diagonal plaquette weights. The principal change requires two finite-p derivatives of the auxiliary field. It does not require two derivatives of the base potential or of its input perturbations. The finite gauge chain and the literal output retain their $C^{1,\alpha}$ regularity. These distinctions permit the physical weighted curvature atlas to enter the construction.

3.49.1. *Fixed strong base data and the stronger output space.* Fix $0 < \alpha < 1$, a finite $p > 4/(1-\alpha)$, and a finite requested carrier rate κ. Work on an admitted SCF and NGC determining geometry with its complete carriers, separation reserves and true bare boundary. The reference U_* is a given real current-regular field with strict margins. The base has the form

$$U = e^{i\eta E} U_*,$$

in a smaller common $C^{1,\alpha}$ tube, and J is a bounded independent current. The full amplitude of J, rather than only its touching restriction, is used here. No point bound for the actual unweighted or weighted Wilson current at the present complex base is assumed. All comparison frames, smooth reconstructions and the literal node extension are fixed at U_*.

The constant parameter is $a = (a_1, \dots, a_4)$, near 1. Replace each $\mu\nu$ Wilson plaquette coefficient by $a_\mu a_\nu$. Write

$$F^a_U(A) = \mathcal{A}^a_{\Omega_0}(e^{i\eta A} U), \qquad j^a_U = (F^a_U)'(0), \qquad H^a_U = (F^a_U)''(0). \tag{3.mccclxxvii}$$

The normalization is that of eq. 3.mcccl and the actual normal coordinates of CNG. The averaging map, site restoration, row mass a_f, and finite gauge chain are unchanged. In particular a_f is not a component of a. Every adjoint below is the physical bilinear transpose; analytic parameters are not conjugated.

Use the force space $\mathcal{F}_p$, field strong space $\mathcal{A}_\alpha$, row datum space $\mathcal{B}$, and multiplier space $\mathcal{W}$ of SCF. On a complete enlarged scale-ξ_y cell set

$$\|A\|_{\mathcal{W}_{p,y}} = \sum_{r=0}^{2} \xi_y^{1+r-4/p} \|D_*^r A\|_{L^p(B_y^+)}. \tag{3.mccclxxviii}$$

All mixed second differences are included. The measure is the physical fine measure. Fixed further cell enlargements accommodate the finite nested estimates. On a bare cell the rescaled mesh is one and this is a finite atomic norm. Uniform discrete Morrey and fixed smooth reconstruction give

$$\mathcal{W}_p \longrightarrow \mathcal{A}_\alpha, \qquad \|A\|_{\mathcal{A}_\alpha} \le C \|A\|_{\mathcal{W}_p}. \tag{3.mccclxxix}$$

Changing D_* to the covariant difference at a base in the stated tube gives an equivalent norm: the difference of the second differences contains only the connection difference, its first difference, and at most one difference of A. It uses no second difference of E.

Put $\mathcal{X}_p = \mathcal{W}_p \oplus \mathcal{W}$ and $\mathcal{Z} = \mathcal{F}_p \oplus \mathcal{B}$. Family norms are the row and each-input column sums of eq. 3.mcxciii, using these cell Banach spaces. They include the supremum of each coefficient on its larger common local base domain before the carrier sum. Full tags, short joins and read collars are charged with $\sigma_c(X) = b_L + d_c(X)$. Choose the primitive families at a stronger rate κ_+, reserving the costs of supported base slots and their output counts. The constant a is a global analytic parameter; it is not a spatial input tag.

3.49.2. *The plane Hessian on a complex strong base.*

Lemma 3.203 (A local principal perturbation)**.** Let $V_a = H^a_U - H^1_U$. It has a local holomorphic coefficient family satisfying

$$\|\mathbf{V}_a\|_{\mathcal{W}_p\to\mathcal{F}_p;\kappa_+} \le C \max_\mu |a_\mu - 1|. \tag{3.mccclxxx}$$

This is a coefficientwise local-data supremum bound on the complex strong tube. The base variable is E in $C^{1,\alpha}$, not in $W^{2,p}$. No current derivative or point bound for j^a_U is required. ■

Proof. Rescale a nonbare cell to length one, with mesh $h = \eta/\xi_y$. Apply the exact four-edge insertion formula eq. 3.dlxiii to one orientation plane. In the same normalization as eq. 3.dcccxcvi, its assembled Hessian is

$$H_{U,\mu\nu} = \mathrm{d}^\sharp_{U,\mu\nu}\mathrm{d}_{U,\mu\nu} + Z_{U,\mu\nu}. \tag{3.mccclxxxi}$$

Here $\mathrm{d}_{U,\mu\nu}$ is the corresponding component of the covariant curl; Z is a finite-shift kernel on a complete two-step collar, with both coefficient sums at most $C\sup_p |P_p - I|/h^2$.

Indeed the exact plaquette insertion differs from the covariant curl by a matrix E_p of size $C|P_p - I|/h$. Expand

$$(\mathrm{d} + E_p)^\sharp(\mathrm{d} + E_p) - \mathrm{d}^\sharp\mathrm{d} = \mathrm{d}^\sharp E_p + E_p^\sharp\mathrm{d} + E_p^\sharp E_p.$$

Multiply their finite stencil entries, whose curl entries have size C/h. The first two products have size $C|P_p - I|/h^2$; the last is smaller on the stated plaquette domain. The remaining insertion term has that same bound. This is multiplication of shifted matrices, not differentiation of the curvature. The incoming and outgoing stencil counts are bounded. The argument works for each plane before any planes are added.

In the complex strong tube the rescaled plaquette satisfies $|P_p - I| \le Ch^2$. Each term of $\mathrm{d}^\sharp_{U,\mu\nu}\mathrm{d}_{U,\mu\nu}A$ is a transported mixed second covariant difference, up to bounded lower-order shifts. It is bounded in cell L^p by the displayed $W^{2,p}$ norm. Thus $H_{U,\mu\nu} : \mathcal{W}_p \to \mathcal{F}_p$ has a uniform local bound. Restoring the scale gives $\xi_y^{3-4/p}$ on its force, exactly the second derivative term in eq. 3.mccclxxviii.

This reasoning also explains the harmless normal-coordinate current coefficients. The single-link current is a fixed sum of plaquette insertions divided by h^3, so $h|j_U| \le C\sup_p |P_p - I|/h^2$, even if $|j_U|$ is not bounded. Terms with that coefficient are bounded finite-shift terms; no derivative of it is taken. On true bare stencils the rescaled mesh is one and the exact finite matrices give the same conclusion.

Relative to the fixed real frame, the first covariant difference changes by a bounded local multiplication and shift depending analytically on E. Its first difference depends only on E, DE. Consequently the second-difference operator in this proof is holomorphic from the strong base ball into $\mathcal{W}_p \to \mathcal{F}_p$, with a uniform bound on its larger local domain. Fixed smooth slot reconstruction uses derivatives only through order two on the field slot and through order one on the base slot.

Finally

$$V_a = \sum_{\mu<\nu}(a_\mu a_\nu - 1)H_{U,\mu\nu}.$$

There are six planes. Assign the bounded local stars, endpoint tags and actual background collar before taking the coefficient norm. Their local-data suprema obey the bounds just proved, so their finite row and column sums give eq. 3.mccclxxx. □

3.49.3. *Two derivatives in the unweighted primitive families.*

Lemma 3.204 (A coefficientwise stronger output)**.** The unweighted families needed for G_0, the positive normalized row inverse $\mathcal{T}_0^{-1}$, and the strong kinematic maps may be chosen so that

$$\|\mathbf{G}_0\|_{\mathcal{F}_p\to\mathcal{W}_p;\kappa_+} \le C. \tag{3.mccclxxxii}$$

The same local-data supremum convention holds. Kinematic maps have the spaces stated in SCF; in particular $\Lambda : \mathcal{A}_\alpha \to \mathcal{Y}_{2,\alpha}$ and $S : \mathcal{A}_\alpha \to \mathcal{A}_\alpha$. No $W^{2,p}$ assertion about S is made. ■

Proof. Retain the second differences at the output of the local positive field inverse in Lem. 3.161. Its energy column and complete row average bound first give local H^1. The component Laplacian equation then gives $W^{2,2}$, gradient L^3, next $W^{2,3}$, and gradient L^8 with bounded field. If $p \le 8$, finish at p; for $p > 8$, use 8 first and then p. All cutoffs lie in a fixed larger complete output collar. Coefficient bounds in the comparison frame use only its $C^{1,\alpha}$ potential. The complex tube has the same bounds. Before Morrey, this proves

$$\|\chi I_D \chi\, 1_z f\|_{\mathcal{W}_{p,y}} \le C e^{-sd(y,z)} \|f\|_{\mathcal{F}_{p,z}}.$$

This does not assert global $W^{2,p}$ regularity for an uncut Dirichlet solution across its artificial boundary.

The slow commutator still maps this output into $\mathcal{F}_p$ with norm C_p/m: its terms contain $D\chi\, Dv$, $D^2\chi\, v$, complete row differences, and finite-shift curvature terms with one cutoff difference. None uses a third output difference. The weighted centre sums in the positive local walk therefore give a normally convergent family $\mathbf{G}_F : \mathcal{F}_p \to \mathcal{W}_p$. The column and error bounds are uniform on the larger local coefficient domains, so taking their suprema before summing leaves the same positive majorants.

The actual Woodbury identity is

$$G_0 = G_F + G_F(D\widehat{F})\widehat{\Theta}^{-1}(D\widehat{F})^\sharp G_F.$$

Keep the improved output at the leftmost G_F. The site column $D\widehat{F}$ is a bounded force of amplitude three. Its transpose on a strong field has a bounded counting-row pairing, since $\xi^{-3}\xi^{-1}\xi^4 = 1$. All remaining factors use their existing strong or energy bounds. This proves eq. 3.mccclxxxii without differentiating a projection kernel. Unit counting field-row injection has force density of amplitude three by eq. 3.cmlxxxvi, so the improved output also applies at each required row source.

For completeness the positive coarse inversions retain the stronger local-data convention of Lem. 3.164. A combined short power of length m has each entry at most $C(q')^m$ uniformly on the larger coefficient tube. Its declared endpoint ball has polynomially many possible endpoints. Summing their separate suprema costs $C(1 + B_m)^4(q')^m$, not the smaller Hilbert-row bound available at one common base point. Choose the finite power and long cutoff using this polynomial; exponential decay still makes the norm small. Reblocking and the prescribed rate reserves proceed before any weight or current radius is chosen. The exact positive coarse matrices and their gaps have not changed. This proves the required coefficientwise bound through $\widehat{\Theta}^{-1}$ and $\mathcal{T}_0^{-1}$. □

3.49.4. *Weighted inverses in the prescribed order.* Write $B_U[J]$ for the unchanged finite-gauge current operator, and let $S = 1 - D\Lambda$. Define complete operators in the following order:

$$(G_0^a)^{-1} = H_U^a + DRD^\sharp + Q^\sharp a_f Q, \tag{3.mccclxxxiii}$$

$$(G^a)^{-1} = (G_0^a)^{-1} - B_U[J], \qquad H^a = G^a Q^\sharp (QG^a Q^\sharp)^{-1}, \tag{3.mccclxxxiv}$$

$$\omega^a = (H^a)^\sharp J, \qquad C_a = S^\sharp \Delta_U^{(2)}[\omega^a] S, \tag{3.mccclxxxv}$$

$$(G_1^a)^{-1} = (G^a)^{-1} - C_a, \qquad H_1^a = G_1^a Q^\sharp (QG_1^a Q^\sharp)^{-1}. \tag{3.mccclxxxvi}$$

The first lift inside ω^a is fixed before the second inverse is formed.

Proposition 3.205 (Weighted full row-saddle families)**.** On a fixed smaller base tube, weight polydisc and full independent-current ball, the operators above have exact holomorphic local families. The field inverses map $\mathcal{F}_p$ to $\mathcal{W}_p$, and the row lifts map $\mathcal{B}$ to $\mathcal{W}_p$. The second full saddle has a bounded family

$$\mathfrak{I}_{U,J}^a : \mathcal{Z} \longrightarrow \mathcal{X}_p, \qquad (G_1^a)^{-1} A - Q^\sharp \nu = f, \quad QA = d. \tag{3.mccclxxxvii}$$

Its coefficientwise local-data supremum norm at the reserved rate is bounded uniformly in depth, compatible volume and admitted shape. The rooted multiplier family has amplitude at most $C\|J\|_{\infty,3}$. ∎

Proof. First use the genuinely principal family from Lem. 3.203:

$$\mathbf{G}_0^a = \mathbf{G}_0 \star \sum_{n\ge 0} (-\mathbf{V}_a \star \mathbf{G}_0)^{\star n}. \tag{3.mccclxxxviii}$$

Its loop is on $\mathcal{F}_p$; the field output of each G_0 is $\mathcal{W}_p$. Choose the larger weight polydisc so its loop norm is below $1/4$. The series is normally convergent and its complete sum is the exact inverse in eq. 3.mccclxxxiii. Moreover $\mathbf{G}_0^a - \mathbf{G}_0$ has norm $C|a-1|$. This step does not assume invertibility of a new local weighted compression.

SCF gives $\mathbf{B}_U[J] : \mathcal{A}_\alpha \to \mathcal{F}_p$ of norm $C\gamma$, $\gamma = \|J\|_{\infty,3}$, with no derivative of J. Use eq. 3.mccclxxix at its input. Then

$$\mathbf{G}^a = \mathbf{G}_0^a \star \sum_{n\ge 0} (\mathbf{B}_U[J] \star \mathbf{G}_0^a)^{\star n} \tag{3.mccclxxxix}$$

converges after decreasing γ. It retains the stronger output at its leftmost factor.

The physical row normalization is kept explicit:

$$\mathcal{Q}_n = \Xi_\Gamma^2 a_f^{1/2} Q, \qquad \mathcal{Q}_n^\sharp = Q^\sharp a_f^{1/2} \Xi_\Gamma^{-2}. \tag{3.mcccxc}$$

The first map has counting-row output, and the second is its counting-to-physical transpose. Put $\mathcal{T}_0 = \mathcal{Q}_n G_0 \mathcal{Q}_n^\sharp$. Its inverse is already constructed. For $\mathcal{T}^a = \mathcal{Q}_n G^a \mathcal{Q}_n^\sharp$ the complete local families satisfy

$$\|\mathcal{T}^{\mathbf{a}} - \mathcal{T}_{\mathbf{0}}\| \le C(|a-1| + \gamma).$$

Decrease the weight disc and then the current radius so the following exact family converges:

$$(\mathcal{T}^{\mathbf{a}})^{-\mathbf{1}} = \mathcal{T}_{\mathbf{0}}^{-\mathbf{1}} \star \sum_{n\ge 0} [-(\mathcal{T}^{\mathbf{a}} - \mathcal{T}_{\mathbf{0}}) \star \mathcal{T}_{\mathbf{0}}^{-\mathbf{1}}]^{\star n}. \tag{3.mcccxci}$$

Thus H^a is obtained by actual row inversion, not by inferring a new gap from a completed operator bound. The physical lift is $G^a \mathcal{Q}_n^\sharp (\mathcal{T}^a)^{-1} \Xi_\Gamma^2 a_f^{1/2}$.

Pair its current coefficients in that order. A datum $b_c = \xi_c^{-1} e$ at one row obeys

$$\langle H^a b_c, J\rangle = \xi_c^3 \omega_c^a \cdot e.$$

The same absolute row and column sums as in eq. 3.mx prove

$$\sup_c \sum_X e^{\kappa_+ \sigma_c(X)} \xi_c^3 |\omega_{c,X}^a| \le C\gamma.$$

Keep the original fine-current bond in each carrier. The complete bare contribution may be retained here since the full current is small; its second constraint jet is zero. This is the first-lift readout throughout.

The actual two-leg row estimate gives $\Delta_U^{(2)}[\omega^a]$ as a bounded point-force family on strong fields. Composing with the SCF $S, S^\sharp$ families gives $\mathbf{C}_a : \mathcal{A}_\alpha \to \mathcal{F}_p$ of norm $C\gamma$. Consequently

$$\mathbf{G}_1^a = \mathbf{G}^a \star \sum_{n\ge 0} (\mathbf{C}_a \star \mathbf{G}^a)^{\star n} \tag{3.mcccxcii}$$

has the required $W^{2,p}$ output. Its normalized row matrix differs from $\mathcal{T}_0$ by $C(|a-1|+\gamma)$. Apply eq. 3.mcccxci with that difference to construct its exact inverse and then H_1^a.

In physical row spaces write $\mathcal{S}_1^a = Q G_1^a Q^\sharp$. The full saddle is exactly

$$\begin{aligned} A &= G_1^a f + H_1^a (d - Q G_1^a f), \\ \nu &= (\mathcal{S}_1^a)^{-1} (d - Q G_1^a f). \end{aligned} \tag{3.mcccxciii}$$

The row injection is a force of amplitude three; its normalized density is the one used in the preceding step. These identities prove the spaces and bounds. Each Neumann series is dominated by products of positive coefficientwise suprema on the larger local domains. There is no exchange of a global supremum with a conditionally convergent carrier sum. □

The order of choices is important. Fix the rates, p, α, reference margins and all carrier geometry first. Establish the stronger primitive constants. Choose the weight polydisc from the principal and row loop bounds, then the independent-current radius from both current loops and both row inversions. Choose the nonlinear datum and supported base radii last. None depends on fine mesh, depth or volume. These choices do not identify the carrier tile with a prescribed history cube or assert that a one-history-cube separation supplies these larger collars.

3.49.5. *The centered weighted auxiliary equation.* Keep the actual finite gauge map Π_U of eq. 3.mcxlii, and put

$$\Xi(A) = \Pi_U(A) - SA, \quad N_q(c) = \mathfrak{q}_U(c) - Qc, \quad r(A) = \mathfrak{q}_U(\Pi_U(A)). \tag{3.mcccxciv}$$

The inputs to Π are $A, \Lambda A, D\Lambda A$. The identity $\mathrm{Ad}(U_b)(\Lambda A)_+ = (\Lambda A)_- - \eta D\Lambda A$ cancels its apparent division by η before expansion. BHR and SCF therefore give $\Pi : \mathcal{W}_p \to \mathcal{A}_\alpha$, with $\Pi'(0) = S$ and $\Xi(A) = O(\|A\|^2_{\mathcal{W}_p})$ in the strong norm. Two differences of Π would require a third site difference of ΛA. No such estimate is part of this construction.

With ω^a fixed in the A derivative, define

$$\begin{aligned}\mathcal{L}^a_{U,J}(A) = {} & F^a_U(A) - F^a_U(0) - \langle j^a_U, A\rangle - \langle J, \Xi(A)\rangle \\ & - \langle \omega^a, N_q(\Pi_U(A))\rangle + \tfrac{1}{2}\langle RD^\sharp A, RD^\sharp A\rangle \\ & + \tfrac{1}{2}\langle r(A), a_f r(A)\rangle.\end{aligned} \tag{3.mcccxcv}$$

It is a finite-dimensional holomorphic scalar at each finite lattice. Its uniformly bounded nonlinear force families are obtained after centering, as proved next. The actual j^a_U is subtracted even if it is rough.

Lemma 3.206 (The Hessian and its subtracted force family)**.** The exact first two auxiliary jets are

$$(\mathcal{L}^a_{U,J})'(0) = 0, \qquad (\mathcal{L}^a_{U,J})''(0) = (G^a_1)^{-1}. \tag{3.mcccxcvi}$$

Let $N^a_{\mathcal{L}}(A) = (\mathcal{L}^a_{U,J})'(A) - (G^a_1)^{-1}A$. The source tuple

$$\mathcal{R}^a(A,\nu) = \begin{pmatrix} -N^a_{\mathcal{L}}(A) + (r'(A) - Q)^\sharp \nu \\ -(r(A) - QA)\end{pmatrix} \tag{3.mcccxcvii}$$

has an exact analytic local family into $\mathcal{Z}$ with divided coefficient bounds $C_0 C_1^m$ for every degree $m \geq 2$. Constant and linear jets are absent in each filed representative. The coefficientwise larger local-data norms are uniform on the weight polydisc. ■

Proof. The current quadratic jet is precisely $B_U[J]$, because Π is the selected finite chain. The constraint-current jet is $S^\sharp \Delta^{(2)}_U[\omega^a]S$, since $N_q(0) = DN_q(0) = 0$. The penalty contributes $DRD^\sharp$, and $r'(0) = QS = Q$ gives $Q^\sharp a_f Q$ from the row mass. The remaining Hessian is H^a_U. These are exactly the terms in eq. 3.mccclxxxvi, with their stated signs.

For the Wilson force perform the subtraction separately in each orientation plane, pairing the two incident plaquettes on an output bond before estimating. The relative logarithmic calculation of Lem. 3.146 applies plane by plane. It gives the local point-force bound

$$\|(F^a_U)'(A) - j^a_U - H^a_U A\|_{\infty,3} \leq C\|A\|^2_{\mathcal{A}_\alpha}. \tag{3.mcccxcviii}$$

Here the constant and linear jets were removed before filing the paired local force, not canceled between separately estimated carriers. To recall the rough-base step, in a unit cell write $P_h(A) =$

$(ih)^{-1}\log(e^{ihA}e^{iha_0})$, with a_0 bounded in $C^{1,\alpha}$. Its remainder after the linear A jet has first spatial difference $O(hr^2)$ and second difference $O(r^2)$. The apparent terms hAD^2A and $h^2A^2D^2a_0$ use $\|D^2A\|_\infty \le Ch^{-1}\|DA\|_\infty$ and the corresponding estimate for a_0. The linearization difference multiplying D^2A has its factor h. Thus no second base derivative or base-current amplitude survives. Multiplication by the six bounded constants $a_\mu a_\nu$ preserves the bound and holomorphy. A bounded point force enters $\mathcal{F}_p$ with its physical cell normalization.

For completeness, the remaining force identities must keep their valid source types. The constraint value is

$$r(A) - QA = Q\Xi(A) + N_q(\Pi(A)). \tag{3.mcccxcix}$$

For the multiplier force one has

$$\begin{aligned}(r'(A) - Q)^\sharp\nu = \Xi'(A)^\sharp Q^\sharp\nu + S^\sharp DN_q(\Pi(A))^\sharp\nu \\ + \Xi'(A)^\sharp DN_q(\Pi(A))^\sharp\nu.\end{aligned} \tag{3.mcd}$$

The row transposes in this expression are bounded point forces by their actual fixed-leg density. A derivative of Ξ, paired with such a force, has the exact adjoint-factory form

$$f_0 + \Lambda^\sharp h + \Lambda^\sharp D^\sharp f_d.$$

Its inputs have grades three, four and three, respectively. SCF bounds the first two pointwise and the last in finite $\mathcal{F}_p$. It does not put a generic finite-p force into a factory that requires a point force.

Let $C_\omega = \Delta_U^{(2)}[\omega^a]$. The subtracted constraint-current gradient is exactly

$$\begin{aligned}&\nabla\langle\omega^a, N_q(\Pi(A))\rangle - S^\sharp C_\omega SA \\ &\quad = S^\sharp\{C_\omega\Xi(A) + DN_q(\Pi(A))^\sharp\omega^a - C_\omega\Pi(A)\} + \Xi'(A)^\sharp DN_q(\Pi(A))^\sharp\omega^a.\end{aligned} \tag{3.mcdi}$$

The braces are point forces quadratic in A. The outside $S^\sharp$ uses its finite-p bound; the last term uses the same point-force factory. The row-mass remainder is

$$r'(A)^\sharp a_f r(A) - Q^\sharp a_f QA = (r'(A) - Q)^\sharp a_f r(A) + Q^\sharp a_f(r(A) - QA). \tag{3.mcdii}$$

Since $a_f \asymp \xi^{-2}$, its datum input has the required multiplier amplitude three. Finally remove the exact quadratic scalar jet $\langle A, B_U[J]A\rangle/2$ from the nonlinear current term before its factory expansion. Its residual is quadratic in A, with size $C\gamma\|A\|^2$. The gauge penalty is exactly linear in the gradient and has no remaining nonlinear vertex.

All these expressions have at least two joint factors of (A,ν) after the displayed subtractions. Their complete read sets and local strong bounds are the NGC local vertices. The only new local operation, the weighted Wilson sum, has been verified above. Uniform Banach Cauchy bounds on a larger strong ball, followed by the embedding from $\mathcal{W}_p$, give divided coefficients $C_0C_1^m$ into $\mathcal{Z}$. Substitution and the SCF factory bounds preserve their coefficientwise local-data sums. This proves the claim with the arity zeros already removed in each representative. □

3.49.6. *The actual selected germ and its connected trees.* The weighted auxiliary equation is

$$(\mathcal{L}^a_{U,J})'(A) - r'(A)^\sharp\nu = 0, \qquad r(A) = b. \tag{3.mcdiii}$$

Using eq. 3.mcccxciii, it is exactly

$$x = L^a_P b + \mathfrak{N}^a_P(x), \qquad L^a_P b = \mathfrak{I}^a_{U,J}(0,b), \qquad \mathfrak{N}^a_P = \mathfrak{I}^a_{U,J}\mathcal{R}^a, \quad x = (A,\nu). \tag{3.mcdiv}$$

The nonlinear family is a series $\sum_{m\ge2} V^a_{m,P}[x^m]$ with $\|\mathbf{V}^a_{m,P}\|_{\kappa_+} \le C_0C_1^m$. Its linear output space is $\mathcal{X}_p$, while all finite-gauge vertices use the included strong field.

Proposition 3.207 (All-degree weighted selected families)**.** On smaller uniform base, weight and independent-current domains, there is a unique small solution of eq. 3.mcdiii with auxiliary field in $\mathcal{W}_p$. It is holomorphic and has exact connected datum families satisfying

$$x(P,a,b)=\sum_{n\ge1}\mathbf{x}_n^a(P)[b^n],\qquad \sum_{n\ge1}r^n\|\mathbf{x}_n^a\|_{\kappa_+}\le Cr\quad(0<r\le r_b). \tag{3.mcdv}$$

Every coefficient retains all output, input and base read sets, including those of the inverse factors. The supremum on the larger local base and weight domains is included inside this family norm. ■

Proof. The exact fixed point is a contraction on a sufficiently small $\mathcal{X}_p$ ball. For the connected representation expand it in ordered rooted trees. A leaf is the exact family $L_P^a b$, and an internal vertex of arity $m\ge2$ is $V_{m,P}^a$. An n-leaf tree has at most $n-1$ internal vertices. Join its carriers at each shared internal cell, retaining the canonical endpoint tags and fixed short joins. This includes every background read set, not just the tree joining datum positions.

The positive scalar majorant is

$$t=C_{\mathrm{lin}}r+\sum_{m\ge2}C_0C_1^m t^m. \tag{3.mcdvi}$$

Choose r_b so its map preserves $[0,2C_{\mathrm{lin}}r_b]$ and its derivative there is below $1/2$. Iteration from zero gives the convergent sum of all ordered tree weights, bounded by $2C_{\mathrm{lin}}r$. Row sums bound every internal index except along a distinguished input path, where the corresponding column sums apply. The guarded carrier union is submultiplicative. It follows that the actual divided coefficient norms are bounded by this positive series. No additional factorial enters.

The coefficientwise local-data bounds of the linear families and vertices were established before these products. Thus the same positive majorant bounds the sum of their separate suprema. Normal convergence permits substitution into the actual equation. Its sum is in the contraction ball and hence is the selected solution, not merely a formal expansion. □

3.49.7. *Literal inputs and the bounded current update.* For literal coarse data use the actual map $b=b_U(B)$ of eq. 3.mxxxiii, including $Db_U(0)$. Its explicit outward inverse reads the prescribed finer interior rows without a depth product. The NGC local analytic family for this map is unchanged by a. Substitute it into eq. 3.mcdv, decreasing the literal radius so its absolute image lies in the reduced ball. Put

$$C=\Pi_U(A),\qquad \delta\omega=\nu-a_f b_U(B).$$

The selected point-current update is

$$J^a_{\mathrm{new}}=\mathcal{E}^{-\sharp}_{\eta C}\{D\mathfrak{q}_U(C)^\sharp(\omega^a+\delta\omega)+J-Q^\sharp\omega^a\}. \tag{3.mcdvii}$$

Here $\mathcal{E}$ is the same divided exponential differential as in CNG. Its zero datum jet is J. For filing the increment use the exact expression

$$\begin{aligned}J^a_{\mathrm{new}}-J&=(\mathcal{E}^{-\sharp}_{\eta C}-1)J\\&\quad+\mathcal{E}^{-\sharp}_{\eta C}\{DN_q(C)^\sharp\omega^a+D\mathfrak{q}_U(C)^\sharp\delta\omega\}.\end{aligned} \tag{3.mcdviii}$$

Every displayed summand has positive datum degree and point-force amplitude three. In particular there is no termwise cancellation of large bare currents in these estimates; the present independent current is bounded in its full amplitude norm.

Let g be the actual node correction with the fixed extension E_n, and define the literal output by

$$\widehat{U}=(e^{i\eta C}U)^g=e^{i\eta\widehat{A}}U,\qquad \widehat{J}=\mathrm{Ad}(g_-)J^a_{\mathrm{new}}. \tag{3.mcdix}$$

The node argument has a connected $\mathcal{Y}_{2,\alpha}$ family. At assigned scale ξ_y, the actual intermediate node factors have size $C_Lr\xi_t/\xi_y$; their absolute sum is bounded by C_Lr, since $\sum_{t\le j_y}\xi_t/\xi_y\le L/(L-1)$. Their read stars obey the same geometric bound. Thus literalization has no C^k accumulation. Its

divided logarithm is a local analytic function of $C, \zeta, D\zeta$, where $g = e^{i\zeta}$. One field difference uses at most two site differences.

Consequently $C, \widehat{A}$ have strong connected families; $\nu, \delta\omega$ have multiplier families, and $J^a_{\mathrm{new}} - J, \widehat{J} - J$ have point-force families. All have a function-family bound Cr with the same carrier convention as eq. 3.mcdv. The auxiliary field A retains $\mathcal{W}_p$. No $W^{2,p}$ bound for the general C or literal $\widehat{A}$ is inferred from this construction.

3.49.8. *Joint supported-base and global-weight coefficients.* Fix an interior base pair $P_0 = (e^{i\eta E_0} U_*, J_0)$ and an interior weight a_0. Reconstruct base changes exactly as in NGC:

$$E = E_0 + \sum_y \mathcal{R}_y e_y, \qquad J = J_0 + \sum_y \mathcal{O}_y j_y,$$

using supported strong $C^{1,\alpha}$ field slots and bounded current ownership slots. No $W^{2,p}$ condition is imposed on e_y. Write $a = a_0 + \epsilon$, with four global complex components.

Proposition 3.208 (Joint connected Taylor bounds)**.** On fixed smaller slot, literal datum and weight balls, every output increment just listed has an exact joint divided Taylor expansion with

$$\sum_{n\geq 1,\ell,t\geq 0} r^n \delta^\ell \zeta^t \|\mathbf{F}_{n,\ell,t}\|_\kappa \leq Cr. \tag{3.mcdx}$$

Here n is datum degree, ℓ is supported base-slot degree and t is total degree in the four global weight variables. The norm has output and all spatial input row/column bounds; there is no spatial column assigned to a global weight derivative. ■

Proof. For a full carrier X, bounded-overlap reconstruction of its base slots lies in the larger local strong/current domain. The number of slots it reads is $n_X \leq C_{L,M_c}\sigma_c(X)$, by the complete collar counting of eq. 3.mccviii. Their Banach-valued Cauchy and polarization bounds cost at most C^ℓ for each distribution of degree. Summing these distributions at a smaller slot radius costs $(1-C\delta_1)^{-n_X}$, bounded by $\exp(C'\delta_1 C_{L,M_c}\sigma_c(X))$. Choose δ_1 inside the reserved carrier-rate budget and take the actual $\delta \leq \delta_1/2$. The resulting factor $(\delta/\delta_1)^\ell$ justifies summing degreewise supremum norms.

For a column anchored at a supported base input, reserve an additional rate larger than $\log D_L + 1$, where D_L is the bounded degree of the tag graph. A possible output at tag distance j then has its factor $e^{-\upsilon j}$, where $\upsilon > \log D_L + 1$, which sums against the bounded-degree output count. This is the same base-column estimate as in NGC; it does not count fine coordinates within a Banach slot.

The coefficient functions are jointly holomorphic in the four global weight variables on a larger fixed polydisc. Weight Cauchy costs

$$\sum_{\beta\in\mathbb{N}^4} (\zeta/\rho_a)^{|\beta|} = (1 - \zeta/\rho_a)^{-4}$$

for a sufficiently small ζ. This is a fixed factor, independent of the carrier and its size. It requires no extra spatial tag. Combining these bounds with the datum tree majorant proves eq. 3.mcdx. Every output increment vanishes at $B = 0$ for every base and weight, with that zero removed before filing; hence $n \geq 1$. Normal convergence identifies the joint series with the same selected germ and literal update. □

3.49.9. *Physical restriction through the curvature atlas.* Physical matching uses a supplied weighted physical critical pair and its controlled local physical branch. It is not a producer for arbitrary proper coarse data. Suppose first that

$$J = j^a_U = Q^\sharp \omega_{\mathrm{phys}} \tag{3.mcdxi}$$

is within the independent-current radius. Then $QH^a = 1$ gives $\omega^a = \omega_{\mathrm{phys}}$ from the first lift. Weighted fine gauge invariance implies the exact scalar identity

$$\begin{aligned}\mathcal{L}^a_{U,j^a_U}(A) = F^a_U(\Pi_U(A)) - F^a_U(0) - \langle \omega_{\mathrm{phys}}, r(A)\rangle \\ + \tfrac{1}{2}\langle RD^\sharp A, RD^\sharp A\rangle + \tfrac{1}{2}\langle r(A), a_f r(A)\rangle.\end{aligned} \tag{3.mcdxii}$$

Indeed $F^a_U(\Pi_U(A)) = F^a_U(A)$, $QS = Q$, and the two centered linear/current terms combine to $-\langle \omega_{\mathrm{phys}}, Q\Pi_U(A)\rangle$. The nonlinear constraint term supplies its remainder. This is an exact weighted identity, not a comparison of Hessians alone.

Proposition 3.209 (Admission and matching of WCA physical pairs)**.** Restrict the WCA weight polydisc, curvature ceiling and datum radius by the fixed constants of this subsection. Every real physical WCA pair, and its smaller complex physical continuation, lies in the present strong-base and independent-current domain through its smooth real CTA trial. At that pair the selected weighted germ and its literal update coincide with the continued physical WCA orbit and actual weighted left current. The all-degree connected and joint bounds above apply to these local perturbation germs. ■

Proof. At a real coarse centre the CTA trial U_* has uniform local all-C^m potentials and unweighted curvature/current $O(\kappa)$. It is a valid real current-regular reference for SCF, BHR and NGC, even with large holonomies and nontrivial bundle topology. WCA puts its literal weighted orbit in a strong tube of this trial of size $C\kappa$, and proves $j_a(U) = Q^\sharp_U \omega_a$ with both point amplitudes $C\kappa$. On a smaller coarse complex ball the bounds are $C(\kappa+\rho)$. Choose these below the present strong and current margins and use the intersection of the two weight polydiscs. The unweighted current of the weighted orbit need not be point-small. The hypotheses concern its strong distance from the smooth real trial, which WCA supplies.

Consider the supplied physical WCA branch about this pair. The unchanged actual mean-slice chart puts it in $RD^\sharp A_{\mathrm{phys}} = 0$, with $\mathfrak{q}_U(A_{\mathrm{phys}}) = b_U(B)$, by its actual assigned node correction. This is the kinematic chart of PNC and NGC on the strong tube. Its site estimates use the bounded local $C^{1,\alpha}$ coefficients and completed site families available there. The finite gauge is the actual chart gauge; the equation $q\lambda = 0$ alone is not being treated as an exact top-fixed finite gauge. The given branch has $\|A_{\mathrm{phys}}\|_{\mathcal{A}_\alpha} \le C\|B\|_{\mathcal{B}}$, by WCA's localized strong response and this gauge chart.

Its multiplier difference is small in amplitude as well. Pair its weighted equation with $H^a_1(\mathfrak{q}'_U(A_{\mathrm{phys}})H^a_1)^{-1}$. This is an actual nearby row right inverse. Compare with the base equation, integrating by parts plane by plane in the Wilson difference. Only first field differences and the exponentially summable energy columns of this lift occur. The variation of the right inverse has size $C\|A_{\mathrm{phys}}\|_{\mathcal{A}_\alpha}$, and the base weighted current is bounded. Thus the multiplier difference has bound $C\|A_{\mathrm{phys}}\|_{\mathcal{A}_\alpha}$. This is the weak readout used in RTC and WCA, applied to the difference from the critical base; there is no nonstationary defect here.

There is no assumed $W^{2,p}$ estimate for this competing branch. Each finite array has a finite such norm. Its physical linearized full precision is the one in eq. 3.mccclxxxvi: the weighted finite-chain and Lagrangian Ward identities are exactly those of Lem. 3.200. Apply $\mathfrak{I}^a_{U,j^a_U}$ to its equation after subtracting this linearization. The weighted centered Wilson residual and the actual second constraint remainder give force bound $C\|A_{\mathrm{phys}}\|^2_{\mathcal{A}_\alpha}$; the multiplier product has the same bound by the weak readout. The datum remainder is quadratic. More explicitly, put $N_F(A) = (F^a_U)'(A) - j^a_U - H^a_U A$ and $C_\omega = \Delta^{(2)}_U[\omega_{\mathrm{phys}}]$. In the physical slice the source and row unknown are

$$\begin{aligned} f &= -N_F(A) + DN_q(A)^\sharp \omega_{\mathrm{phys}} - C_\omega A + DN_q(A)^\sharp \delta\omega_{\mathrm{phys}} - Q^\sharp a_f N_q(A), \\ d &= b_U(B) - N_q(A), \qquad \nu = \delta\omega_{\mathrm{phys}} + a_f b_U(B). \end{aligned} \tag{3.mcdxiii}$$

Every force summand is quadratic with the just established weak multiplier bound. The last force is the retained artificial row-mass correction; it has not been omitted. Consequently

$$\|A_{\mathrm{phys}}\|_{\mathcal{W}_p} + \|\delta\omega_{\mathrm{phys}}\|_{\mathcal{W}} \le C\{\|b_U(B)\|_{\mathcal{B}} + \|A_{\mathrm{phys}}\|^2_{\mathcal{A}_\alpha}\}.$$

For sufficiently small B this lies inside the auxiliary contraction ball. On its exact slice $\Pi_U(A_{\mathrm{phys}}) = A_{\mathrm{phys}}$. Differentiate eq. 3.mcdxii: the physical pair solves the auxiliary system with $\nu = \delta\omega_{\mathrm{phys}} + a_f b_U(B)$. The penalty derivative vanishes there. Contraction uniqueness identifies the auxiliary and physical slice solutions. The actual node gauge then identifies their literal representatives.

At the physical pair, eq. 3.mcdvii reduces to the actual normal-to-left differential conversion of the weighted stationarity equation. It is therefore the weighted left current of the updated field. Its gauge transform in eq. 3.mcdix is the actual literal weighted current. All arguments use algebraic identities and uniform norm estimates on the smaller complex domains, so holomorphic continuation retains the matching. No unrelated weighted PNC producer outside the supplied WCA branch was imported. □

Off current the first reduced-datum jets are

$$D_b A(0) = H_1^a, \qquad D_b C(0) = S H_1^a.$$

They are not equated. Literal data add $Db_U(0)$ and the actual fine node-gauge derivative. On a physical WCA overlap, both sums represent the same weighted physical orbit by the exact matching, so their total action and actual current agree under the declared gauge transition. Individual filed coefficients are not asserted gauge invariant or reference independent.

For small periods perform the primitive construction, coarse inverse, nonlinear vertices and tree products on one sufficiently large common cover before any carrier projection. Retain lifted data and winding joins, then deck-average the classical coefficient families and descend their sums. The norms have the same positive majorants, and uniqueness identifies the descended sum with the finite periodic selected equation. This is descent of classical operators and critical germs, not an equality of quantum partition functions on different covers.

This result supplies the weighted all-degree selected germ and its physical WCA restriction. It constructs neither a trial for arbitrary proper coarse data nor independent background cube discs. It proves no weighted nonflat formation/tower/deletion statement, and it does not identify a separately prescribed off-current core convention merely from agreement of its quadratic precision.

4. Effective interactions and large fields

We now organize one integration step and its iteration. The local estimates separate the relevant terms from the remainder, while the history sum controls regions in which the small-field expansion is unavailable. The source-dependent construction must preserve both normalization and the stated analytic domains. The estimates below specify where each of these requirements enters the induction.

4.1. **Separated correlations from local source bounds.**

4.1.1. *From local source estimates to separated correlation limits.* Local analytic energy estimates and a bound on the residual finite-volume integral imply bounds on separated correlations. This section proves that implication. Its hypotheses remain to be established for four-dimensional gauge theory: exact transport of a measure alone gives neither a partition-function bound nor decay of the dependence on older scales.

4.1.1.1. Finite-dimensional starting point. Let $\mathcal{P}$ be a finite set of plaquettes, let $G = \mathrm{SU}(2)$, and assign one variable $U_b \in G$ to each positively oriented bond. Opposite orientations carry $U_{-b} = U_b^{-1}$. The product of normalized Haar measures is denoted by dU. Write

$$a_p(U) = 1 - \tfrac{1}{2} \operatorname{Re} \operatorname{tr} U_p,$$
$$A(U) = \sum_{p \in \mathcal{P}} a_p(U).$$

Since $0 \le a_p \le 2$, the probability measure

$$d\mu_\beta(U) = Z_\beta^{-1} e^{-\beta A(U)} dU,$$
$$Z_\beta = \int e^{-\beta A(U)} dU$$

is well defined for every real β. Given bounded real functions f_i on plaquette barycentres, set $X_i = \sum_p f_i(x_p) a_p(U)$ and

$$\Gamma(z) = \int e^{\sum_i z_i X_i} d\mu_\beta.$$

The bound $|X_i| \le 2 \sum_p |f_i(x_p)|$ implies uniform domination on every compact subset of $\mathbb{C}^n$. Differentiation under the integral therefore proves that Γ is entire. Since $\Gamma(0) = 1$, it has a holomorphic logarithm in a neighbourhood of the origin, and the joint cumulant is defined by

$$\langle X_1; \dots; X_n \rangle = \partial_{z_1} \cdots \partial_{z_n} \log \Gamma(0).$$

The neighbourhood obtained this way can depend on the number of plaquettes.

If T is a fixed linear operation on finite measures which preserves their total mass, then $T(e^{\sum z_i X_i} \mu_\beta)$ has total mass $\Gamma(z)$. For a finite sequence of such operations the same conclusion follows by induction. If T is specified only on gauge-invariant densities, all insertions in this assertion must be gauge invariant. Neither linearity nor mass preservation supplies a uniform analytic bound on the resulting density.

4.1.1.2. A zero-free disc from a normalized bound.

Lemma 4.1. Let $c_i > 0$ and put $\|z\|_c = \sum_i c_i |z_i|$. Suppose h is holomorphic on $\|z\|_c < 1$, $h(0) = 1$, and $|h| \le Q$, where $Q \ge 1$. Then

$$|h(z) - 1| \le (Q+1) \|z\|_c.$$

In particular h is nonzero on $\|z\|_c < (Q+1)^{-1}$. On the smaller ball $\|z\|_c < [2(Q+1)]^{-1}$ its principal logarithm satisfies $|\operatorname{Log} h| \le \log 2$. ■

Proof. For $z \ne 0$ write $z = tv$, where $t = \|z\|_c$ and $\|v\|_c = 1$. The function $(h(\zeta v) - 1)/(Q+1)$ maps the unit disc into its closed unit disc and vanishes at zero. The Schwarz lemma gives the first estimate. Strictness on the stated open balls follows by using slightly smaller compact discs and taking limits. For $|u| \le 1/2$, the logarithmic series gives

$$|\operatorname{Log}(1+u)| \le \sum_{k \ge 1} \frac{|u|^k}{k} = -\log(1 - |u|) \le \log 2.$$

The same series defines a single holomorphic branch on that ball. □

Corollary 4.2. Suppose $\Gamma = e^{\mathcal{E}} h$ near zero, where $\mathcal{E}(0) = 0$ and the lemma applies to h. Then

$$|\partial_{z_1} \cdots \partial_{z_n} (\log \Gamma - \mathcal{E})(0)| \le \log 2 \, [2(Q+1)n]^n \prod_i c_i. \qquad \blacksquare\square$$

Proof. Use Cauchy's integral formula on a polydisc with radii strictly smaller than $[2(Q+1)nc_i]^{-1}$. The sum of the weighted radii is less than $[2(Q+1)]^{-1}$. Each variable is differentiated once, so no factorial occurs in this application of the formula. Let the radii increase to their stated values. □

The dependence on Q is material. For example, $\cosh(Vz)$ is the moment-generating function of a random variable taking the values V and $-V$ with equal probabilities. It is at most e^V on the unit disc, but has a zero at $i\pi/(2V)$. Thus an exponential-in-volume estimate alone cannot give a volume-independent zero-free disc.

4.1.1.3. A precise local-energy hypothesis. Fix $L > 1$, a finite physical volume V, and a scale index $s \ge 0$, with physical scale $a_s = L^{-s}$. A local domain D has an integer size $m(D) \ge 0$ and a dependence region D^+. Assume there are constants $C_0, C_1, \kappa_{\text{ent}}$ such that

$$\operatorname{diam} D^+ \le C_0 a_s (m(D) + 1),$$

and, for every fixed compact test support B, the number of domains of size m whose dependence region meets B is at most

$$C_1 V a_s^{-4} e^{\kappa_{\text{ent}} m}.$$

The factor V is a finite-volume allowance; a more local counting estimate can replace it when available.

For cutoff K let $e_{K,s,D}(w)$, $0 \le s < K$, be holomorphic on the source ball

$$\sum_i |z_i| \|f_i\|_* / r < 1,$$

$$w = \sum_i z_i f_i,$$

where $r > 0$ is independent of K. Suppose

$$e_{K,s,D}(0) = 0,$$

$$|e_{K,s,D}(w)| \le A e^{-\kappa m(D)},$$

$$\kappa > \kappa_{\text{ent}}.$$

Finally suppose $e_{K,s,D}$ depends on w only through its values in D^+. These statements are the local-energy hypothesis. They include analyticity, an entropy gap, and geometric control of the dependence region.

Proposition 4.3. Let $n \ge 2$ and suppose the supports of $f_1, \dots, f_n$ have pairwise distance at least $d > 0$. Under the local-energy hypothesis,

$$\left| \partial_{z_1} \cdots \partial_{z_n} \sum_{s<K} \sum_D e_{K,s,D}(w) \Big|_{z=0} \right| \le CAV \max\{1, d^{-4}\} (n/r)^n \prod_i \|f_i\|_*.$$

The constant is independent of K; it can depend on L, C_0, C_1 and the entropy gap. ■

Proof. If D^+ misses one support, the energy is independent of the corresponding variable, and the mixed derivative vanishes. Every contributing domain therefore meets both the first and second supports. Consequently

$$m(D) \geq d/(C_0 a_s) - 1.$$

Cauchy's formula with radii approaching $r/(n\|f_i\|_*)$ bounds each derivative by

$$A(n/r)^n \prod_i \|f_i\|_* \, e^{-\kappa m(D)}.$$

A zero test function makes the assertion immediate, so these radii may be assumed finite. The entropy estimate and a geometric series in m bound the sum at scale s by a constant times

$$AV a_s^{-4} \exp(-cd/a_s),$$

with a larger harmless constant when d/a_s is bounded. It remains to estimate $\sum_{s\geq 0} L^{4s} e^{-cdL^s}$.

For $0 < d \leq 1$, let s_* be the largest integer with $dL^{s_*} \leq 1$. The sum over $s \leq s_*$ is at most $CL^{4s_*} \leq Cd^{-4}$. Writing $s = s_* + j$ in the remaining sum bounds it by

$$Cd^{-4} \sum_{j\geq 1} L^{4j} e^{-c' L^j},$$

which converges by the ratio test. For $d > 1$, replace d by 1 in the exponential. This proves the stated uniform bound. At each fixed cutoff the domain sums converge normally on smaller source balls, permitting termwise differentiation there. Only the separated mixed-derivative estimate is asserted uniformly as the number of scales grows; the undifferentiated energy sums need not converge in that limit. □

If in addition $\Gamma_K = e^{\mathcal{E}_K} h_K$, where $\mathcal{E}_K = \sum_{s,D} e_{K,s,D}$ and $|h_K| \leq Q(V)$ with $h_K(0) = 1$, the corollary above gives a cutoff-independent bound on every separated cumulant. This conclusion remains a finite-volume conclusion when Q depends on V.

4.1.1.4. What a comparison of cutoffs must prove. Uniform boundedness gives compactness only after equicontinuity and a suitable countable test class have been supplied. Convergence along a prescribed whole sequence requires more. One sufficient condition is a summable comparison: for every fixed separated tuple,

$$|S_{K+1}(f_1, \ldots, f_n) - S_K(f_1, \ldots, f_n)| \leq C(f_1, \ldots, f_n)\epsilon_K,$$

$$\sum_K \epsilon_K < \infty.$$

The triangle inequality then makes the sequence Cauchy. Its tail is bounded by $C \sum_{k\geq K} \epsilon_k$.

A local proof of this comparison can split the scales at $K/2$. At $s \leq K/2$, it is enough to compare paired local energies with a bound

$$|e_{K+1,s,D} - e_{K,s,D}| \leq C(1+s)\epsilon_K e^{-\kappa m(D)}.$$

At $s > K/2$, the individual energy bounds already give a tail controlled by $\sum_{s>K/2} L^{4s} e^{-cdL^s}$. This tail is summable in K. The factor $1 + s$ in the paired bound is harmless because $\sum_s (1 + s) L^{4s} e^{-cdL^s} < \infty$ for each $d > 0$. The residual integrals must also be compared on a common zero-free source ball. If both residuals are within $1/2$ of 1, then the logarithmic difference is bounded by

twice the difference of the residuals, using the line segment between their values and the derivative $1/z$ of the logarithm. Cauchy's formula converts this bound into a cumulant comparison.

These are consequences of an actual paired estimate. A bound for two covariant constant-source lists does not automatically prove the estimate for position-dependent arrays. Similarly, ordinary holomorphy in an unweighted norm does not create geometric factors for the age of an inherited activity. Those factors must be present in a separately established weighted estimate or in the domain and bound of a weighted holomorphic extension.

4.1.1.5. A conditional tuning lemma. Let F_K be a real differentiable renormalized-coupling coordinate on an interval I_K, and suppose

$$2/3 \le F_K'(\beta) \le 4/3$$
$$(\beta \in I_K).$$

If F_K takes values on both sides of x_*, the intermediate value theorem gives a unique $\beta_K \in I_K$ with $F_K(\beta_K) = x_*$. Moreover,

$$\tfrac{2}{3}|\beta - \beta'| \le |F_K(\beta) - F_K(\beta')| \le \tfrac{4}{3}|\beta - \beta'|.$$

Both inequalities follow from the mean value theorem on the interval between the two points. The inverse coordinate is therefore Lipschitz with constant $3/2$ on its image. If $F_K(\beta) = \beta - \sum_{j\le K} b_j(\beta)$, the derivative hypothesis follows from $\sum_j \sup_{I_K} |b_j'| \le 1/3$. Existence of the interval, the crossing of the target, and the derivative estimate remain hypotheses to be established by the construction.

The conclusions of this section concern separated correlation functionals. They do not, without additional estimates, provide extensions across coincident points, reflection-positive distributions on the full test-function algebra, rotation covariance, or a characterization of the resulting scalar observable sector as a Yang–Mills theory. Those are additional mathematical steps with their own hypotheses.

4.2. **A pointed Hessian and its action counterterm.** For one local interaction, we identify the marginal quadratic term of its pointed total composed with the free response defined below. This term determines the correction to the Wilson coupling; the renormalisation step must subtract it with that interaction's own coefficient and action normalization before estimating the nonlinear remainder. The calculation treats each base point separately. The bulk sum is a convolution, although an individual pointed total need not be. The nonlinear window remainder and its field-domain estimates are not consequences of this quadratic calculation.

The pointed object and the analytic hypotheses. Work in coarse lattice units on $\mathbb{Z}^4$. An independently oriented bond (x, μ) starts at x and ends at $x+e_\mu$. A real field $B_\mu(x)$ is a traceless Hermitian matrix. Choose a color basis t_a, $1 \le a \le 3$, orthonormal for $\langle A, C\rangle = \frac{1}{2}\operatorname{Tr}(AC)$. Thus $B = \sum_a B^a t_a$. Complexification is bilinear, not sesquilinear. The normalization gives the quadratic Wilson action

$$A(e^{itB}) = \frac{t^2}{2}\sum_p |\mathrm{d}B(p)|^2 + O(t^3) \tag{4.i}$$

on every finite set of plaquettes. Here d is the oriented lattice curl and each coordinate-plane plaquette is counted once.

An individual member G has the pointed pair total, in its exponential chart,

$$\mathcal{G}_z(e^{i\eta A}, J) = \sum_{X \ni z} G(X; (e^{i\eta A}, J), z), \qquad z \in \mathbb{Z}^4. \tag{4.ii}$$

The bare spacing η can differ from the coarse unit spacing. There are no stored spectators in a regular member. Assume the following analytic and geometric properties of this actual family.

The sum in eq. 4.ii and its first two derivatives converge normally in the neighborhoods where they are used. Every summand is local in its pair variables and invariant under all local gauge transformations for which the arguments remain in its declared domain. In particular it is invariant under constant adjoint rotations. Let $\mathcal{P}(B)$ be the actual background pair formed from a sufficiently small finitely supported coarse field, with $\mathcal{P}(0) = (1, 0)$. It is twice differentiable, is gauge covariant, and has first response, expressed in this potential chart,

$$hB = D\mathcal{P}(0)B = (HB, D_1^* D_1 HB). \tag{4.iii}$$

The precise linear map H is part of the background construction; it is not replaced by a convolution chosen for this proof. Put $F_z(B) = \mathcal{G}_z(\mathcal{P}(B))$. Assume the pointed totals are covariant under unit translations and the full hypercubic group, including reflections. These are properties of one individual member at all its base points. They do not require two different members chosen at different sites to be related.

Finally assume an absolute exponential Hessian moment bound. With $\delta^a_{x,\mu}$ the field of color a at one coarse bond, let

$$\mathcal{K}_z^{\mu\nu;ab}(x, y) = \sum_{X \ni z} D^2 G(X, (1, 0), z)[h\delta^a_{x,\mu}, h\delta^b_{y,\nu}]. \tag{4.iv}$$

All derivatives of a pair function are taken in the (A, J) chart of eq. 4.ii, including its factor η. For some $m > 0$ assume

$$\sum_{\mu,\nu,a,b} \sum_{x,y\in\mathbb{Z}^4} e^{m(|x-z|+|y-z|)} |\mathcal{K}_z^{\mu\nu;ab}(x, y)| \le C_m. \tag{4.v}$$

The corresponding derivative representation on finitely supported fields is assumed, as is usual when the normally convergent localized Hessians are composed with the free response. This bound and the actual background/core hypotheses are model inputs here. In particular, this section does not infer a uniformly bounded coefficient extractor from a potential norm on a shrinking field ball.

We first justify that eq. 4.iv really is the Hessian of F_z. Constant adjoint invariance makes the first derivative of each summand of eq. 4.ii zero at $(1, 0)$: each coefficient of a potential or current coordinate would be an invariant linear functional on the adjoint color space, which has no fixed vector. This applies to its finitely many local coordinates and hence to every direction supplied by h. The normal convergence permits summation. In the second-order chain rule the term containing $D\mathcal{G}_z(1, 0)D^2\mathcal{P}(0)$ is therefore zero. Consequently eq. 4.iv, with the displayed actual h, is exactly $D^2F_z(0)$.

The exponential moment hypothesis has a concrete sufficient localized form. Suppose the analytic core contains a usable pair norm ball of radius a_{core}, and on it $|G(X, \cdot, z)| \le ge^{-\kappa d(X)}$. Suppose also

$$\|h\delta^a_{x,\mu}\|_{1;X} \le Ce^{-\delta \operatorname{dist}(x,X)}, \qquad \#\{X \ni z : q \le d(X) < q + 1\} \le Ce^{\kappa_D q}, \qquad \kappa > \kappa_D,$$

and $\operatorname{diam}(X) \le C_M(d(X) + 1)$, with fixed localization cube size. These are the core, response and entropy conditions used in quadratic extraction. Two-variable Cauchy gives

$$|D^2G(X, 0, z)[h\delta_x, h\delta_y]| \le Cga_{\mathrm{core}}^{-2} e^{-\kappa d(X)} e^{-\delta(\operatorname{dist}(x,X)+\operatorname{dist}(y,X))}.$$

Choose $m < \delta/2$ so small that $2mC_M < (\kappa - \kappa_D)/2$. Since $z \in X$, inserting the weight in eq. 4.v costs at most $e^{2mC_M(d(X)+1)}$ after retaining the two response distances. The remaining sums over x and y cost at most $C(d(X) + 1)^8$: enclose X in a box of diameter $C_M(d(X) + 1)$ and sum the exponentially decreasing distances outside it. The rooted domain count now gives

$$C_m \le Cga_{\mathrm{core}}^{-2} \sum_{q\ge 0} (q + 1)^8 e^{-(\kappa-\kappa_D-2mC_M)q} \le C' ga_{\mathrm{core}}^{-2}. \tag{4.vi}$$

Thus eq. 4.v need not be introduced as a new physical estimate when these localized hypotheses have already been supplied. The factor a_{core}^{-2} is retained. The coordinate normalization and near-zero core inclusions needed to use this Cauchy estimate are treated in § 4.23.

Color, symmetry, and the local gauge Ward identity. Constant adjoint invariance implies

$$\mathcal{K}_z^{\mu\nu;ab}(x,y) = \delta_{ab} K_z^{\mu\nu}(x,y), \qquad K_z^{\mu\nu}(x,y) = \frac{1}{3}\sum_{a=1}^{3} \mathcal{K}_z^{\mu\nu;aa}(x,y). \tag{4.vii}$$

For a direct proof, fix the spatial indices and view the color coefficients as a 3×3 complex matrix. Adjoint rotations through π about the color axes force its off-diagonal entries to zero, and rotations interchanging the axes make its diagonal entries equal. The adjoint action of SU(2) contains these rotations. This also proves the assertion for complex members. Equality of mixed derivatives gives

$$K_z^{\mu\nu}(x,y) = K_z^{\nu\mu}(y,x). \tag{4.viii}$$

For a real member all these coefficients are real. Thus its bulk kernel is self-adjoint in addition to being bilinearly symmetric. No positivity of a Hessian is assumed.

For a finitely supported Lie-algebra-valued site function χ, write $(\mathrm{d}\chi)_\mu(x) = \chi(x+e_\mu) - \chi(x)$. Gauge covariance of $\mathcal{P}$ and gauge invariance of the member give $F_z(B^g) = F_z(B)$, where B^g is the logarithmic coarse bond field after a small gauge transformation. Choose the gauge convention $U(x,\mu)^g = g(x)^{-1}U(x,\mu)g(x+e_\mu)$, so the derivative at the identity of $g = e^{it\chi}$ is $\mathrm{d}\chi$. Differentiate this identity once in t and once in a finitely supported field direction C. The mixed derivative of the gauge coordinate itself is multiplied by $DF_z(0) = 0$. Therefore

$$D^2F_z(0)[\mathrm{d}\chi, C] = 0. \tag{4.ix}$$

The other sign convention for gauge transformations gives the same zero identity. The argument initially uses real directions and extends complex bilinearly. It uses neither a noncompact gauge transformation nor a polynomial field in a nonlinear field domain.

Polynomial extensions justified by absolute moments. For fields of polynomial growth define the extended Hessian by

$$\mathcal{H}_z(B,C) = \sum_{\mu,\nu,a}\sum_{x,y} K_z^{\mu\nu}(x,y) B_\mu^a(x) C_\nu^a(y). \tag{4.x}$$

Every such sum converges absolutely by eq. 4.v. Compact cutoffs converge to it by dominated convergence, independently of the cutoffs. This defines an extension of the quadratic jet, not a value of the nonlinear member at an unbounded polynomial field.

The Ward identity extends to polynomial gauge parameters and polynomial second arguments. To prove it, let χ be a polynomial of degree q on sites and let $\chi_R(x) = \chi(x)\vartheta(x/R)$ with a fixed smooth compact cutoff equal to one near zero. Its forward differences converge pointwise to $\mathrm{d}\chi$, and satisfy a bound

$$|\mathrm{d}\chi_R(x)| \le C_\chi(1+|x|)^{\max(q-1,0)} \quad (R \ge 1).$$

Indeed away from the cutoff annulus the usual polynomial difference has this bound; on the annulus the extra difference of the cutoff costs R^{-1} and $|x|$ is comparable to R. Apply eq. 4.ix with a single-bond second argument and pass to the limit using eq. 4.v. Summing against any polynomial second argument is then legitimate by absolute convergence. The radius of the nonlinear gauge chart may depend on R: only its derivative at zero was used for each fixed R.

In particular the linear polynomial $\chi(x) = x_\mu t_a$ gives the separate row and column zeroth moments

$$\sum_x K_z^{\mu\nu}(x,y) = 0, \qquad \sum_y K_z^{\mu\nu}(x,y) = 0. \tag{4.xi}$$

The second identity follows also from eq. 4.viii. Both hold for each fixed remaining edge and pair of directions, not only after a full trace.

For the moment at $z = 0$ set, initially in lower bond-start coordinates,

$$T_{\mu\nu,\kappa\lambda} = \sum_{x,y} K_0^{\mu\nu}(x,y) x_\kappa y_\lambda. \tag{4.xii}$$

For a symmetric matrix S, the quadratic gauge polynomial $\chi(x) = \frac{1}{2}\sum_{\mu,\kappa} S_{\mu\kappa}x_\mu x_\kappa t_a$ has forward difference

$$(\mathrm{d}\chi)_\mu(x) = \sum_\kappa S_{\mu\kappa}x_\kappa + \tfrac{1}{2}S_{\mu\mu}.$$

Use the polynomial Ward identity with second argument $C_\nu(y) = y_\lambda t_a$ at one direction ν. The constant term vanishes by eq. 4.xi. Since S is arbitrary symmetric, one obtains

$$T_{\mu\nu,\kappa\lambda} = -T_{\kappa\nu,\mu\lambda}, \qquad T_{\mu\nu,\kappa\lambda} = -T_{\mu\lambda,\kappa\nu}. \tag{4.xiii}$$

The second identity follows by interchanging the two Hessian arguments and repeating the first. These are exactly the two antisymmetries which remove symmetric gradients.

The bulk sum and its second moment. Unit translation covariance of this individual member gives $K_z^{\mu\nu}(x,y) = K_0^{\mu\nu}(x-z, y-z)$. The bulk quadratic kernel is

$$\Pi^{\mu\nu}(x,y) = \sum_z K_z^{\mu\nu}(x,y) = \pi_{\mu\nu}(y-x), \qquad \pi_{\mu\nu}(u) = \sum_x K_0^{\mu\nu}(x, x+u). \tag{4.xiv}$$

All sums converge absolutely. In fact, for $0 < m' \le m$,

$$\sum_u e^{m'|u|}|\pi_{\mu\nu}(u)| \le \sum_{x,y} e^{m'(|x|+|y|)}|K_0^{\mu\nu}(x,y)| < \infty. \tag{4.xv}$$

For fixed x, y, translation of z in eq. 4.xiv is a sub-sum of the same absolute double sum. This proves both the bulk formula and every rearrangement below. Only this bulk object is a convolution. The original $K_0(x,y)$ continues to have two independent spatial arguments.

The zeroth and first bulk moments vanish by eq. 4.xi. Its second moment is

$$\begin{aligned} P_{\mu\nu,\kappa\lambda} &:= \sum_u \pi_{\mu\nu}(u)u_\kappa u_\lambda \\ &= \sum_{x,y} K_0^{\mu\nu}(x,y)(y_\kappa - x_\kappa)(y_\lambda - x_\lambda) \\ &= -T_{\mu\nu,\kappa\lambda} - T_{\mu\nu,\lambda\kappa}. \end{aligned} \tag{4.xvi}$$

The pure $y_\kappa y_\lambda$ term is zero after summing x by its row identity, and the pure $x_\kappa x_\lambda$ term is zero after summing y. This is the reason for both minus signs; no pointwise convolution identity for K_0 has been used.

The Fourier series $\widehat{\pi}_{\mu\nu}(k) = \sum_u \pi_{\mu\nu}(u)e^{ik\cdot u}$ is holomorphic for sufficiently small $|\operatorname{Im} k|$ by eq. 4.xv. In particular $\partial_\kappa\partial_\lambda\widehat{\pi}_{\mu\nu}(0) = -P_{\mu\nu,\kappa\lambda}$. This optional Fourier description concerns the bulk sum alone.

Bond midpoints and the hypercubic tensor. Under reflections, lower bond starts undergo a direction-dependent integer displacement. To apply tensor symmetry without dropping that displacement, move first to bond-midpoint coordinates $\widetilde{x} = x + e_\mu/2$ and $\widetilde{y} = y + e_\nu/2$. The value of T does not change: expanding $\widetilde{x}_\kappa\widetilde{y}_\lambda$ adds only terms of the forms $\sum_{x,y} K_0 y_\lambda$, $\sum_{x,y} K_0 x_\kappa$ and $\sum_{x,y} K_0$, all zero by eq. 4.xi. The displacement u changes by the constant $(e_\nu - e_\mu)/2$. Because the bulk zeroth and first moments are zero, its second moment P is also unchanged. Thus the lower-start extractor and the midpoint extractor agree exactly.

The midpoint bond sets are $\mathbb{Z}^4 + e_\mu/2$. A signed permutation w with $we_\mu = s_\mu e_{\sigma(\mu)}$ maps this set to the midpoint set of direction $\sigma(\mu)$; a negative orientation contributes the sign s_μ to a one-form. Pointed covariance at the fixed base point zero and the ordinary transformation of the midpoint coordinates therefore give

$$T_{\sigma(\mu)\sigma(\nu),\sigma(\kappa)\sigma(\lambda)} = s_\mu s_\nu s_\kappa s_\lambda T_{\mu\nu,\kappa\lambda}. \tag{4.xvii}$$

There is no affine correction left in this formula; the preceding moment calculation proved that it vanished.

We now classify this tensor directly. By eq. 4.xiii it is zero if $\mu = \kappa$ or $\nu = \lambda$. Reflecting one coordinate in eq. 4.xvii shows that each coordinate label must occur an even number of times among

the four indices of a nonzero entry. The two antisymmetric pairs must consequently be the same unordered pair. The only possibilities are $T_{\mu\mu,\kappa\kappa}$ and $T_{\mu\kappa,\kappa\mu}$ for $\mu \neq \kappa$. Permutations make all the first values equal to a number b; eq. 4.xiii makes the second values $-b$. Hence

$$T_{\mu\nu,\kappa\lambda} = b(\delta_{\mu\nu}\delta_{\kappa\lambda} - \delta_{\mu\lambda}\delta_{\kappa\nu}). \tag{4.xviii}$$

Full reflections are used here: four distinct indices, including a possible alternating tensor, are excluded by a single reflection. This is not merely an argument using proper rotations.

Combining eq. 4.xvi with eq. 4.xviii gives

$$P_{\mu\nu,\kappa\lambda} = b(\delta_{\mu\lambda}\delta_{\kappa\nu} + \delta_{\mu\kappa}\delta_{\lambda\nu} - 2\delta_{\mu\nu}\delta_{\kappa\lambda}), \qquad b = P_{\mu\nu,\mu\nu} \quad (\mu \neq \nu). \tag{4.xix}$$

Thus the extractor is explicitly $b[G] = \sum_u \pi_{\mu\nu}(u)u_\mu u_\nu$ for any distinct μ, ν. It has no extra color factor, because eq. 4.vii used the average of the three diagonal color Hessians. The quadratic term of the bulk symbol is $b(|k|^2\delta_{\mu\nu} - k_\mu k_\nu)$; higher lattice derivative terms have not been set to zero.

For fixed actual h, the extractor is complex linear in the member and ignores additive constants. It is continuous in the exponential Hessian moment norm: the absolute second moment is bounded by that norm times $\sup_{r\geq 0} r^2 e^{-mr}$, with a harmless choice of a smaller exponential weight. Normal convergence in that norm also permits termwise extraction and preserves holomorphy in a member parameter. These are Hessian-norm statements, and make no assertion that the Hessian norm is uniformly bounded by a potential norm on coupling-dependent shrinking cores.

The affine quadratic jet and the tent action. Let $B_\mu(x) = a_\mu + \sum_\kappa C_{\mu\kappa}(x-z)_\kappa$, using midpoint coordinates or lower starts. The difference is a constant one-form, which the Ward identity annihilates. eq. 4.xi removes every occurrence of a, and eq. 4.xviii proves

$$\frac{1}{2}\mathcal{H}_z(B,B) = \frac{b}{2}\sum_{\mu<\nu} |C_{\nu\mu} - C_{\mu\nu}|^2. \tag{4.xx}$$

For complex fields the squared norm means the bilinear color pairing; for real fields it is the ordinary squared norm. The identity follows by expanding $\sum_{\mu,\kappa}|C_{\mu\kappa}|^2 - \sum_{\mu,\nu}\langle C_{\mu\nu}, C_{\nu\mu}\rangle$ into unordered pairs. In particular the axial affine choice $\ell_\mu(x) = \sum_{\kappa<\mu}(x-z)_\kappa F_{\kappa\mu}$ has curl F and quadratic jet $\frac{b}{2}\sum_{\mu<\nu}|F_{\mu\nu}|^2$.

To identify this with the member's own action counterterm, one more normalization of the actual free response is needed. Assume that on an affine coarse field ℓ of constant curl it reproduces the same affine bare potential modulo a lattice gradient, and its current component is zero. This is an affine-response statement about the actual averaging/background problem, not a consequence of the tensor classification. For this normalization argument assume also that, at each bare bond in a bounded coarse region, the matrix elements of H in the coarse input bond decay exponentially in its distance from that region. Their constants must be uniform in its finitely many bare bonds at fixed η. This is a precise sufficient free-response input. It makes $H(\ell\vartheta(\cdot/R))$ converge at every such bond to an absolutely convergent polynomially weighted matrix sum, by dominated convergence. Thus its affine reproduction statement is an equality of well-defined extended first responses, with no nonlinear affine field inserted outside its analytic domain.

This input also gives the moment bound needed to apply the tensor theorem to the pointed action itself. Its Hessian is a finite sum over the bare plaquettes in a unit tent of products of first differences of H. The exponential bounds at their finitely many bonds give a product bound $C_\eta e^{-m_H(|x-z|+|y-z|)}$. Summing in the two input bonds with any smaller exponential weight proves eq. 4.v for this action. This absolute convergence statement does not assert that C_η has a uniform cutoff bound; any such bound is a further quantitative input.

There is a useful stronger scope. Write $\mathrm{d}_\eta H(p) = \eta^{-1}\sum_{b\in\partial p} H(b)$ with oriented signs. If the actual response satisfies the physical first-difference bound

$$|\mathrm{d}_\eta H \delta^a_{x,\mu}(p)| \leq Ce^{-m_H|x-z|} \qquad (h_z(p) > 0),$$

uniformly in η, then the moment constant for the pointed action is uniform in η as well. Indeed, its kernel contains

$$\sum_p \eta^4 h_z(p)(\mathrm{d}_\eta H\delta_x)(p)\cdot(\mathrm{d}_\eta H\delta_y)(p).$$

The exact quadrature proved below makes the weighted plaquette sum one in each orientation. Consequently this kernel is bounded by $Ce^{-m_H(|x-z|+|y-z|)}$, and any smaller exponential moment is summable uniformly. This explains precisely why physical first differences, rather than identity-only bounds on bare values, remove the possible C_η loss.

Let $\eta = 1/N_0$ for an integer $N_0 \geq 1$, and use the midpoint tents

$$h_z(p) = \prod_{r=1}^{4}(1-|p_r - z_r|)_+, \qquad A_z(U) = \sum_{\mu<\nu}\sum_{p_{\mu\nu}} h_z(p)A_p(U). \tag{4.xxi}$$

For each fixed plaquette orientation,

$$\eta^4 \sum_{p_{\mu\nu}} h_z(p) = 1. \tag{4.xxii}$$

Here its barycenters have half-mesh shifts in directions μ,ν and zero shifts in the other directions. The one-dimensional unshifted identity is $N_0^{-1}[1+2\sum_{r=1}^{N_0-1}(1-r/N_0)]=1$. For the half-mesh shift it is $2N_0^{-1}\sum_{r=0}^{N_0-1}(1-(r+1/2)/N_0)=1$. Multiplication of these four identities proves eq. 4.xxii, including the coarse case $N_0=1$. Also $\sum_z h_z(p)=1$, since the two neighboring one-dimensional tents sum to one in each coordinate.

For a bare affine potential of curl F, the first variation of a plaquette holonomy in the chart $U_b = e^{it\eta A_b}$ is $it\eta^2 F_{\mu\nu}$. eq. 4.i, gradient invariance and eq. 4.xxii therefore give

$$\frac{1}{2}D^2(A_z\circ\mathcal{P})(0)[\ell,\ell] = \frac{1}{2}\sum_{\mu<\nu}|F_{\mu\nu}|^2. \tag{4.xxiii}$$

The affine-response hypothesis was used exactly in this line. The same pointed tensor theorem applies to this pointed action, so eq. 4.xx identifies its extractor as $b[A_z]=1$. Consequently

$$D^2(F_z - b[G](A_z\circ\mathcal{P}))(0)[\ell,\ell] = 0 \tag{4.xxiv}$$

for every affine constant-curvature field. Polarization gives the corresponding mixed affine identity. This proves the exact extractor-to-counterterm match with the normalization $A(e^{iB}) = \frac{1}{2}|\mathrm{d}B|^2 + O(B^3)$.

Selecting different members at different sites. The proof can be applied separately to each member $G^{[z]}$ chosen at a site. Within that member the family at all hypothetical base points is translation covariant, so its own bulk extractor $b[G^{[z]}]$ is defined by eq. 4.xiv and eq. 4.xix. Its pointed total at the actual site z is canceled by that number times A_z, by eq. 4.xxiv. No translation covariance of the array $z\mapsto G^{[z]}$ has been used.

This distinction is necessary for an inhomogeneous scalar source: one may freeze it to a different constant-source member at each site, but must use the coefficient of that same member at that site. Equality of two unpointed totals alone does not identify their separate site weights. Likewise the classification above does not prove a nonlinear third-order or Hölder remainder. That step still requires the actual localized response, its uniform field-domain inclusion and its stated analytic derivative bounds on the window.

4.3. **The nonlinear remainder in a pointed window.** The algebraic cancellation of a pointed Hessian concerns the second derivative at the identity. Its use at a nonlinear background requires a local Taylor estimate. We prove that estimate from the background hypotheses, retaining the domain assertions that make the compositions meaningful. In particular, the datum is large compared with its value close to the base point. A Taylor bound using only its global supremum would lose the required power of the scale ratio.

The background inputs and their coordinate radii. Work first in units in which the coarse spacing of a single-scale window is one. The background package A1–A3 is used in the following explicit form. On a box with collars there is a holomorphic potential/current representative $\Phi_\Lambda(B)$, with $\Phi_\Lambda(0) = 0$, for the actual constrained critical orbit. Its datum domain contains

$$\mathcal{B}_{r_B} = \{B : \text{determining bonds} \longrightarrow \mathfrak{su}(2)^{\mathbb{C}} : \sup_c |B(c)| < r_B\}. \tag{4.xxv}$$

Here $B(c)$ is a dimensionless logarithm of a group-valued coarse bond. This is a product of balls at bonds. It has no coupled derivative restriction. The orbit representative, its current, and the response estimates hold throughout this complex domain. Core and tower memberships under restriction and substitution are also part of A1; they are not inferred from the formal existence of a logarithm. All differentiations and coordinate sums below are first carried out on finite boxes. Their uniform bounds permit the stated coherent infinite-volume limits; no representation of a derivative on an infinite ℓ^∞ space by coordinate derivatives is assumed.

For clarity, the output norm over a top of local spacing ξ_y is

$$Z_y = (\xi_y H, \xi_y^2 \nabla H, \xi_y^3 J), \qquad |Z_y| = \max\{\xi_y|H|,\ \xi_y^2|\nabla H|,\ \xi_y^3|J|\}. \tag{4.xxvi}$$

The first-response bound supplied by A3 is

$$|\partial_{B(c)} Z_y(B)[e]| \le C e^{-md(y,y_c)}|e|, \qquad B \in \mathcal{B}_{r_B}, \tag{4.xxvii}$$

together with the stated spatial Hölder bound for ∇H. The distance is the local-scale path distance. On the central homogeneous part of the window, eq. 4.xxvii uses level-j distances and the output weights are one. Constants may depend on the fixed window size, the decay rate and the Hölder exponent, but not on the bare mesh, the torus or the number of preceding steps.

In the central part of the old box the top spacing is one in the old units. The finer tops in the tower collar are handled by the weighted row sum for the actual response. We compare affine data on this same determining set, with its prescribed seam rows.

Choose a fixed basis of the three-dimensional complex colour space. If $\sup|B| \le r_B/2$, varying one basis coordinate by $|s| < c_{\mathrm{col}} r_B/2$ stays in eq. 4.xxv, where $c_{\mathrm{col}} > 0$ depends only on this choice of norm and basis. Thus there is an admissible coordinate Cauchy radius independent of the number of bonds. The factors ξ_y in eq. 4.xxvi are output weights and commute with this Cauchy estimate. If instead a physical potential datum is written $a(c) = B(c)/\xi_c$, its coordinate radius is $c_{\mathrm{col}} r_B/(2\xi_c)$, and $\partial_{a(c)} = \xi_c \partial_{B(c)}$. Contracting a second derivative against $a(c)a(c')$ cancels both input factors $\xi_c, \xi_{c'}$. No inverse local spacing is lost by using dimensionless bond coordinates.

Lemma 4.4 (Product decay for the second response)**.** On $\mathcal{B}_{r_B/2}$, the first-response hypothesis implies

$$|\partial_{B(c)}\partial_{B(c')} Z_y(B)[e, e']| \le \frac{C}{r_B} e^{-\frac{m}{2}(d(y,y_c)+d(y,y_{c'}))}|e|\,|e'|. \tag{4.xxviii}$$

The same conclusion holds for the local first-order pair norm on a domain X, with $d(y, y_c)$ replaced by $\mathrm{dist}(c, X)$. ■

Proof. Apply the coordinate Cauchy estimate to $\partial_{B(c)} Z_y(B)[e]$, using a slightly smaller fixed fraction of the radius just specified. This gives $C r_B^{-1} e^{-md(y,y_c)}|e|\,|e'|$. The finite-dimensional holomorphic map has symmetric second derivatives, so the same argument interchanging c, c' gives the corresponding bound with c'. The smaller of two positive bounds is at most their geometric mean, which proves eq. 4.xxviii. Taking the supremum over the output bonds, first differences and current components gives the stated local norm version. Colour indices cost only a fixed factor. □

This argument uses response decay at every complex datum in a ball. Decay of the linear response at $B = 0$ alone is insufficient.

Weighted polynomial data and the local expansion. Fix a base point z, a scale ratio $0 < \sigma \le 1$, and a window whose distance from z to its boundary is comparable with σ^{-1}. Write a for a radius of a regular member, a_{out} for the output field radius and

$$\rho = a_{\mathrm{out}}/a \ge 1, \qquad a \le C_0 r_B, \qquad a_{\mathrm{out}} \le c_0, \qquad 0 < \alpha \le 1. \tag{4.xxix}$$

The constant c_0 is chosen small enough for the matrix charts. A fixed constant C_{ax} in the axial datum estimate below is understood. The local Taylor argument requires the full axial datum in $\mathcal{B}_{r_B/2}$. The central rows have bound $C_{\mathrm{ax}} a_{\mathrm{out}}\sigma$; the remote rows require their own absolute bound in the same chart. The gain σ on the central rows does not bound the remote ones. Once both bounds are below $r_B/2$, the entire segment from zero lies in this polydisc.

For the flat-reference windows, this absolute domain condition has a choice uniform in the depth. Use a fixed continuation radius $r_{\mathrm{abs}} > 0$, smaller if necessary than the common row and node-gauge radii, as r_B. Fix the window geometry first. The full induced datum of the upper background has bound $C_M A_0$, whereas its central rows have the additional factor σ, as in the proof of Prop. 3.135. A fluctuation of amplitude A_{fl} changes a level-q raw row by at most $CL^{q-k}A_{\mathrm{fl}}$, with $q \le j \le k$. First omit the independent raw correction and call the physical datum D. If $A_0, A_{\mathrm{fl}} \le a_{\mathrm{abs}}$, its full norm is at most $C_M a_{\mathrm{abs}}$. Construct the old axial change from this uncorrected datum. Its comb in the settled layer has $O(\sigma^{-1})$ links of logarithmic size $O(C_M a_{\mathrm{abs}}\sigma)$, so the node gauge has logarithm $O(C_M a_{\mathrm{abs}})$. Extend that logarithm with a cutoff supported inside the settled layer. On every row the transformed datum is the product of its original value and its two endpoint gauge factors.

For an independent raw correction E, hold this gauge g fixed with respect to E. It may still depend holomorphically on the physical input. In additive datum coordinates its action is the rowwise map

$$\mathcal{G}_g(D)(c) = \frac{1}{i}\log\Big[g(c_-)e^{iD(c)}g(c_+)^{-1}\Big].$$

The endpoint factors and their inverses have bounded norms, and these products lie in a fixed smaller logarithm chart. The bounded derivatives of the exponential and logarithm therefore give

$$\|\mathcal{G}_g(D+E) - \mathcal{G}_g(D)\|_\infty \le C\|E\|_\infty.$$

There is no comb-length factor in this rowwise estimate. With the prescribed correction norm below a_{abs}, the full axial datum consequently satisfies

$$\|\widehat{B}\|_\infty \le C_{\mathrm{win}}(M)a_{\mathrm{abs}} \le r_{\mathrm{abs}}/4. \tag{4.xxx}$$

This is absolute admission of the correction disc. No central factor σ is assigned to an arbitrary correction, and the axial gauge is not reconstructed from that correction. Choose a_{abs} after M and r_{abs}, also below the ceiling $a_I(M)$ of Prop. 3.135. All contour logarithms and the complex gauge covariance then stay in their fixed charts. The constants do not depend on the depth: only the comb length contains σ^{-1}, and its link size supplies the compensating σ. This is an absolute-domain check for the actual admitted window maps. It does not enlarge a regular member's prescribed core: its membership and the local Taylor ball of radius a remain separate requirements. It also does not imply the proportional remote-datum bound Ca_{out} used below. That bound is needed to retain a_{out} in the exponentially small response from the remote rows. If only an absolute remote bound is available, its response must instead be retained as a separate tail. For another family with radii r_B that vary with age, the full-datum inclusion remains a separate hypothesis; the central age estimate alone does not establish it. A harmless enlargement of the radius ratio to at least one is allowed. For a domain X containing z, let $D = 2 + \operatorname{diam} X$, in the present units.

For the combined background and fluctuation we need, on the central rows before choosing the old axial gauge, a logarithm B with

$$|B| \le Ca_{\mathrm{out}}\sigma, \quad |\nabla B| \le Ca_{\mathrm{out}}\sigma^2, \quad |\nabla B(x) - \nabla B(x')| \le Ca_{\mathrm{out}}\sigma^{2+\alpha}|x-x'|^\alpha. \tag{4.xxxi}$$

Here is the passage from the common-frame field estimate to these row bounds. Write a for the bare bond logarithm of the product field, with $\eta_k^{-1}\mathsf{a}$ bounded by Ca_{out} in $C^{1,\alpha}$ in level-k units. Translate the central double-block carriers, including the one-row translates used for the differences, to a common carrier. The actual order-j row map on a smaller absolute sup ball has first and second derivative norms bounded by CL^j and CL^{2j}, by directional Cauchy estimates. An old step has length σ in upper units. The sup and first-difference estimates therefore give the first two bounds in eq. 4.xxxi. For two rows r old spacings apart, applying the first derivative to the difference of the increments costs $Ca_{\mathrm{out}}\sigma^{2+\alpha}|r|^{\alpha}$. The change of the point at which that derivative is applied costs $Ca_{\mathrm{out}}^2\sigma^4|r|$ by the second derivative bound. The latter fits the former on $|r| \le C/\sigma$.

The decoupled field estimate is covariant for the input connection. To use it here we must verify the spatial regularity of that connection in the same frame as the box field on the complete central carriers. A bound on the gauge condition number controls the shifted link sizes. The first differences also use the change of that frame along the links. The localization uses the relative frame and its restoring identity.

All statements in this section require the actual pair and its restrictions to remain in the member's prescribed core. The small chart ball used for Taylor's formula must be contained in that core. The radius a is a fixed fraction of its curvature radius. Throughout the admitted core $|\partial\mathbf{U}(p)-1| \le Ca\eta_j^2$, so its own tent action obeys $|A(h_z,\mathbf{U})| \le Ca^2$, by the determinant identity and exact tent plaquette count. This is a bound on the whole core, not just its contained chart ball.

In the axial gauge about z, the datum has a local form

$$\widehat{B}(c) = \ell_F(c) + r(c), \qquad \ell_{F,\mu}(x) = \sum_{\kappa<\mu} (x-z)_\kappa F_{\kappa\mu}, \tag{4.xxxii}$$

where $|F| \le Ca_{\mathrm{out}}\sigma^2$, and

$$|\widehat{B}(c)| \le Ca_{\mathrm{out}}\sigma^2(1+|c-z|), \qquad |r(c)| \le Ca_{\mathrm{out}}\sigma^{2+\alpha}(1+|c-z|)^2. \tag{4.xxxiii}$$

These estimates are for the central rows. On the remote rows the full axial datum is bounded by Ca_{out} on the admitted box chart. The distance of those rows from an inner domain is at least c/σ in the local-scale metric.

Here are details of eq. 4.xxxii–eq. 4.xxxiii. Fixing the transports along a coordinate comb to the identity expresses a remaining bond as a product of at most $C(1+|c-z|)$ transported plaquette holonomies. With constant plaquette strengths, the linear part of this product is exactly ℓ_F. eq. 4.xxxi shows that a plaquette logarithm differs from its value at z by at most

$$C\big[a_{\mathrm{out}}\sigma^{2+\alpha}(1+|c-z|)^{\alpha} + a_{\mathrm{out}}^2\sigma^3(1+|c-z|)\big].$$

The second term includes differentiation of the non-Abelian commutator. Conjugating a plaquette logarithm by a comb transport adds at most $Ca_{\mathrm{out}}^2\sigma^3(1+|c-z|)$. Since a_{out} is bounded and $\sigma^{1-\alpha} \le 1$, both errors are bounded by $Ca_{\mathrm{out}}\sigma^{2+\alpha}(1+|c-z|)$. Summing along the strip proves the second bound in eq. 4.xxxiii.

For completeness, the finite-product estimate used here follows by differentiating $P(t) = \prod_i e^{tX_i}$ twice: if $\sum_i |X_i| \le c$, then $\sup_{0\le t\le 1}|P''(t)| \le C(\sum_i |X_i|)^2$. The analytic logarithm in this fixed matrix ball has bounded first two derivatives, so

$$\left|\log\prod_i e^{X_i} - \sum_i X_i\right| \le C\left(\sum_i |X_i|\right)^2.$$

Its error here is at most $Ca_{\mathrm{out}}^2\sigma^4(1+|c-z|)^2$, which is absorbed in eq. 4.xxxiii. The unexpanded product bound gives the first bound of eq. 4.xxxiii. All transports stay in a fixed matrix ball, because the original comb has length $O(\sigma^{-1})$ and its original bond logarithms are $O(a_{\mathrm{out}}\sigma)$.

We shall use the elementary weighted sum

$$\sum_{c\in\mathbb{Z}^4} e^{-\mu\,\mathrm{dist}(c,X)}(1+|c-z|)^k \le C_{\mu,k}D^{k+4}, \qquad k\ge 0. \tag{4.xxxiv}$$

Indeed $|c-z|\le D+\mathrm{dist}(c,X)+C$. The shell at distance between q and $q+1$ is contained in a box with at most $C(D+q+1)^4$ bonds. Bounding each shell by this larger number and summing $e^{-\mu q}(D+q+1)^{k+4}$ proves eq. 4.xxxiv. Only a polynomial in D is spent. Every power needed below is fixed.

Let $\widehat{B}^\circ$ agree with $\widehat{B}$ on the central rows and vanish on the remote ones. The weighted first-response bound along the segment between the two data gives

$$\|\Phi_\Lambda(\widehat{B})-\Phi_\Lambda(\widehat{B}^\circ)\|_X \le C a_{\mathrm{out}} e^{-c/\sigma}.$$

The support is remote from X in the tower metric. We use the homogeneous sums on the central data.

Integrate the first response on the segment $t\widehat{B}^\circ$, and then use eq. 4.xxvii, eq. 4.xxxiii and eq. 4.xxxiv. With a fixed integer s, increased below when necessary, this gives

$$\|\Phi_\Lambda(\widehat{B}^\circ)\|_X \le CD^s a_{\mathrm{out}}\sigma^2, \qquad \|D\Phi_\Lambda(0)r\|_X \le CD^s a_{\mathrm{out}}\sigma^{2+\alpha}. \tag{4.xxxv}$$

The remote first-response bound gives the same first bound for $\Phi_\Lambda(\widehat{B})$. Taylor's formula with integral remainder for Φ_Λ, followed by eq. 4.xxviii and the product of the two weighted sums, gives

$$\|\Phi_\Lambda(\widehat{B}^\circ)-D\Phi_\Lambda(0)\widehat{B}^\circ\|_X \le \frac{CD^s}{r_B}a_{\mathrm{out}}^2\sigma^4. \tag{4.xxxvi}$$

The use of eq. 4.xxxiv in eq. 4.xxxvi is essential. Using only $\sup|\widehat{B}|=O(a_{\mathrm{out}}\sigma)$ would produce the wrong power σ^2 in its right-hand side.

The finite-box linear response. Take the depth-j truncation of the upper window tower. Fix a constant curvature tensor F in one real colour direction. Use the affine potential in eq. 4.xxxii on the bare lattice, and on every inner bare bond take $U_t=\exp(i\eta_j t a_F)$. Prescribe the actual averages of this field on every determining row, including the finer rows of the tower. Every inner bond of a plaquette crossing the exterior is a fixed level-zero row, since the first inward layer is separated from that exterior. Variations therefore act only at bonds where the full current is defined. There the opposite abelian plaquette contributions to the Wilson current cancel. Thus U_t is critical for its own datum. On the fixed finite box it is regular for small real t, and regular uniqueness identifies the box orbit at that datum.

On a level-q row c, the first datum is $L^{q-j}a_F(c_-)$ in level-j units. The centered block average reproduces the affine transverse coordinates and the longitudinal line average leaves $a_{F,\mu}$ unchanged. The actual composition gives the same result at every scale, as in Lem. 5.17. The literal first average gives the same affine datum. In an endpoint block, a contour integral from the centre has terms linear in a coordinate displacement or bilinear in two distinct displacements. Each has zero centered mean. Thus the endpoint contour terms cancel in the linearized literal average and only the straight corridor term remains. Differentiating the orbit identity gives the linear pair L_F of this box, equal to the affine field modulo a fine gradient, with zero linear current. Linearity gives the same conclusion for complex colours. The pointed Hessian kills that gradient, since the activity is gauge invariant and its first derivative at the identity is zero.

On the central rows of level j, the affine datum is ℓ_F of eq. 4.xxxii in the same linear frame. Extend this central datum by zero on the other rows in the expression below. If X is at distance at least cR from those other rows, with $R\asymp\sigma^{-1}$, the difference from the full affine datum is bounded by $C|F|(1+R)^s$ and supported at that distance. The first-response estimate on the same tower, using the uniform weighted sum over tops, gives

$$\|D\Phi_\Lambda(0)\ell_F-L_F\|_X \le C|F|(R+1)^s e^{-cR}. \tag{4.xxxvii}$$

The central sum with its linear growth and this outer sum also give $\|L_F\|_X \le CD^s|F|$. The comparison uses the literal affine datum on the prescribed finite tower.

For $R \asymp \sigma^{-1}$, $(R+1)^s e^{-cR} \le C_\alpha \sigma^\alpha$. Combining eq. 4.xxxii, eq. 4.xxxv–eq. 4.xxxvii and the first-response bound on the remote datum, we obtain

$$\begin{aligned} \Phi_\Lambda(\widehat{B}) = L_F + E_X, \qquad \|L_F\|_X \le CD^s a_{\mathrm{out}}\sigma^2, \\ \|E_X\|_X \le CD^s \left[a_{\mathrm{out}}\sigma^{2+\alpha} + r_B^{-1}a_{\mathrm{out}}^2\sigma^4\right]. \end{aligned} \tag{4.xxxviii}$$

Domains too large for the interior condition in eq. 4.xxxvii are put into the exponentially long tail. In applications their tree length is at least $c/\sigma - C$.

Taylor's formula for the actual member. Let G_X denote a regular pointed member on X, in its exponential potential/current chart. Assume its supremum on that core is $g_X = \mathtt{g}e^{-\kappa d_j(X)}$, and that its chart contains the ball of radius a. A fixed change of constants allows the use of a ball of radius $2a$ and estimates on its half ball; this is the specified room in the field domains. Constant gauge transformations act by the adjoint representation on both chart components. There is no invariant linear functional on $\mathfrak{su}(2)$, so $DG_X(0) = 0$. In particular the second derivative of the background does not enter the Hessian of this composition:

$$D^2(G_X \circ \Phi_\Lambda)(0)[B, B'] = D^2G_X(0)[D\Phi_\Lambda(0)B, D\Phi_\Lambda(0)B']. \tag{4.xxxix}$$

This assertion concerns regular members without stored colour spectators.

Proposition 4.5 (Pointed nonlinear window remainder)**.** Under the background and domain hypotheses above, for the near domains there is a fixed integer s_1 such that

$$\begin{aligned} G_X(\Phi_\Lambda(\widehat{B})) - G_X(0) = \tfrac{1}{2}D^2G_X(0)[L_F, L_F] + \mathcal{R}_X, \\ |\mathcal{R}_X| \le C\mathtt{g}e^{-\kappa d_j(X)}D^{s_1}\left[\rho^2\sigma^{4+\alpha} + \rho^3\sigma^6\right]. \end{aligned} \tag{4.xl}$$

The same estimate holds after absorbing the member's own tent-action counterterm, with its own Hessian subtracted. ■

Proof. Put $t = D^s\rho\sigma^2$, increasing s to cover every polynomial factor in eq. 4.xxxv–eq. 4.xxxviii. First suppose t is less than a sufficiently small fixed constant. eq. 4.xxxv then places the composed pair in the half chart ball of G_X. Cauchy's formula and Taylor's theorem give

$$\left|G_X(P) - G_X(0) - \tfrac{1}{2}D^2G_X(0)[P,P]\right| \le Cg_X(\|P\|_X/a)^3, \qquad \|D^2G_X(0)\| \le Cg_X/a^2. \tag{4.xli}$$

In eq. 4.xxxviii, divide by a, use $a/r_B \le C_0$, and expand the difference of the two quadratic forms. The product of L_F/a and the first error term is bounded by $CD^{2s}\rho^2\sigma^{4+\alpha}$. The product with the second error term is bounded by $CD^{2s}\rho^3\sigma^6$. The square of the first error is smaller than the first of these bounds. The square of the second is bounded by Ct^4, which is at most a constant times t^3 in this case. The mixed product is bounded by the sum of the squares. Finally the Taylor remainder in eq. 4.xli is at most Cg_Xt^3. Increasing s_1 proves eq. 4.xl.

If t exceeds that fixed small constant, use the actual core bound $|G_X(P) - G_X(0)| \le 2g_X$, rather than Taylor's formula at P. The Hessian estimate still bounds its polynomial value at L_F by Cg_Xt^2. For $t \ge c > 0$, $1 + t^2 \le C_ct^3$, and this proves eq. 4.xl after increasing s_1 again. Thus large radius ratios do not impose an upper bound on the age.

The coefficient of a member obeys $|b(G)| \le C\mathtt{g}/a^2$ by its Hessian moments. The tent action on its fixed local support has norm at most Ca^2. Consequently its counterterm is another holomorphic family of size $C\mathtt{g}$, with bounded support. Apply the same proof to this family and subtract. The affine field and its curvature in the two quadratic terms are the same. □

The exact own-counterterm identity in eq. 4.xxiv of the pointed Hessian cancellation theorem now applies to this last, normalised family: its complete sum of pointed curvature tensors is zero. A sum cut to the window is the complete sum minus the omitted domains. The omitted domains

have $d_j(X) \geq c/\sigma - C$. If the number through a cube of length q is at most $Ce^{\kappa_D q}$ with $\kappa > \kappa_D$, polynomial factors in $D \leq CM(d_j(X)+2)$ are summable. Thus eq. 4.xl, summed over near domains, gives

$$C\mathsf{g}[\rho^2\sigma^{4+\alpha} + \rho^3\sigma^6], \tag{4.xlii}$$

and completing the tensor sum costs at most $C\mathsf{g}\rho^2\sigma^4 e^{-c/\sigma}$. If a far domain is not contained in any non-wrapping chart, its value has only the norm bound and contributes an additional $C\mathsf{g}e^{-c/\sigma}$. Such a term has no justified factor proportional to the actual curvature: a flat field around a hole or a torus cycle need not be a pure gauge. It must be retained when a field-sensitive tail estimate is claimed.

For the radius estimate used in a window, $\rho \geq 1$ permits both exponentially small tails to be absorbed in eq. 4.xlii. Moreover

$$\rho^2\sigma^{4+\alpha} + \rho^3\sigma^6 \leq 2\rho^3\sigma^{4+\alpha}, \qquad \rho \geq 1, \quad \sigma \leq 1, \quad \alpha \leq 1. \tag{4.xliii}$$

There are $O(\sigma^{-4})$ level-j base points in one window of the later scale. Its remaining factor is therefore $C\mathsf{g}\rho^3\sigma^\alpha$. With $\rho^2 \leq C(1+n-j)$ and $\sigma = L^{-(n-j)}$, this is the summable ordinary weight $C\mathsf{g}(1+n-j)^{3/2}L^{-\alpha(n-j)}$. The central part of the input-domain condition holds at every sufficiently old age. Indeed

$$\frac{C_{\mathrm{ax}}a_{\mathrm{out}}\sigma}{r_B} \leq C_{\mathrm{ax}}C_0\rho\sigma \leq C(1+n-j)^{1/2}L^{-(n-j)}.$$

Choose a fixed age $a_\star$ beyond which this is at most $1/2$. The remote datum must independently lie in the same half ball. For the flat-reference windows this follows, at every age, from eq. 4.xxx; it is not a consequence of the displayed age gain. At each of the finitely many younger ages, the given core membership bounds the member and its own counterterm by $C\mathsf{g}(1+\rho^2\sigma^4)$. Here ρ is uniformly bounded and $\sigma \geq L^{-a_\star}$, so this is bounded by a fixed constant times $\mathsf{g}\rho^3\sigma^{4+\alpha}$. This last argument uses the ordinary age bound; it is not valid for an arbitrary unrelated pair (ρ,σ). Each site may carry a different Euclidean member: cancellation and the estimate are performed at that site with that member's own coefficient.

Proposition 4.6 (Vacuum-only window bound)**.** For an analytic gauge-invariant member without stored colour spectators, no lattice covariance is needed to obtain

$$|G_X(\Phi_\Lambda(\widehat{B})) - G_X(0)| \leq C\mathsf{g}e^{-\kappa d_j(X)}D^{s_2}\rho^2\sigma^4. \tag{4.xliv}$$

After the domains in a window have been summed, the bound is $C\mathsf{g}\rho^2\sigma^4$, with the same qualifications on remote, non-wrapping charts and young ages as above. ■

Proof. Gauge invariance under constant colour rotations again gives $DG_X(0) = 0$, independently of any spatial symmetry. By eq. 4.xxxv, with $t = D^s\rho\sigma^2$, the local pair lies in the half chart ball whenever $t < c$. Cauchy's estimate for the second-order Taylor remainder then gives Cg_Xt^2. For $t \geq c$, use the core bound $2g_X \leq C_c g_X t^2$. This proves eq. 4.xliv, and the domain entropy absorbs its fixed polynomial in D. A remote domain not admitting a chart contributes only $C\mathsf{g}e^{-c/\sigma}$; it is bounded by $C\mathsf{g}\rho^2\sigma^4$ for $\rho \geq 1$. If the central input-disc condition is unavailable at finitely many young ages, while the remote condition is supplied as above, the core bound is absorbed since $\rho \geq 1$ and $\sigma \geq L^{-a_\star}$. Finally the $O(\sigma^{-4})$ sites in the window cancel σ^4, leaving the ordinary weight ρ^2 for a defect or a remainder. □

4.4. **Localized complex Gaussian comparison.** The finite regular expansion uses a normalized Gaussian functional on a local set of fluctuation coordinates. Its auxiliary Gaussian can have as many coordinates as the surrounding volume. We prove its comparison bound without paying for that auxiliary dimension. The argument permits sharp, measurable cutoffs; it never shifts their arguments into the complex domain.

The local matrices and the normalized functional. All matrix norms below are operator norms for the Euclidean complex space. Transposition is bilinear transposition, not conjugate transposition. Let $C = C^{\mathsf{T}}$ be an invertible complex m-by-m matrix and let Γ be a complex m-by-n matrix, where $m \geq 1$ and $n \geq 0$. Assume real reference matrices $C_0 = C_0^{\mathsf{T}} > 0$ and Γ_0, and one constant $K \geq 1$, such that

$$\|C_0\| + \|C_0^{-1}\| + \|\Gamma_0\| \leq K, \qquad \|C - C_0\| + \|\Gamma - \Gamma_0\| \leq \varepsilon. \tag{4.xlv}$$

The number ε will be smaller than a constant depending only on K. No dimension enters that choice. Define

$$D = C + C\Gamma\Gamma^{\mathsf{T}}C, \qquad D_0 = C_0 + C_0\Gamma_0\Gamma_0^{\mathsf{T}}C_0. \tag{4.xlvi}$$

The real matrix D_0 is positive definite. In the small neighborhood in eq. 4.xlv, normalized Gaussian densities are defined by

$$d\mu_D(b) = (2\pi)^{-m/2}(\det D)^{-1/2}e^{-b^{\mathsf{T}}D^{-1}b/2}\,db, \qquad b \in \mathbb{R}^m. \tag{4.xlvii}$$

The square root is the holomorphic continuation of the positive root at the reference. We justify both convergence and normalization below.

The auxiliary representation of the localized functional is

$$\mathcal{J}_{C,\Gamma}[F] = \int d\mu_{I_n}(\xi)\, e^{-\xi^{\mathsf{T}}\Gamma^{\mathsf{T}}C\Gamma\xi/2} \int d\mu_C(b)\, e^{b^{\mathsf{T}}\Gamma\xi}F(b). \tag{4.xlviii}$$

For $n = 0$ the outer integral is absent. An integrand F need only be Borel measurable on $\mathbb{R}^m$. Suppose

$$|F(b)| \leq F_0 e^{\rho|b|^2}, \qquad F_0 \geq 0, \quad \rho \geq 0. \tag{4.xlix}$$

Proposition 4.7 (Local Gaussian comparison)**.** There are positive constants $\varepsilon_0(K), \rho_0(K)$ and A_K, independent of m, n, such that eq. 4.xlv, $\varepsilon \leq \varepsilon_0$ and $\rho \leq \rho_0$ imply absolute convergence of eq. 4.xlviii,

$$\mathcal{J}_{C,\Gamma}[F] = \int F\, d\mu_D, \qquad \mathcal{J}_{C,\Gamma}[1] = 1, \qquad |\mathcal{J}_{C,\Gamma}[F]| \leq F_0 e^{A_K(\varepsilon+\rho)m}. \tag{4.l}$$

The last estimate also bounds $\int |F|\,|d\mu_D|$. In particular its exponential cost uses the local dimension m, even when the auxiliary dimension n grows with the full volume. ∎

Accretivity, integration and the determinant branch.

Proof. The joint precision in eq. 4.xlviii is the symmetric block matrix

$$Q = \begin{pmatrix} C^{-1} & -\Gamma \\ -\Gamma^{\mathsf{T}} & I_n + \Gamma^{\mathsf{T}}C\Gamma \end{pmatrix}. \tag{4.li}$$

At the real reference it factors as

$$Q_0 = L_0^{\mathsf{T}} \begin{pmatrix} C_0^{-1} & 0 \\ 0 & I_n \end{pmatrix} L_0, \qquad L_0 = \begin{pmatrix} I_m & -C_0\Gamma_0 \\ 0 & I_n \end{pmatrix}. \tag{4.lii}$$

Both $\|L_0\|$ and $\|L_0^{-1}\|$ are at most $1 + K^2$. Thus $Q_0 \geq c_K I$ for a positive c_K. The resolvent identity for $C^{-1} - C_0^{-1}$, followed by expanding the products in eq. 4.li, gives $\|Q - Q_0\| \leq A_K\varepsilon$ for small ε; the constants depend only on K. For real (b, ξ), consequently,

$$\mathrm{Re}(b,\xi)^{\mathsf{T}}Q(b,\xi) \geq (c_K/2)(|b|^2 + |\xi|^2).$$

Choose $\rho_0 < c_K/8$. This proves absolute convergence of the joint integral with eq. 4.xlix, hence Fubini's theorem applies. It does not yet give the desired dimension bound; taking its absolute value before integrating ξ would pay unnecessarily for n.

Set $A = I_n + \Gamma^{\mathsf{T}}C\Gamma$. It is a small perturbation of the real positive matrix $I_n + \Gamma_0^{\mathsf{T}}C_0\Gamma_0$. Integrate ξ first. The normalized Gaussian exponential formula gives the factor

$$(\det A)^{-1/2} \exp\{b^{\mathsf{T}}\Gamma A^{-1}\Gamma^{\mathsf{T}}b/2\}.$$

This formula for a complex linear force does not require a contour change. One proof normalizes the complex Gaussian first and differentiates its exponential transform in the force. Integration by parts, justified by accretivity, gives $\nabla_\ell G = A^{-1}\ell G$, with $G(0) = 1$, and hence $G(\ell) = e^{\ell^{\mathsf{T}} A^{-1}\ell/2}$.

For completeness, the normalization used in that proof follows without a complex change of variables. On an accretive symmetric precision neighborhood the real-space integral is holomorphic by a fixed Gaussian majorant. It equals $(\det A)^{-1/2}$ at every real positive symmetric matrix there by real orthogonal diagonalization and the one-dimensional real Gaussian integral. Successive one-variable identity theorems in the independent symmetric matrix entries extend the equality to the complex neighborhood, with the root continued from its positive value. The real symmetric matrices have a full set of real coordinates for this argument; no identity is being extended from a lower-dimensional background graph.

The elementary inverse and determinant identities are

$$\begin{aligned} D^{-1} &= C^{-1} - \Gamma(I_n + \Gamma^{\mathsf{T}} C\Gamma)^{-1}\Gamma^{\mathsf{T}}, \\ \det D &= \det C \, \det(I_n + \Gamma^{\mathsf{T}} C\Gamma). \end{aligned} \tag{4.liii}$$

The inverse identity follows by multiplication with eq. 4.xlvi. For the determinant identity, eliminate either off-diagonal block in $\left(\begin{smallmatrix} I_m & -C\Gamma \\ \Gamma^{\mathsf{T}} & I_n \end{smallmatrix}\right)$; this proves $\det(I_m + C\Gamma\Gamma^{\mathsf{T}}) = \det(I_n + \Gamma^{\mathsf{T}} C\Gamma)$. The roots in eq. 4.liii agree at the real reference, and agree throughout the connected small perturbation neighborhood by continuity and nonvanishing. The remaining b integral is precisely eq. 4.xlvii. This proves the first identity in eq. 4.l, including for Borel F, since no complex argument of F was introduced. The same normalization argument gives $\int d\mu_D = 1$.

The local-dimension estimate. The reference bounds imply $D_0 \geq C_0$, $\|D_0\| \leq A_K$ and $\|D_0^{-1}\| \leq K$. Expanding eq. 4.xlvi yields

$$T = D_0^{-1/2}(D - D_0)D_0^{-1/2}, \qquad \|T\| \leq A_K\varepsilon =: \eta. \tag{4.liv}$$

Shrink ε_0 so that $\eta \leq 1/4$. Then $D^{-1} = D_0^{-1/2}(I+T)^{-1}D_0^{-1/2}$ and $\|(I+T)^{-1} - I\| \leq \eta/(1-\eta)$. For the real symmetric matrix

$$R = D_0^{1/2}(\operatorname{Re} D^{-1} - 2\rho I_m)D_0^{1/2}$$

we obtain $\|R - I_m\| \leq A_K(\varepsilon + \rho) =: u$. Shrink the constants further so that $u \leq 1/2$. Taking the absolute value of the *marginal* density, and then integrating the real positive Gaussian, gives

$$\int e^{\rho|b|^2}|d\mu_D(b)| = |\det(I+T)|^{-1/2}(\det R)^{-1/2} \leq (1-\eta)^{-m/2}(1-u)^{-m/2}. \tag{4.lv}$$

Every singular value of $I+T$ is at least $1-\eta$, and every eigenvalue of R is at least $1-u$. Finally $-\log(1-v) \leq 2v$ for $0 \leq v \leq 1/2$ proves eq. 4.l. □

Sharp failures, holomorphic parameters, and scope. Partition the real coordinates into disjoint bond blocks. If a set P_0 of distinct blocks fails the tests $|b_\beta| < \mathfrak{b}$, then $\sum_{\beta\in P_0}|b_\beta|^2 \geq |P_0|\mathfrak{b}^2$. Therefore, for $\gamma \geq 0$ with $\rho + \gamma/2 \leq \rho_0$, eq. 4.lv gives

$$\int \prod_{\beta\in P_0} \mathbf{1}_{\{|b_\beta|\geq\mathfrak{b}\}} e^{\rho|b|^2}|d\mu_D| \leq \exp\{A_K(\varepsilon + \rho + \gamma/2)m - \gamma\mathfrak{b}^2|P_0|/2\}. \tag{4.lvi}$$

This is a product-of-failures estimate, with one Gaussian tail per distinct tested bond. Multiplication by additional indicators only improves the bound.

If the matrices and the potential part of an integrand depend holomorphically on external parameters, and the sharp cutoff sets remain fixed, the same estimates give a parameter-independent Gaussian majorant on each smaller parameter neighborhood. Fubini and Morera then prove holomorphy of the integrals. No holomorphy of a characteristic function in its real field argument is asserted or required.

The rescaled structure $(\tau^{-1}C, \tau^{1/2}\Gamma)$ has effective covariance $\tau^{-1}D$. For real τ in a fixed compact subinterval of $(0,\infty)$, rescale the real reference in the same way; all constants remain uniform. A small complex displacement of τ is included in the matrix perturbation.

In the regular step, let $N_c(Z)$ be the number of coarse localization cubes. The local free-bond color-coordinate count obeys $m \le c(LM)^4 N_c(Z)$. Consequently eq. 4.l supplies the factor $\exp\{A_K(LM)^4(\varepsilon+\rho)N_c(Z)\}$, and eq. 4.lvi supplies the failed-cutoff tail. If a Gaussian comparison instead uses the symbol $N(Z)$ for the local coordinate count itself, its bound is $\exp\{A_K(\varepsilon+\rho)N(Z)\}$, with no second factor $(LM)^4$. These are two conventions for the same local cost. The matrix gap and kernel closeness are the actual A2–A3 inputs; this section proves the resulting finite-dimensional integration estimate.

Completeness is separate. Equality of this local functional with a marginal of one whole-torus Gaussian requires the actual completeness identity for its effective covariance. In the source construction that identity is supplied on complete physical pairs and their physical-data continuation. Arbitrary independent-current cores need only their own local holomorphic functionals and the bounds proved here. This theorem does not manufacture a global covariance on those cores, verify nonlinear background/core estimates, or establish a Gaussian law for actual averaging disintegrations.

4.5. **Local interactions and their source response.** The local part of a renormalization step has several distinct operations. A function of a fluctuation is first localized, its Gaussian integral is expanded, the connected logarithm is pointed at bonds, and an old gauge-invariant function is rewritten on a new constrained background. These operations have different domains. Their order is part of the definition of the step.

We work at a fixed finite cutoff and volume until uniform estimates have been established. A local pair $P = (U, J)$ consists of the admitted potential data and current data on the specified local domain. Those coordinates may be independent. A complete physical pair is denoted p_W; its current is the one induced by the actual constrained background belonging to the datum W. At such pairs the complete Gaussian structure reproduces the physical fluctuation integral. An identity on the set of pairs p_W is not an identity on an open set of independent pairs P.

We use three fluctuation coordinates. The free Gaussian coordinates are B; the constrained physical fluctuation is $\phi(B)$; and the background response supplies the actual field $U_P(B)$. Their typical sizes have the form

$$g = \theta^{-1/2}, \qquad \alpha = g\,A(\theta), \qquad \delta = s\alpha, \qquad 0 < s \le s_\star. \tag{4.lvii}$$

The analytic size $A(\theta)$, the cutoff in the coordinates B, and the physical radius δ are separate quantities. In particular a bound on a cutoff box in B does not furnish a holomorphic continuation to a ball of radius α/g. The larger ball used below is obtained from the actual unscaled constraint chart and the admitted datum polydiscs of the background response.

At a fixed real reference θ, two scalar-source presentations are useful. In the variable-profile presentation the real action weight x, the calibration, Gaussian, determinant branches and cutoffs are fixed; the profile is carried as an older potential member. Its new source energy is the difference of the localized fluctuation functions. In a constant-shift presentation one may instead change the action weight and compensate the free action, numerical terms and scalar counterterm. Differentiating that presentation changes more than the older potential. We use the first presentation for the insertion and source-gradient estimates in this section. Numerical or constant-shift identities require their own reference-change rule.

For clarity, the primitive data needed for the local argument are the following.

(i) The actual local Gaussian matrices have a uniform real reference gap and a small complex perturbation on every admitted local core and every enlarged decoupling disc. Their local

scalar-coordinate dimension is at most $c(LM)^4$ times the coarse-cube count. The auxiliary dimension may be the volume of the surrounding torus.

(ii) The background and window maps are jointly holomorphic on the specified datum and current domains, including all actual local substitutions, fine brackets and fluctuation amplifications used below. Their first-response, compatible-boundary and spatial regularity bounds are uniform in cutoff and volume.

(iii) Fine restrictions are hereditary; at all interpolation parameters equal to one they reproduce the original local function. A component separated from the declared root and containing a differenced cube gives zero. The actual coarse collar is a fixed-width union of neighboring cubes, rather than a rectangular bounding box of a thin domain.

(iv) The actual pointing is formed from its free-potential, cutoff and interaction legs. The interaction leg uses its actual bond densities. We prove a sufficient explicit convention below, and distinguish it from an identification with a separately prescribed pointing.

These are matrix, map and support assertions. They do not assume the activity bound, its source derivative, the many-scale recurrence, or the old-origin Hessian concluded below.

The roles of the six constructions are successive. The unmarked expansion first provides a spare potential slot. Cauchy's formula in that slot gives derivatives in the norm of the inserted potential. The pointing argument then differentiates the actual bond density. Window-first normalization supplies the old potential direction with its small radius factor before any fine bracket is applied. The source-gradient recurrence and the larger fluctuation-domain argument finally propagate the first jet and bound the old Hessian.

There is one common normalization issue throughout. If H is an old action member, the new fluctuation direction is

$$v(P,B) = H(U_P(B)) - H(U_P(0)). \tag{4.lviii}$$

The omitted value $H(U_P(0))$ is carried by the old background action. It is not subtracted a second time from the logarithmic fluctuation integral. Equally, when a new scalar coefficient is extracted from a pointed member, it is that member's own tent action that is subtracted. A coefficient obtained from a different pointing or a different background readout cannot be substituted by name.

All norm bounds in this section are on fixed admitted local cores. When a complex parameter is varied, a cutoff remains fixed at its real reference value and is a function of real integration coordinates. The reference measure, geometric indices and filing rule are also fixed. A moving cutoff or changing history fibre must first be expressed over a common reference operation before a norm-holomorphy argument applies. The last section records precisely how the local estimates interact with a finite history and its retained inner Wilson weight.

4.5.1. *The actual unmarked expansion.* We derive the activity and local logarithm bounds from the finite Mayer, cutoff and coarse-decoupling formulas. The Gaussian estimate is used at a potential budget larger than the physical one. No logarithm or nonvanishing assertion is needed at that larger budget. Only after the activities have been estimated do we apply the proved hard-core polymer theorem.

All bounds below are local on the specified complex potential/current cores. At complete physical pairs the completeness identity also identifies their gas with the regular fluctuation integral. No global Gaussian on an arbitrary independent-current pair is assumed.

The actual formulas and their analytic inputs. Fix a finite four-dimensional periodic cube lattice, with fine localization cubes of side M and coarse cubes of side LM. Both grids tile the torus. Lengths d_f and d_c are tree lengths in fine and coarse cube units. There are a fixed finite number of potential types: the free, intrinsic, already formed older, and optional inserted potential groups may each be combined within their type before the Mayer expansion. Thus this type count is independent of the number of older levels or source profiles. A tagged fine domain Y includes its

type in its name; geometry ignores this tag. For the actual local potentials assume

$$|V(Y;P,B)| \le a_Y e^{-\lambda_V d_f(Y)} \left(1 + M^{-4} \sum_{b \subset Y} |B(b)|^2\right), \qquad a_Y \le a,$$
$$a = \sum_{\text{types}} \|\mathbf{V}^{\text{type}}\|_{\lambda_V}. \tag{4.lix}$$

The potentials are holomorphic on their declared complex fluctuation boxes and external cores. If a potential is defined only on a box, the corresponding sharp cutoff is kept wherever that potential occurs. The free potential, when present, is defined on all real fluctuation coordinates.

Let $\mathbf{D}$ be a selected set of tagged domains. Write Y_0 for the union of the free-bond sets requiring a field box among those selections, and let P_0 be a set of distinct failed-cutoff bonds outside Y_0. The exact integrand is

$$F_{\mathbf{D},P_0} = (-1)^{|P_0|} \chi_{Y_0} \prod_{b \in P_0} (1 - \chi_b) \prod_{Y \in \mathbf{D}} (e^{V(Y)} - 1), \qquad \chi_b = \mathbf{1}_{\{|B(b)| < \mathfrak{b}\}}. \tag{4.lx}$$

The cutoff product on Y_0 makes every selected factor well defined. Outside that product its integrand is set to zero. This convention introduces no complex argument into a characteristic function.

For any set S of fine cubes, let $\mathcal{N}_f(S)$ consist of S and its fixed first layer of neighbors in the given cubical adjacency. Define $S^\sharp$ to be the union of the coarse cubes containing at least one fine cube of $\mathcal{N}_f(S)$. This is a local cube union, not a rectangular bounding box. A bond uses its incident fine cubes in this definition. The collar preserves unions. A fixed number of additional neighboring cube layers is permitted only if it is part of the assigned collar in every structural identity; its fixed width is then included in the constants.

For the index $\iota = (\mathbf{D}, P_0)$, let $Z_0(\iota)$ be its actual fine support, including the globally defined selected potentials and the failed bonds. Its coarse collar is $Z_0^\sharp$. For $Z \supset Z_0^\sharp$, the actual terms and activities are

$$T(Z,\iota) = \prod_{\Delta \in Z \setminus Z_0^\sharp} \int_0^1 ds_\Delta \, \partial_{s_\Delta} \, \mathcal{J}(Z_0; s_Z)[F_{\mathbf{D},P_0}],$$
$$H(Z) = \sum_\iota T(Z,\iota). \tag{4.lxi}$$

Here $s_Z = 1$ on $Z_0^\sharp$, has the displayed parameters on the remaining cubes of Z, and is zero elsewhere. Polymers Z are nonempty wall-connected coarse domains. The empty selection contributes only the gas's leading one. It is omitted from H: on a nonempty Z, its term has a derivative of the normalized constant functional $\mathcal{J}[1] = 1$, and is zero. Disconnected regions factor into their wall-components rather than being counted again as single polymers.

The local functional $\mathcal{J}$ has the actual matrix representation and reference bounds of the local Gaussian comparison theorem. Uniformly on independent coarse parameter discs

$$|s_\Delta| < R_s, \qquad R_s > 2, \tag{4.lxii}$$

its matrix perturbation is at most ε, its gap constant is K, and its local real scalar-coordinate dimension obeys

$$m(Z_0; s_Z) \le c_m (LM)^4 N, \qquad N = \#Z. \tag{4.lxiii}$$

The auxiliary Gaussian dimension is unrestricted. For an integrand bounded by $F_* e^{\rho |B|^2}$, including distinct failed tests P_0, the proved comparison gives

$$|\mathcal{J}[F]| \le F_* \exp\Big\{ A_K(\varepsilon + \rho + \gamma/2)m - \gamma \mathfrak{b}^2 |P_0|/2 \Big\} \tag{4.lxiv}$$

when $\gamma > 0$, $\varepsilon \le \varepsilon_0(K)$, and $\rho + \gamma/2 \le \rho_0(K)$. This is the marginal local-coordinate estimate; no factor using the exterior auxiliary dimension is allowed. The potentials, matrices and integrals are jointly holomorphic in the scalar potential couplings and s, with the fixed cutoff sets just described.

The remaining structural hypotheses are the actual heredity, normalized-functional and wall-factorization identities. They identify eq. 4.lxi with the finite expansion on complete physical pairs and define coherent local terms on every local complex core. These hypotheses concern the assigned operators and supports. They are not consequences of a numerical Gaussian bound.

The two geometric counts. Let $Y^\sharp$ be the locally defined coarse collar above. All neighborhood widths are fixed independently of L and of the diameter or shape of Y. There is a fixed geometric constant C_h such that

$$\#Y^\sharp \le C_h \left(1 + \frac{d_f(Y)}{L}\right). \tag{4.lxv}$$

To prove this, take a fine covering tree for Y, with length within one of its infimum, and traverse every edge twice. After adding a bounded initial segment, this gives a closed walk of length at most $C(d_f(Y)+1)$ passing within a fixed fine-cube distance of every cube of Y. Split the walk into segments of length at most L. Each segment and its fixed fine collar meet a bounded number of coarse cubes, independent of $L \ge 2$. The number of segments is at most $C(1 + d_f(Y)/L)$. This proves eq. 4.lxv, also on the periodic graph. A failed bond has a coarse collar with at most a fixed number of cubes. Therefore, writing

$$r = \#\mathbf{D}, \qquad v = \#P_0, \qquad h = \#(Z \setminus Z_0^\sharp),$$

and increasing C_h once,

$$N \le C_h \left[r + \frac{1}{L} \sum_{Y \in \mathbf{D}} d_f(Y) + v + h \right]. \tag{4.lxvi}$$

There is no term proportional to the surrounding volume.

We also use the rooted fine-domain entropy bound. For every $\xi > \kappa_f$,

$$S_\xi := \sup_{\text{fine cube } q} \sum_{\text{tagged } Y \ni q} e^{-\xi d_f(Y)} < \infty. \tag{4.lxvii}$$

One direct counting proof rounds a covering tree to the bounded-degree graph of fine cubes, traverses its edges twice starting at q, and records which neighboring cubes are selected in Y. The walk has length at most $C(d_f(Y)+1)$. Its choices and the selection flags are bounded by a fixed constant to that power. This proves exponential rooted entropy, uniformly on the torus. The fixed number of type tags changes that constant only. In particular, if $\mathcal{Y}(Z) = \{Y : Y^\sharp \subset Z\}$,

$$\sum_{Y \in \mathcal{Y}(Z)} e^{-\xi d_f(Y)} \le c_f L^4 S_\xi N. \tag{4.lxviii}$$

This follows by charging a domain to any one of its fine cubes and summing over all fine cubes in Z; overcounting only enlarges the bound. The number of free bonds whose collars fit in Z is at most $n_b N$, where

$$n_b \le c_b (LM)^4. \tag{4.lxix}$$

The bond count in eq. 4.lxix and the scalar-coordinate dimension in eq. 4.lxiii are distinct counts. Neither is counted twice.

A Gaussian-only budget and repeated Schwarz. Choose a positive number W_0, independent of cutoff and volume, small enough for a Gaussian tilt, and choose $\lambda_0 > \kappa_f$. This is not yet the physical potential budget. For every selected tagged domain introduce its own coupling ζ_Y. For $a > 0$ use the radii

$$\mathcal{R}_Y = \frac{W_0}{a} e^{(\lambda_V - \lambda_0) d_f(Y)}. \tag{4.lxx}$$

We will require $a \le W_0/2$, so every radius exceeds one. On the product of these discs, the local density bound in eq. 4.lxvii gives

$$\sum_{Y\in\mathbf{D}} |\zeta_Y V(Y;P,B)| \le W_0 \sum_{Y\in\mathbf{D}} e^{-\lambda_0 d_f(Y)} \left(1 + M^{-4} \sum_{b\subset Y} |B(b)|^2\right) \le C_p W_0 L^4 N + C_p W_0 M^{-4} |B|^2. \tag{4.lxxi}$$

The constant C_p includes the finite tags and their rooted sums, but no number of selected domains or global volume. The quadratic term uses the rooted sum at each bond. The constant term uses the fine-cube count in eq. 4.lxviii.

Choose W_0, γ so that

$$C_p W_0 M^{-4} + \gamma/2 \le \rho_0(K). \tag{4.lxxii}$$

For complex ζ_Y the Mayer product is bounded by $2^r \exp(\sum_Y |\zeta_Y V(Y)|)$. Apply eq. 4.lxiv with the tilt in eq. 4.lxxi. Uniformly on both parameter polydiscs its integral is at most

$$2^r e^{C_0 N} p^v, \qquad p = e^{-\gamma \mathfrak{b}^2/2}, \quad C_0 = C_p W_0 L^4 + A_K c_m (LM)^4 (\varepsilon + C_p W_0 M^{-4} + \gamma/2). \tag{4.lxxiii}$$

The failed tests are distinct bond blocks, so the tail is p^v. The Gaussian theorem was applied only to a fixed real integration space with measurable cutoffs. There is no zero-freeness assertion on this larger coupling polydisc.

The integral vanishes whenever any selected $\zeta_Y = 0$. Repeated Schwarz on the polydisc consequently divides the bound by $\prod_Y \mathcal{R}_Y$ at $\zeta_Y = 1$. For clarity, division by $\prod_Y \zeta_Y$ has removable singularities; apply the maximum principle on smaller polydiscs and let their radii increase to eq. 4.lxx. This proves the product factor without a factorial. Mixed coarse Cauchy on circles centered at $s_\Delta \in [0,1]$, of radii tending to $R_s - 1$, then gives the literal term bound

$$|T(Z,\mathbf{D},P_0)| \le e^{C_0 N} \left(\frac{2a}{W_0}\right)^r e^{-(\lambda_V - \lambda_0)\sum_{Y\in\mathbf{D}} d_f(Y)} p^v (R_s - 1)^{-h}. \tag{4.lxxiv}$$

The coupling derivatives and the coarse derivatives commute by joint holomorphy and the same Gaussian domination. If $a = 0$, all nonempty Mayer selections are zero. Apply the same estimate to the cutoff-only terms, with $r = 0$; this is also the limiting interpretation of eq. 4.lxxiv.

The activity bound, including its linear amplitude. Fix a desired activity rate $\Lambda > 0$. For wall-connected coarse polymers there is a fixed c_ℓ such that

$$\ell(Z) := d_c(Z) + 5 \le c_\ell N. \tag{4.lxxv}$$

A cube-adjacency spanning tree proves $d_c(Z) \le CN$; the added five is absorbed because $N \ge 1$. Choose

$$K_* = 2 + c_\ell \Lambda, \qquad \Theta = C_h (C_0 + K_*). \tag{4.lxxvi}$$

Choose one $\sigma_0 > \kappa_f$, and impose the explicit rate conditions

$$\lambda_V - \lambda_0 \ge \Theta/L + \sigma_0, \qquad \log(R_s - 1) \ge \Theta. \tag{4.lxxvii}$$

Using eq. 4.lxvi to pay for $e^{(C_0+K_*)N}$, eq. 4.lxxiv becomes

$$|T(Z,\mathbf{D},P_0)| \le e^{-K_* N} \prod_{Y\in\mathbf{D}} \left(\frac{2a}{W_0} e^{\Theta} e^{-\sigma_0 d_f(Y)}\right) \prod_{b\in P_0} (p e^{\Theta}). \tag{4.lxxviii}$$

The unused factor $((R_s - 1)^{-1} e^{\Theta})^h$ is at most one. Every selection has thereby paid its own part of the hull cost. This is the place where the coarse hull estimate retains the favorable $d_f(Y)/L$.

At fixed Z, dropping the restriction $P_0 \cap Y_0 = \emptyset$ only enlarges the nonnegative sum. All selected domains and failed bonds still have collars inside Z, so eq. 4.lxviii–eq. 4.lxix give

$$\begin{aligned}\sum_{\substack{\mathbf{D},P_0\\(\mathbf{D},P_0)\neq(\emptyset,\emptyset)}} \prod_{Y\in\mathbf{D}} u_Y \prod_{b\in P_0} q &\le \prod_{Y\in\mathcal{Y}(Z)} (1+u_Y) \prod_{b:b^\sharp\subset Z} (1+q) - 1 \\ &\le e^{\tau N} - 1,\end{aligned} \tag{4.lxxix}$$

where

$$\begin{aligned} u_Y &= (2a/W_0)e^{\Theta} e^{-\sigma_0 d_f(Y)}, \qquad q = pe^{\Theta}, \\ p_\star &= n_b p, \qquad \tau = e^{\Theta}\left[\frac{2c_f L^4 S_{\sigma_0}}{W_0} a + p_\star\right]. \end{aligned} \tag{4.lxxx}$$

The products are finite in finite volume. In particular no factor from bonds outside Z has been inserted. The subtraction of one is essential: it retains a selected potential or failed cutoff, rather than creating a unit amplitude for every Z.

Take the physical smallness conditions

$$a \le W_0/2, \qquad \tau \le 1. \tag{4.lxxxi}$$

For $N \ge 1$, $e^{\tau N} - 1 \le \tau N e^{\tau N}$ and $N \le e^N$. eq. 4.lxxviii–eq. 4.lxxxi prove

$$\begin{aligned} |H(Z)| &\le e^{-K_* N}(e^{\tau N} - 1) \le \tau e^{-(K_*-2)N} \\ &\le C_\tau (a + p_\star) e^{-\Lambda \ell(Z)}, \\ C_\tau &= e^{\Theta} \max\left\{\frac{2c_f L^4 S_{\sigma_0}}{W_0}, 1\right\}. \end{aligned} \tag{4.lxxxii}$$

This is an estimate for the actual activities eq. 4.lxi. Their smallness has not been assumed. The larger Gaussian budget W_0 was used only to bound the analytic integrals; the physical budget in eq. 4.lxxxi is smaller and is what makes the activity amplitude at most one.

The actual union filing and the local logarithm. Choose a desired logarithmic output rate $\mu > 0$, and set $g_* = \Lambda - \mu$. Let $N \le C_v(d_c(Z) + 1)$, and let the number of coarse polymers containing a fixed cube with $m \le d_c(Z) < m + 1$ be at most $C_D e^{\kappa_D m}$. These geometric bounds follow from bounded-degree cube covering walks as above. There is a fixed c_{adj} such that polymers incompatible with Z contain at least one cube in a set of at most $c_{\mathrm{adj}} N$ cubes: use Z and its wall neighbors.

For these counting estimates use the positive norm majorants

$$h_Z = \sup_{P_Z} |H(Z; P_Z)|, \qquad \widehat{w}_Z = h_Z e^{\mu \ell(Z)},$$

where the supremum is over the declared local core of Z, not over restrictions of one global field. At a fixed core pair P_X on X, actual activities are used only for polymers $Z \subset X$, with their values obtained by the assigned hereditary restrictions. Their weighted absolute values are bounded by $\widehat{w}_Z$. The bound with amplitude $\tau \le 1$ in eq. 4.lxxxii gives

$$\sup_q \sum_{Z \ni q} \widehat{w}_Z e^{\#Z} \le \tau\, C_D e^{2C_v} e^{-5g_*} \sum_{m\ge 0} e^{-(g_* - \kappa_D - C_v)m} =: \tau B_*. \tag{4.lxxxiii}$$

Choose the rates so that

$$g_* > \kappa_D + C_v, \qquad c_{\mathrm{adj}} B_* \le 1. \tag{4.lxxxiv}$$

The explicit factor e^{-5g_*} allows the last inequality by increasing the rate gap. Only the upper bound $\tau \le 1$ is needed here. It follows that

$$\sum_{Z' : Z' \not\sim Z} \widehat{w}_{Z'} e^{\#Z'} \le c_{\mathrm{adj}} N \tau B_* \le N. \tag{4.lxxxv}$$

This verifies, for the actual activities, the criterion of the already proved hard-core tree theorem, with the root weight $\#Z$. In particular it verifies that criterion on every hereditary subsystem $Z \subset X$, without assigning actual fields outside X.

If two polymers are incompatible, their covering trees can be joined at a common cube or wall with length at most five in four dimensions. For a connected incompatibility list this gives

$$\ell\left(\bigcup_{i=1}^{n} Z_i\right) \le \sum_{i=1}^{n} \ell(Z_i). \tag{4.lxxxvi}$$

Indeed a spanning tree of the incompatibility graph has $n-1$ joins, and $d_c(\cup_i Z_i) \le \sum_i d_c(Z_i) + 5(n-1)$. Thus the union filing has the same exponential weight.

Define the actual local logarithmic term by

$$E(X) = \sum_{n\ge 1} \frac{1}{n!} \sum_{\cup_i Z_i = X} \phi(Z_1, \dots, Z_n) \prod_i H(Z_i), \tag{4.lxxxvii}$$

where ϕ is the connected hard-core graph coefficient. For a fixed cube $q \in X$, mark a vertex whose polymer contains q. This only enlarges the absolute series. Symmetry of the ordered list changes its factor $1/n!$ into $1/(n-1)!$. When dropping the union restriction, retain $Z_i \subset X$ for the actual terms at P_X. Use eq. 4.lxxxvi, and then the rooted tree theorem for that subsystem, dominated by the numerical majorants $\widehat{w}$. Only the subsequent nonnegative majorant sum may be enlarged to all geometric polymers containing q. The result is

$$\begin{aligned} e^{\mu \ell(X)} |E(X)| &\le \sum_{\substack{Z \subset X \\ Z \ni q}} \widehat{w}_Z e^{\#Z} \le \tau B_* \\ &\le C(a + p_\star). \end{aligned} \tag{4.lxxxviii}$$

There is no factor $\#X$ or ambient volume in this local estimate. It proves the unmarked potential-ball majorant used in the finite insertion theorem.

Uniform convergence on smaller external and coupling domains follows from these same positive majorants. The actual local functions are holomorphic, so their union-filed sum is holomorphic on each declared core. At complete physical pairs, the complete-Gaussian and wall-factorization identities identify the gas with the finite regular integral; the hard-core theorem then gives $\exp(\sum_X E(X)) = \Xi \neq 0$. On general local cores the activity and logarithm bounds do not require that global Gaussian interpretation.

Parameter choices and the available insertion slot. All constants above concern fixed geometry and the actual matrix/core package. One must verify eq. 4.lxii–eq. 4.lxiv and eq. 4.lxxii, eq. 4.lxxvii, eq. 4.lxxxi, eq. 4.lxxxiv together. For example, it suffices that the matrix package control $A_K c_m (LM)^4 \varepsilon$ by a fixed constant on the chosen decoupling discs. Choose W_0 so its two contributions to C_0 are bounded, and choose positive γ of order at most $(LM)^{-4}$ to bound its contribution. Then C_0 is bounded independently of exterior volume. One can choose the target rate gap, the coarse parameter radius and λ_V by eq. 4.lxxvi–eq. 4.lxxvii, and finally make a small and $\mathfrak{b}$ large to obtain eq. 4.lxxxi. This lists explicit sufficient inequalities; it does not assert them for a matrix family whose constants have not been controlled on the required enlarged discs.

For an explicit insertion budget, put

$$A_a = \frac{2 c_f L^4 S_{\sigma_0}}{W_0}, \qquad a_* = \min\left\{ \frac{W_0}{2}, \frac{1}{4 e^{\Theta} A_a} \right\}, \qquad p_\star \le \frac{1}{4 e^{\Theta}}.$$

Then every total norm $a \le a_*$ has $\tau \le 1/2$ and satisfies eq. 4.lxxxi, uniformly above this cutoff threshold. If the base total potential norm is at most $a_*/2$, reserve one additional potential slot of norm $w_\star \le a_*/2$. The entire slot stays within eq. 4.lxxxi and hence within eq. 4.lxxxii–eq. 4.lxxxviii. This proves the local uninserted majorant uniformly on that slot without assuming a zero-free

activity domain. The constants may depend on the fixed localization parameters and rate choices, but not on cutoff, torus size, old-level count or the auxiliary Gaussian dimension.

4.5.2. *A small potential direction and its first jet.* We keep the calibration, the real action weight, the Gaussian structure, the cutoffs and the background maps fixed. The result below concerns the finite regular fluctuation integral. It does not enlarge the source domain of a large-field history operation. This distinction permits a small potential direction to be used at its actual norm. Localized terms and their insertion estimates are defined on the specified complex local cores, with potential and current independent there. Their sum is identified with a complete Gaussian integral only at physical complete background pairs $P = p_W$. An identity on that graph is not extended to arbitrary independent currents.

The fixed-reference integral. Let $\theta \geq \theta_{\min}$, $g = \theta^{-1/2}$, and $\tau = x/\theta$, with $|\tau - 1| < \sigma_\star$. The fixed small number $\sigma_\star$, the allowed external pairs and their Gaussian gap are restricted by the ordinary Gaussian comparison and potential allowance below. In particular the decoupled precisions stay in their coercive regime and the free potential leaves the declared allowance; no assertion is made for arbitrary positive x/θ. The sourced run considered here keeps $x > 0$ fixed. At a physical complete background pair $P = p_W$, in the fluctuation coordinates B on the non-pivot bonds, the reference measure is the normalized Gaussian with covariance $\tau^{-1}C(P)$. The same identity holds on a holomorphic continuation in physical background data wherever that continuation and the ordinary Gaussian bounds have been supplied. It is not an identity on every complex core pair. Put

$$\Xi(P,z) = \int d\mu_{\tau^{-1}C(P)}(B) \prod_b \chi_b(B) \exp\left\{ \sum_Y V(Y;P,B) + z \sum_Y v(Y;P,B) \right\}. \tag{4.lxxxix}$$

The parameter z enters only the potentials. In particular the covariance, the cutoff thresholds and the Gaussian determinant do not depend on z. Here the cutoffs are sharp indicators $\chi_b(B) = \mathbf{1}\{|B(b)| < \mathfrak{b}\}$ on free bonds. For a bond set A, write $\chi_A = \prod_{b\in A} \chi_b$ and $\chi_A^c = \prod_{b\in A}(1-\chi_b)$. Thus the latter denotes a product of complements. After the old action at the background has been carried separately, the new fluctuation increment is

$$\mathcal{E}(P,z) = \mathcal{N}[\theta;x](P) + \log \Xi(P,z). \tag{4.xc}$$

The field-independent Gaussian number includes $-\frac{3}{2}|\mathfrak{X}| \log \tau$, as well as the Haar-coordinate, scaling and gauge-fixing counts. The localised normalizer $\mathbf{N}^\circ$ and the free-potential family $\mathbf{G}_\tau$ also use the fixed (θ, x). All these quantities have zero z-derivative. Moving z into x, and differentiating the resulting Gaussian determinant, would describe a different presentation.

For an inserted exponent H, the potential actually inserted is its fluctuation difference. Thus, when the fibre field is $U_P(B)$ and $U_P(0)$ is its background, at a physical complete pair,

$$\sum_Y v(Y;P,B) = H(U_P(B)) - H(U_P(0)). \tag{4.xci}$$

Consequently the background subtraction in the step functional is already present in eq. 4.lxxxix; it must not be subtracted a second time. Equivalently, the raw fibre integral with the additional exponent $zH(U_P(B))$ has the extra factor $e^{zH(U_P(0))}$ outside eq. 4.lxxxix. That factor belongs to the separately carried old action, rather than to the newly generated cluster activities.

The ordinary Gaussian expansion used here. We state the analytic inputs at the level at which they are applied. On an arbitrary complex local core pair P, the actual localized Gaussian functionals $\mathcal{J}(Z_0; s; P)$, potentials and union-filed terms below are defined by their local rules. We do not assume that the complete values for different Z_0 all arise as marginals of one global Gaussian at

that P. A potential has norm

$$|V(Y;P,B)| \le \|\mathbf{V}\|_\lambda e^{-\lambda d(Y)} \left(1 + M^{-4} \sum_{b\subset Y} |B(b)|^2\right) \tag{4.xcii}$$

on its specified complex field box. The potential may be defined only there: the cutoff product on its domain is kept in every term in which it occurs. The ordinary Gaussian comparison estimate bounds a localized decoupled functional by $F_0 e^{CuN(Z)}$ when its integrand is bounded by $F_0 e^{\rho|B|^2}$, with $u = \widehat{\varepsilon} + \rho$. Here $N(Z)$ counts the affected real scalar Gaussian coordinates, of order $(LM)^4 N_c(Z)$, where $N_c(Z)$ is the number of coarse cubes. In the cube-count convention the same bound is $F_0 e^{C(LM)^4 u N_c(Z)}$; the dimension factor is counted once. The Gaussian reference gap, radii and tilt are chosen so these factors are bounded per coarse cube. The decoupling parameters have a fixed enlarged complex disc. These are the ordinary background/Gaussian inputs; no source derivative is contained in them.

Choose a potential allowance $w_\star > 0$, independent of the cutoff and volume, small enough for the following ordinary expansion. The base potentials use at most a fixed number of slots, and leave one slot available for an additional potential of norm at most $w_\star$. The same Gaussian comparison, rooted domain count and decoupling majorant are valid throughout this allowance. The convergent hard-core expansion gives local logarithmic terms $E(X)$ and bounds

$$|E(X)| \le C_\star e^{-\lambda_{\mathrm{out}} d(X)}. \tag{4.xciii}$$

The constant is uniform in all allowed external pairs, decoupling parameters and potentials. This is the ordinary uninserted polymer majorant, not an assumed differentiability bound for a renormalization map.

Here is the explicit finite expansion to which that majorant applies. Let $\mathbf{D}$ be a set of selected interaction domains. Write Y_0 for the union of their free-bond sets on which a field box is required; a globally defined free potential does not contribute to this union. Let $P_0 \subset \mathfrak{X} \setminus Y_0$ be a set of failed fluctuation cutoffs. The indicator identities $\chi_b^2 = \chi_b$ and $\chi_b(1-\chi_b) = 0$ give exactly $\prod_b \chi_b = \chi_{Y_0} \sum_{P_0 \subset \mathfrak{X}\setminus Y_0} (-1)^{|P_0|} \chi^c_{P_0}$. Before decoupling, its integrand is

$$F_{\mathbf{D},P_0}(z) = (-1)^{|P_0|} \chi_{Y_0} \chi^c_{P_0} \prod_{Y\in\mathbf{D}} (e^{V(Y)+zv(Y)} - 1). \tag{4.xciv}$$

The empty choice $(\mathbf{D}, P_0) = (\emptyset, \emptyset)$ supplies the leading one in the gas and is omitted from its activities. All polymer domains Z are nonempty and wall-connected, so no $H(\emptyset)$ is defined. Disconnected regions are products of their wall-component activities, rather than additional single polymers. Equivalently, for a nonempty Z the empty choice has at least one decoupling derivative of the normalized constant functional $\mathcal{J}[1] = 1$ and contributes zero. The index Y carries one of the fixed potential-type tags used in the unmarked expansion. Its cutoff requirement is fixed by its support and type: a boxed type uses the common indicators on all free bonds in that support, as in the definition of Y_0, while the globally defined free type requires none. Older levels and source origins do not add cutoff types. Before forming the product, sum all origins having the same support and type into that type's potential. This grouping is performed before taking absolute majorants, and the norm in eq. 4.xcii is the norm of the grouped potential. Indeed, for finitely many origins on that same support,

$$e^{\sum_o V_o} - 1 = \sum_{\emptyset \ne I \subset \{o\}} \prod_{o\in I} (e^{V_o} - 1).$$

Linearity of the local Gaussian functional and of the decoupling operations therefore preserves the complete integral and its union filing. The estimate is applied to the grouped left-hand side; it does not require an absolute majorant for the separate terms on the right. An individual origin can still be selected as the marked direction v, without adding a Mayer type. The geometric support

and its tree length ignore the fixed type tag. For each support index $\iota = (\mathbf{D}, P_0)$ let $Z_0(\iota)$ be its support. The decoupled activities are formed by

$$\begin{aligned} T(Z,\iota;z) &= \prod_{\Delta\subset Z\setminus Z_0(\iota)^\sharp} \int_0^1 ds_\Delta\, \partial_{s_\Delta}\, \mathcal{J}(Z_0(\iota);s_Z)[F_{\mathbf{D},P_0}(z)], \\ H(Z,z) &= \sum_\iota T(Z,\iota;z). \end{aligned} \tag{4.xcv}$$

In this formula s_Z is one on $Z_0(\iota)^\sharp$, is the displayed free parameter on $Z\setminus Z_0(\iota)^\sharp$, and is zero outside Z. The normalized Gaussian functional $\mathcal{J}$ is independent of z. At a physical complete pair $P = p_W$, its complete-structure identity is

$$\mathcal{J}(Z_0;1)[F] = \int d\mu_{\tau^{-1}C(P)}(B)\, F(B).$$

This physical identity, together with interpolation of every remaining coarse-cube parameter and the ordinary decoupling property, is what identifies the gas with eq. 4.lxxxix. Two polymers are compatible when they have neither a cube nor a wall in common. Multiplicativity over their wall-components yields $\Xi = \sum_{\Gamma\ \text{compatible}} \prod_{Z\in\Gamma} H(Z)$, with empty product one, at a physical complete pair. On general local cores, the same local formulas define activities and their union-filed terms without asserting one global Gaussian representation. Those logarithmic terms are

$$E(X,z) = \sum_{n\ge1} \frac{1}{n!} \sum_{\cup_{i=1}^n Z_i = X} \rho^T(Z_1,\dots,Z_n) \prod_{i=1}^n H(Z_i,z). \tag{4.xcvi}$$

Here $\rho^T(Z_1,\dots,Z_n)$ is the sum over connected graphs on $\{1,\dots,n\}$ of the products of their edge weights; an edge has weight -1 for an incompatible pair and zero otherwise. For $n = 1$, $\rho^T = 1$. Every sum is first formed in finite volume; the logarithmic series and its differentiated series are justified by the same absolute majorants.

Proposition 4.8 (The inserted-potential estimate)**.** Let $\varepsilon = \|\mathbf{v}\|_\lambda$. Under the ordinary local Gaussian/polymer hypotheses above, on every specified complex local core pair,

$$|\partial_z E(X,z)|_{z=0}| \le C\varepsilon e^{-\lambda_{\mathrm{out}} d(X)}. \tag{4.xcvii}$$

At a complete physical pair $P = p_W$, its sum over X is the normalized expectation

$$\partial_z \log \Xi(P,z)|_{z=0} = \frac{\int d\mu \prod_b \chi_b\, e^{\sum_Y V(Y)} \sum_Y v(Y)}{\int d\mu \prod_b \chi_b\, e^{\sum_Y V(Y)}}. \tag{4.xcviii}$$

There is no volume factor in the local estimate in eq. 4.xcvii. ∎

Proof. If $\varepsilon = 0$, every inserted potential vanishes on its domain and the assertion is immediate. Otherwise take the actual auxiliary potential $z\mathbf{v}$ on $|z| < w_\star/\varepsilon$. This is a legitimate potential in the actual local Mayer and decoupling expressions, regardless of whether it would be an admissible physical source for a history construction. The ordinary Gaussian comparison and the polymer criterion hold on this disc. Every integrand and every activity is holomorphic there; Gaussian domination and the parameter-independent majorant give holomorphy of the union-filed series eq. 4.xcvi. This local argument does not require one global Gaussian at a general independent-current core pair. Apply Cauchy's estimate on $|z| = w_\star/(2\varepsilon)$ to eq. 4.xciii. It gives eq. 4.xcvii with constant $2C_\star/w_\star$, which depends only on fixed ordinary allowances.

The same argument gives a norm derivative, which is useful when the actual source family of potentials is nonlinear. On the potential space with its fixed declared domains, joint holomorphy on every two-dimensional affine plane makes the directional derivative complex linear: the degree-one term of $E_X(\mathbf{V} + z_1\mathbf{h}_1 + z_2\mathbf{h}_2)$ is the sum of its two degree-one terms. Cauchy's estimate makes this

linear map bounded. For $\|\mathbf{h}\|_\lambda < w_\star/2$, apply one-variable Cauchy to $t \mapsto E_X(\mathbf{V}+t\mathbf{h})$ on the disc $|t| < w_\star/\|\mathbf{h}\|_\lambda$. Summing its Taylor coefficients of degree at least two gives

$$|E_X(\mathbf{V}+\mathbf{h}) - E_X(\mathbf{V}) - DE_X(\mathbf{V})[\mathbf{h}]| \le CC_\star \frac{\|\mathbf{h}\|_\lambda^2}{w_\star^2} e^{-\lambda_{\mathrm{out}} d(X)}.$$

All constants are uniform in the external core pair, so this is also the remainder bound in the unpointed supremum norm $\|F\|_{\mathrm{out}} = \sup_{X,P} e^{\lambda_{\mathrm{out}} d(X)} |F_X(P)|$. It does not assert a pointed or stronger rooted norm bound. Uniform local Lipschitz bounds on smaller potential balls give the unique continuous extension to the potential-norm completion. The displayed remainder passes to that extension and proves Fréchet differentiability there as well. If an actual ordinary source family satisfies $\mathbf{V}(w) = \mathbf{V}(0) + w\dot{\mathbf{V}} + o(|w|)$ in that norm, the remainder bound proves its chain rule $\partial_w E_X(\mathbf{V}(w))|_0 = DE_X(\mathbf{V}(0))[\dot{\mathbf{V}}]$. Pointwise holomorphy of $\mathbf{V}(w)$ on its ordinary source disc, with a uniform potential-norm bound there, gives its norm Taylor expansion by the same uniform Cauchy estimates. Thus the auxiliary linear direction computes the actual first source jet; the nonlinear physical source family need not exist on the large auxiliary-potential disc.

This is also the marked-activity derivative of the explicit expansion. The derivative of eq. 4.xciv replaces precisely one selected factor by

$$v(Y) e^{V(Y)} \prod_{\substack{Y' \in \mathbf{D} \\ Y' \neq Y}} (e^{V(Y')} - 1). \tag{4.xcix}$$

Domains with $V(Y) = 0$ are included: their unmarked term is zero, but their derivative need not be zero. In a term with a marked potential the cutoff on its domain is retained. Derivatives commute with eq. 4.xcv by the same Gaussian comparison and with eq. 4.xcvi by absolute convergence. Thus this proof differentiates the actual finite interaction formula, not a hypothetical normed map without a specified integral. The pinned cluster estimate is what keeps the local Cauchy bound in eq. 4.xciii independent of volume.

At a complete physical pair, the sum rule for the ordinary cluster expansion gives $\exp(\sum_X E(X,z)) = \Xi(P,z) \neq 0$. Differentiating it and the finite integral proves eq. 4.xcviii. The denominator is this one regular Gaussian integral; no division by the full sourced partition function or by a history mass is used. □

The actual scalar action direction. Let $H_u(U) = A(u,U)$, where u is a bounded function on bare plaquettes. It is filed by assigning a plaquette to the union of the fixed cubes containing its corners. In the background field domain, $|\partial U(p) - 1| \le C\alpha\eta^2$. The identity $a_p(U) = \frac{1}{2}\det(1 - \partial U(p))$ gives a raw local action member of norm at most $CM^4\alpha^2 \sup|u|$. It has no coupling counterterm at this stage.

More precisely, at a complete physical pair the potential in eq. 4.xci is a first difference of this action. Suppose the actual background response and its decoupled substitutions stay in their stated field domains and shift a plaquette by at most $C\delta\eta^2$, where $0 < \delta \ll \alpha$. Along this shift, the plaquette remains at distance at most $C\alpha\eta^2$ from the identity. The derivative of the determinant of a 2×2 matrix is bounded by a constant times its size, so

$$|a_p(U_P(B)) - a_p(U_P(0))| \le C\alpha\delta\eta^4. \tag{4.c}$$

This proof works at complex pairs. It uses the actual curvature and response bounds, not positivity. On a local core the same determinant bound applies to the two actual substituted plaquette matrices whenever the declared response bounds give these curvature and difference estimates; it does not require a global fibre map there.

We give the quantitative fine-response localization separately from the coarse Gaussian decoupling in eq. 4.xcv. For a plaquette p, let $X_0(p)$ be the union of its fixed corner cubes. Its number of cubes is at most a dimensional constant C_{base}, and its tree length is zero. Write $\mathcal{U}(P')$ for the bare configuration used by the actual background evaluation of a pair P', and set $F_p(P') = u(p) a_p(\mathcal{U}(P'))$.

Thus this local function is explicitly a function of a pair. The ordinary response-bracket hypotheses used here are the following. On each $Y \supset X_0(p)$ the same response rule gives

$$\Phi_{p,Y}(s,\nu) = F_p(P|_{X_0(p)} \dot{+} \nu\, \mathfrak{h}_Y(s;B)), \qquad |s_\Delta| < R = e^{\bar\kappa}, \quad |\nu| < \rho,$$

holomorphic jointly on these independent discs, uniformly in the allowed complex external fields and fluctuation box, with

$$\rho \geq c_R \alpha/\delta > 1, \qquad \sup|\Phi_{p,Y}| \leq C\alpha^2\eta^4|u(p)|.$$

Here $c_R > 0$ can contain the fixed loss $e^{-C\bar\kappa}$. In particular all substituted pairs must stay in their actual cores on the whole joint polydisc, not just for real interpolation parameters. The operation $\dot{+}$ shifts the potential and current by the actual response. These are quantitative background and membership hypotheses; the following Cauchy argument does not prove them.

For disjoint fine-cube sets K, N, define the mixed bracket by

$$\Psi[K|N] = \int_{[0,1]^K} \prod_{\Delta\in K} \partial_{s_\Delta} \Psi(s_K + 1_N)\, ds_K,$$

with all other parameters zero. Its scalar-action potential is the bracket of $\Psi(s) = \Phi_{p,Y}(s,1) - \Phi_{p,Y}(s,0)$ with $K = Y\setminus X_0(p)$, $N = X_0(p)$. At $\nu = 0$ the field is the unshifted restricted background. Schwarz's lemma in ν first gives $\sup_s|\Psi(s)| \leq 2C\rho^{-1}\alpha^2\eta^4|u(p)|$. For every $s_\Delta \in [0,1]$, a coordinate Cauchy circle has radius arbitrarily close to $R-1$. Iterated Cauchy therefore bounds the bracket by

$$2C\rho^{-1}\alpha^2\eta^4|u(p)|(R-1)^{-|K|} \leq C_R\alpha\delta\eta^4|u(p)|e^{-(\bar\kappa-1)|K|},$$

where $\bar\kappa \geq 1$. There is no factorial in this estimate, because each independent cube parameter is differentiated once. The ordinary rooting property says that a component containing a differenced cube and missing $X_0(p)$ makes the bracket zero. For the present choice $N = X_0(p)$, every component missing the base has such a differenced cube. No assertion about an arbitrary remote component consisting only of undifferenced parameters is being made. The local response rule agrees with the response built on the active wall-component. Between local ambient domains on which the substitutions are defined it has hereditary consistency, $\Phi_{p,Y}(s,\nu) = \Phi_{p,\Lambda}(s\,\mathbf{1}_Y,\nu)$, with the base parameters set to one. At a complete physical pair on the full lattice its endpoints are

$$\Phi_{p,\Lambda}(1,1) = u(p)a_p(U_P(B)), \qquad \Phi_{p,\Lambda}(1,0) = u(p)a_p(U_P(0)).$$

Apply the finite fundamental theorem of calculus in every fine-cube parameter outside $X_0(p)$, expanding evaluation at one as evaluation at zero plus the integral of the derivative. The resulting sum of brackets equals $\Phi_{p,\Lambda}(1,1) - \Phi_{p,\Lambda}(1,0)$. At a complete physical pair this is exactly $u(p)[a_p(U_P(B)) - a_p(U_P(0))]$. Wall-component consistency identifies each bracket with the corresponding $\Phi_{p,Y}$; rooting removes the disconnected terms. Thus the construction gives a uniformly bounded local extension on every declared core and localizes the actual difference in eq. 4.xci at complete physical pairs.

For a surviving bracket, the ordinary domain geometry gives $d(Y) \leq C_{\mathrm{geo}}(|K|+1)$. At fixed Y there are at most $CM^4\eta^{-4}(|K| + C_{\mathrm{base}})$ possible plaquette anchors. Choose the fixed surplus $\bar\kappa$ so that $\bar\kappa - 1 > C_{\mathrm{geo}}\lambda + 2$, increasing it further if a subsequent rooted-domain entropy sum is included. Sum the displayed bracket bound over its plaquette anchors and use that a linear polynomial times $e^{-2|K|}$ is bounded. This proves

$$\|\mathbf{v}_u\|_\lambda \leq CM^4\alpha\delta\, \sup|u| = CM^4\alpha^2 s\, \sup|u|, \qquad s = \delta/\alpha. \tag{4.ci}$$

The factors η^4 and η^{-4} cancel exactly. The required membership and response estimates on all decoupling substitutions are background inputs. The bracket argument neither creates those inclusions nor replaces them by bounds at real fields.

Combining eq. 4.xcvii with eq. 4.ci proves a one-step unpointed source response of size $C\alpha^2 s\sup|u|$ for the actual local regular family on every declared complex core. Its physical sum

is the source response of the fixed-reference regular integral. The Gaussian normalizer contributes zero derivative. Its interaction vacuum value contributes $\partial_z E(X,(1,0),0)$, which is the source vacuum energy and obeys the same bound. Subtracting it leaves a factor at most two in the estimate.

Own counterterms and the remaining iteration. For a constant source, once the actual bond-density pointing is applied, the derivative member is Euclidean. Its own coefficient is $\partial_z b[E_z]|_0 = b[\partial_z E_z|_0]$, because the free response and the coefficient extractor are fixed and complex linear. The counterterm to remove from the derivative action at site y is therefore this number times $A(h_y, U)$. A coefficient belonging to another member, or a derivative of a Gaussian presentation with a different weight, would not supply that identity.

There are two further tasks before the one-step estimate is a complete multilevel source-response bound. First, renewing the actual pointing uses three bond-indexed interpolation legs. Differentiating a normalized leg expectation produces both the derivative of its leg insertion and a connected expectation of that insertion with $\sum_Y v(Y)$. A root-plus-insertion cluster bound and the path's admissible field room must control those terms before the same estimate is asserted for each pointed term.

Second, the old regular derivative members and the nonconstant source defects have to be inserted again with their own coefficients. A constant-source derivative of size $\alpha_j^2 s_j$ can be normalized by the pointed Hessian theorem. Write $\alpha_H > 0$ for the fixed spatial Hölder exponent, as distinct from an analytic field radius. On a non-wrapping local chart, retaining the *true* radius ratio $\rho_j = \delta_{\mathrm{out}}/\alpha_j$ in the near-domain Taylor proof, before any enlargement to $\max\{1, \rho_j\}$, would give after the fine-site count the contribution

$$C\alpha_j^2 s_j \left[\left(\frac{\delta_{\mathrm{out}}}{\alpha_j} \right)^2 L^{-\alpha_H (n-j)} + \left(\frac{\delta_{\mathrm{out}}}{\alpha_j} \right)^3 L^{-2(n-j)} \right]. \tag{4.cii}$$

Its quadratic part sums to $C\delta_{\mathrm{out}}^2 s_{\mathrm{out}}$ when the ordinary flow and age weights apply. For $\alpha_{\mathrm{out}} \asymp x_{\mathrm{out}}^{-1/2} (\log x_{\mathrm{out}})^q$ and $\delta_{\mathrm{out}} \asymp x_{\mathrm{out}}^{-1/2} (\log x_{\mathrm{out}})^{p_0}$, this is

$$C x_{\mathrm{out}}^{-1} (\log x_{\mathrm{out}})^{3p_0 - q}. \tag{4.ciii}$$

This arithmetic is conditional on that homogeneous local refinement and does not establish the derivative recurrence. In particular the defects must retain the factor $\alpha_j^2 s_j$ as well as the scaled Lipschitz gain. A fixed-disc source bound alone does not provide it. Marked and remote terms need their own uniform fixed-disc bounds. Field-independent tails around holes or torus cycles cannot be assigned an extra ρ_j^2 when $\rho_j < 1$; they require a non-wrapping chart or a separately small class estimate.

Identification with the fixed-reference source family. In the variable-profile presentation the actual regular family has the decomposition

$$\mathcal{E}^{\,w} = N^{\circ} + G_\tau + F^{\,w}, \qquad \mathcal{E}^{\,w} - \mathcal{E}^{\,0} = F^{\,w} - F^{\,0}. \tag{4.civ}$$

Here x, θ, the Gaussian matrices, cutoffs and numerical normalizers are fixed; the variable profile is an older member. Thus N° and G_τ have no source derivative. If its actual potential family is differentiable in the accepted potential norm, the uniform norm-Taylor proof of eq. 4.xcvii applies to each unpointed local logarithm:

$$\begin{aligned} \dot{\mathcal{E}} &= \dot{F}, \\ \partial_w E_X(V(w))\big|_0 &= DE_X(V(0))[\,V'(0)\,]. \end{aligned} \tag{4.cv}$$

The derivative of the pointed density is computed in the next section; it includes both terms of eq. 4.cxvi. These are identities for the fixed presentation, rather than derivative rules for one that also changes its reference data.

For two auxiliary directions of norms A and ε, one spare potential family suffices:

$$\|\lambda a + zv\|_{\lambda_V} \le |\lambda|A + |z|\varepsilon < w_\star. \tag{4.cvi}$$

The two directions are combined in this one slot; they do not increase the allowed number of potential types. The resulting auxiliary Cauchy polydisc is a domain of the local potential expansion. It need not be a domain of physical Wilson sources or of history operations.

4.5.3. *Renewing the actual bond pointing.* An estimate for an unpointed localized logarithm is not by itself an estimate for a particular pointing of that logarithm. We retain the actual three interpolation legs and differentiate their bond densities. For a source filed as an older weight member, the Gaussian structure, free potential, cutoffs and numerical normalizers are fixed. Thus the first, free-potential leg and the second, cutoff leg are independent of this source. Only the interaction leg contributes below. This choice of presentation is essential to the statement.
The finite local logarithm and its actual locality. Fix a finite regular fluctuation integral, its Gaussian reference, its cutoffs and all geometric and external data. Fix nested full complex fluctuation boxes

$$\mathcal{B}_0 = \{B : \sup_b |B(b)| < \mathfrak{b}_0\}, \qquad \mathcal{B}_1 = \{B : \sup_b |B(b)| < (1+\nu)\mathfrak{b}_0\}, \qquad \mathfrak{b}_0 \ge 1, \quad \nu > 0.$$

The ordinary spare-potential estimate below accepts potentials holomorphic and bounded in its growth norm on $\mathcal{B}_0$; all its actual Gaussian cutoff supports lie there. The larger box $\mathcal{B}_1$ is reserved for the one coordinate Cauchy estimate on an inserted potential. Both boxes and the external-pair and decoupling domains are fixed once for this step. Ordinary inputs whose cutoffs fill half their analytic box leave this room by choosing an intermediate $\mathcal{B}_0$. This uses that existing room once, and is not a new shrinking at each source derivative. A local potential family has the Gaussian growth norm

$$|V(Y;P,B)| \le \|\mathbf{V}\|_\lambda e^{-\lambda d(Y)} Q_Y(B), \qquad Q_Y(B) = 1 + M^{-4}\sum_{b\subset Y} |B(b)|^2. \tag{4.cvii}$$

There are finitely many bond variables but arbitrarily many of them as the volume grows. The norm and all constants used below are those of the ordinary regular expansion, uniform in that number. A fixed finite number of potential types can be combined by addition of their norms.

Let $E_X(\mathbf{V})$ denote the actual union-filed logarithmic term of the local Gaussian functionals, Mayer expansion and connected-cluster expansion. These local objects are defined on their independent-current pair cores. Away from complete physical data, their wall-component functionals need not be margins of one global Gaussian measure. Normalized global Gaussian expectations will be used only at a complete physical pair $P = p_W$, or by holomorphic continuation in the physical datum W where the same complete construction is defined. We use the following consequence of its uninserted estimate, as established for the fixed-reference integral in § 4.5. At every base system used below there is an available potential allowance $w_\star > 0$ such that

$$|E_X(\mathbf{V}+\mathbf{U})| \le C_\star e^{-\lambda_{\mathrm{out}} d(X)}, \qquad \|\mathbf{U}\|_\lambda < w_\star. \tag{4.cviii}$$

The actual finite local Gaussian functionals and the absolutely convergent logarithmic series are holomorphic in every finite collection of potential parameters on this allowance. A single additional family is enough: several auxiliary directions are added together in $\mathbf{U}$, with the sum of their norm loads less than $w_\star$.

The locality needed here is part of this actual expansion, not a choice made after taking its logarithm. A contribution filed at X uses only selected interaction domains whose enlarged union is in X. In particular, if a family $\mathbf{a}_b$ vanishes except on domains containing $b^\sharp$, then

$$DE_X(\mathbf{V})[\mathbf{a}_b] = 0, \qquad D^2E_X(\mathbf{V})[\mathbf{a}_b, \mathbf{v}] = 0 \quad \text{if } b^\sharp \not\subset X. \tag{4.cix}$$

The assertions include domains with a zero unmarked potential. In a Mayer derivative their zero factor can be replaced by the nonzero inserted factor, and the marked domain must then be included in the union. Omitting such terms would invalidate both locality and the insertion identity.

Lemma 4.9 (Two derivatives of the actual localized term)**.** For potential families $\mathbf{a}, \mathbf{v}, \mathbf{c}$, the allowance in eq. 4.cviii gives

$$\begin{aligned} |D^2 E_X(\mathbf{V})[\mathbf{a}, \mathbf{v}]| &\le \frac{16 C_\star}{w_\star^2} \|\mathbf{a}\|_\lambda \|\mathbf{v}\|_\lambda e^{-\lambda_{\mathrm{out}} d(X)}, \\ |D E_X(\mathbf{V})[\mathbf{c}]| &\le \frac{2 C_\star}{w_\star} \|\mathbf{c}\|_\lambda e^{-\lambda_{\mathrm{out}} d(X)}. \end{aligned} \tag{4.cx}$$

These derivatives preserve eq. 4.cix. ■

Proof. If either direction in the first estimate has zero norm, the claim is immediate. Otherwise put the single auxiliary family $\zeta \mathbf{a} + z\mathbf{v}$ in the available slot. On the bidisc with radii $w_\star/(4\|\mathbf{a}\|_\lambda)$ and $w_\star/(4\|\mathbf{v}\|_\lambda)$ its total norm is at most $w_\star/2$. Apply the two-variable Cauchy formula to the actual holomorphic term in eq. 4.cviii. For the second estimate use radius $w_\star/(2\|\mathbf{c}\|_\lambda)$. The support assertion follows from the union filing before differentiation. No radius for a full history construction has been enlarged in this argument. □

Thus a separate second-mark estimate is not needed if the actual ordinary bound is already uniform on the full potential allowance in eq. 4.cviii. If only a one-direction derivative bound were known, without this allowance and locality, the lemma would not follow from it.
The interpolation paths and the differentiated density. Let $\mathbf{V}_t$, $0 \le t \le 1$, be the actual interaction leg, with local bond directions $\mathbf{a}_{t,b}$ satisfying

$$\partial_t \mathbf{V}_t = \sum_b \mathbf{a}_{t,b}. \tag{4.cxi}$$

Every summand is supported on domains containing $b^\sharp$. At a finite volume the sum is finite. We assume that the ordinary interpolation construction supplies the uniform bound

$$\sup_b \int_0^1 \|\mathbf{a}_{t,b}\|_\lambda \, dt \le A. \tag{4.cxii}$$

This is a property of the actual unmarked legs and their admissible field domains. It is not inferred merely from an endpoint norm. Uniform ordinary bounds and field room are required throughout the path, with the same allowance in eq. 4.cviii. The third-order vanishing of the intrinsic $V^{G,A}$ makes its t^{-2} radial path regular at zero. It does not by itself identify the actual bond split. We do not replace that split by an Euler decomposition or any other pointing to infer eq. 4.cxii.

For the inserted source let

$$\mathbf{V}_t(s) = \mathbf{V}_t + s\mathbf{v}_t, \qquad \mathbf{a}_{t,b}(s) = \mathbf{a}_{t,b} + s\mathbf{c}_{t,b}, \qquad \partial_t \mathbf{v}_t = \sum_b \mathbf{c}_{t,b}, \tag{4.cxiii}$$

with the same bond support and with $\mathbf{v}_0 = 0$. It is enough that these are the first source derivatives of holomorphic paths; the affine notation in s makes the formula easier to read. Suppose

$$\sup_{0 \le t \le 1} \|\mathbf{v}_t\|_\lambda \le C_v \varepsilon, \qquad \sup_b \int_0^1 \|\mathbf{c}_{t,b}\|_\lambda \, dt \le C_c \varepsilon. \tag{4.cxiv}$$

Choose $|s| C_v \varepsilon < w_\star/4$. The remaining allowance in eq. 4.cviii bounds the first derivative in direction $\mathbf{a}_{t,b} + s\mathbf{c}_{t,b}$ by a constant times $\|\mathbf{a}_{t,b}\|_\lambda + |s|\|\mathbf{c}_{t,b}\|_\lambda$. This is integrable by eq. 4.cxii and eq. 4.cxiv. On a smaller source disc the mixed Cauchy estimate similarly dominates its source derivative. Consequently the actual path integral is holomorphic there and may be differentiated under the integral.

The actual interaction-leg term carrying bond b is

$$E_s^\bullet(X,b)=\int_0^1 DE_X(\mathbf{V}_t(s))[\mathbf{a}_{t,b}(s)]\,dt. \tag{4.cxv}$$

Its source derivative contains two terms:

$$\dot E^\bullet(X,b)=\int_0^1 \Big\{D^2E_X(\mathbf{V}_t)[\mathbf{a}_{t,b},\mathbf{v}_t]+DE_X(\mathbf{V}_t)[\mathbf{c}_{t,b}]\Big\}\,dt. \tag{4.cxvi}$$

The first is the connected root-plus-source term. The second is the direct change of the leg insertion. Neither can be dropped. eq. 4.cx, eq. 4.cxii and eq. 4.cxiv prove

$$|\dot E^\bullet(X,b)|\le C_\star\left(\frac{16AC_v}{w_\star^2}+\frac{2C_c}{w_\star}\right)\varepsilon e^{-\lambda_{\mathrm{out}}d(X)}. \tag{4.cxvii}$$

It is zero unless $b^\sharp\subset X$.

Here is the exact normalized-expectation interpretation on a complete physical pair $P=p_W$. Write $\langle\cdot\rangle_t$ for the normalized, possibly complex, fixed-reference integral with interaction $\sum_Y V_t(Y)$. The denominator is nonzero by the same ordinary expansion. With $a_{t,b}=\sum_Y a_{t,b}(Y)$, $v_t=\sum_Y v_t(Y)$ and $c_{t,b}=\sum_Y c_{t,b}(Y)$,

$$\partial_s\langle a_{t,b}(s)\rangle_{t,s}\big|_{s=0}=\langle c_{t,b}\rangle_t+\langle a_{t,b}v_t\rangle_t-\langle a_{t,b}\rangle_t\langle v_t\rangle_t. \tag{4.cxviii}$$

This follows by differentiating its numerator and denominator. It requires no positivity. On these complete data, summing eq. 4.cxvi over X gives eq. 4.cxviii by the physical sum rule for the actual connected expansion. The disconnected product cancels; an unnormalized insertion would give the wrong formula and could carry a volume factor. On an arbitrary independent-current core, eq. 4.cxvi remains the local derivative identity and bound. It is not identified there with a covariance under an unavailable global Gaussian measure.

The older-weight path and its field room. An older weight enters through its fluctuation difference $v(Y;P,B)$, so $v(Y;P,0)=0$. Its interaction path is $v_t(Y;P,B)=v(Y;P,tB)$, and

$$c_{t,b}(Y;P,B)=\sum_{a=1}^{3}B_b^a\partial_{B_b^a}v(Y;P,tB). \tag{4.cxix}$$

The intrinsic path $t^{-2}V^{G,A}(tB)$ belongs to the terms with the action or gauge-fixing inverse-coupling coefficient. It must not be applied to this older weight. In particular, no artificial vanishing of its linear and quadratic fluctuation terms is assumed.

We spell out sufficient field room for eq. 4.cxiv. Suppose v is holomorphic and obeys eq. 4.cvii with norm ε on $\mathcal{B}_1$, for the actual external pairs and decoupling parameters. We prove the bound on the entire $\mathcal{B}_0$ required by eq. 4.cviii, not merely on real integration points. For real $t\in[0,1]$, vary one coordinate at tB by a complex number of radius

$$r_b=c_\nu(1+|B_b^a|),$$

where $c_\nu>0$ is a sufficiently small fixed fraction of the available room and the fixed color norm. This disc lies in $\mathcal{B}_1$, uniformly for $B\in\mathcal{B}_0$ and in t,b and the number of variables. Moreover its growth factor is bounded by $C_\nu Q_Y(B)$: the one changed coordinate adds at most $C_\nu(1+|B_b^a|^2)$ to the sum defining Q_Y, with M fixed. Cauchy's formula therefore gives

$$|B_b^a\partial_{B_b^a}v(Y;P,tB)|\le C_\nu\varepsilon e^{-\lambda d(Y)}Q_Y(B). \tag{4.cxx}$$

Also $Q_Y(tB)\le Q_Y(B)$, so $\|\mathbf{v}_t\|_\lambda\le\varepsilon$ on the actual cutoff box. Summing the three color coordinates in eq. 4.cxix proves eq. 4.cxiv. The original B is used in this majorant, so no $1/t$ or $\mathfrak{b}_0^2$ loss occurs as t tends to zero. Thus the differentiated root is a potential on exactly $\mathcal{B}_0$, while the undifferentiated source used its one fixed larger box.

A complex disc for a common radial parameter alone would not justify eq. 4.cxx. The individual bond legs require the independent-coordinate field room just used. Nor does an endpoint inserted-potential norm bound the variation of an arbitrary interpolation path. The prescribed path and its ordinary bounds in eq. 4.cxii remain necessary.

Midpoint tents, entropy, and the exact sum rule. Use the actual geometric tents at bond midpoints. The collars in the union filing are assumed large enough that $h_z(b) \neq 0$ implies $z \in b^\sharp \subset X$ for a nonzero bond-root term. The fixed block ratio L gives

$$\sum_{z\in X} h_z(b) = 1, \qquad \sum_b h_z(b) \leq 4L^4. \tag{4.cxxi}$$

These geometric identities are source independent. The renewed pointed source family is therefore

$$\dot{F}(X,z) = \sum_b h_z(b)\dot{E}^\bullet(X,b), \qquad \sup_{X,z} e^{\lambda_{\text{out}} d(X)} |\dot{F}(X,z)| \leq C\varepsilon. \tag{4.cxxii}$$

The constant depends on L, the fixed ordinary allowances, A and the field room, and is independent of volume and field-variable count. No additional source-position factor is spent in this supremum norm.

For completeness, the geometric root cost also remains harmless when an application sums domains through z. If that count at length m is at most $C_D e^{\kappa_D m}$ and $\lambda_{\text{out}} > \kappa_D$, then a smaller output rate costs only

$$4L^4 C\varepsilon \sum_{m\geq 0} (m+1)^q e^{-(\lambda_{\text{out}}-\kappa_D)m} < \infty$$

for every fixed polynomial power q. The two-variable Cauchy estimate has already summed all cluster multiplicities and choices of source domains through the ordinary rooted majorant. No second unsummed count of them is justified or needed. Additional geometric position sums cost a polynomial only when the actual domain geometry supplies that bound. This does not permit unrecorded extra domain types or an exponent loss larger than the available gap.

Finally sum eq. 4.cxv over b at a fixed localization domain X. The chain rule and eq. 4.cxi give $E_X(\mathbf{V}_1(s)) - E_X(\mathbf{V}_0(s))$. Because $\mathbf{v}_0 = 0$, its source derivative is $DE_X(\mathbf{V}_1)[\mathbf{v}_1]$. On every declared local core, eq. 4.cxxi therefore proves the algebraic identity

$$\sum_{z\in X} \dot{F}(X,z) = DE_X(\mathbf{V}_1)[\mathbf{v}_1].$$

At a complete physical pair p_W, the physical Gaussian sum rule then gives

$$\sum_{X,z} \dot{F}(X,z) = \sum_X DE_X(\mathbf{V}_1)[\mathbf{v}_1] = \partial_s \log \Xi(\mathbf{V}_1 + s\mathbf{v}_1)\big|_0. \tag{4.cxxiii}$$

The same formula is valid on the permitted analytic continuation of the physical datum W. This is not continuation from the physical graph to an arbitrary independent current. All sums are finite-volume sums followed by absolutely convergent cluster sums. Coherent infinite-volume extensions of the local families use the same uniform local bounds and companion limits, when supplied.

If the actual reference, union filing and interpolation paths are covariant under lattice isometries and a constant source has that same covariance, these identities also hold after transporting X, b, P. The midpoint tent then gives $\dot{F}(\mathsf{r}X, \mathsf{r}z; \mathsf{r}P) = \dot{F}(X,z;P)$. The same reasoning preserves gauge invariance and reality. These properties are inherited from the actual construction, not inferred from a scalar norm estimate. A nonconstant source does not acquire Euclidean covariance merely from eq. 4.cxxii.

If the source entered a Gaussian structure or the cutoff leg, additional derivatives would be required. With a fixed reference, a cutoff root is in general a boundary functional $N_{t,b}$, not the bounded function $\partial_t\chi/\chi$. Its differentiated normalized density is $N_{t,b}(ve^V)/\Xi - (N_{t,b}(e^V)/\Xi)\langle v\rangle$, plus any direct variation of $N_{t,b}$. If the reference measure also varies, its score contributes to the

denominator derivative as well. The retained Gaussian tail would have to be proved under insertion. The fixed-reference older-weight presentation avoids those additional terms here.

The conclusion is one finite-step pointed insertion estimate. It does not differentiate a full history class, prove closure of the response under iteration, supply the spatial defect gain of a nonconstant profile, or establish the clean-history Gaussian disintegration needed for an interacting two-point law.

The three legs and the normalized intrinsic path. We make the finite structural issue in eq. 4.cxii explicit. The free potential is a compensation of the fixed gauge quadratic form. If $Q^G = \sum_Y Q^G_Y$ and the forms are symmetric in the free real coordinates, put

$$q_b(Y;B) = \tfrac{1}{2}B(b)\cdot(Q^G_Y B)(b), \qquad \sum_b q_b(Y;B) = Q^G_Y(B). \tag{4.cxxiv}$$

The dot product here is bilinear, so the formula has its holomorphic meaning on a complex field box. When the actual row bounds give $\|\mathbf{q}_b\|_{\lambda_V} \le A_G$, the path $-u(1-\tau)Q^G$, $0 \le u \le 1$, has root $-(1-\tau)q_b$. The inserted-potential estimate gives its pointed bound as soon as this globally defined free family and its path fit in the ordinary potential budget. In particular one needs the actual smallness of $|1-\tau|A_G$; this is not a statement for arbitrary positive τ. The gauge form has not been multiplied by the variable action weight.

The cutoff leg is next, before the intrinsic and older potentials have been turned on. Its only interaction is this globally defined quadratic free potential. Each sharp test is brought from infinity to its final position. Its boundary estimate is proved below.

The third leg turns on the Jacobian and older functions by $V_Y(tB)$. The gauge and action remainders are normalized differently:

$$V^{\mathrm{int}}_{t,Y}(B) = t^{-2}V_Y(tB), \qquad V_Y(0) = DV_Y(0) = D^2V_Y(0) = 0. \tag{4.cxxv}$$

The three vanishings concern the intrinsic remainder after its quadratic part has been put in the free Gaussian. Its actual bond derivative includes the derivative of the factor t^{-2}. The diagonal path in eq. 4.cxxv alone does not specify how that derivative is distributed among bonds.

Here is a fully specified sufficient convention. It is a construction of an admissible local pointing; its identification with any separately prescribed pointing remains an exact finite structural question. For every intrinsic domain Y, let $\mathfrak{B}_Y$ be its actual free bonds and choose fixed, field-independent numbers

$$\vartheta_{Y,b} \ge 0, \quad \vartheta_{Y,b} = 0 \ (b \notin \mathfrak{B}_Y), \quad \sum_{b\in\mathfrak{B}_Y} \vartheta_{Y,b} = 1. \tag{4.cxxvi}$$

The choices are covariant under the geometric symmetries of the assigned domains. Equal shares are possible on any nonempty such domain. If there are no free variables, the intrinsic member with the vanishings in eq. 4.cxxv is zero and is omitted. Define

$$\begin{aligned} T_Y(\mathbf{t}) &= \sum_b \vartheta_{Y,b}t_b, \\ \widetilde{V}_Y(\mathbf{t};B) &= T_Y(\mathbf{t})^{-2}V_Y((t_bB(b))_b), \\ a_{t,b}(Y;B) &= t^{-2}B(b)\cdot D_bV_Y(tB) - 2\vartheta_{Y,b}t^{-3}V_Y(tB). \end{aligned} \tag{4.cxxvii}$$

At $\mathbf{t} = t\mathbf{1}$, the second line is exactly eq. 4.cxxv. Differentiating there gives the third line, including its normalization term. Summing over bonds gives $\sum_b a_{t,b}(Y;B) = \partial_t[t^{-2}V_Y(tB)]$. This is an independent-bond interpolation formula; no replacement by an Euler pointing has been made.

We prove its uniform norm and domain assertions. Use the nested boxes in eq. 4.cvii, and suppose that V_Y is holomorphic on the larger one with potential norm at most ε. Fix B in the smaller complex box. A fixed radial disc $|z| < 1 + c_\nu$ maps zB into the larger box. On that disc $Q_Y(zB) \le C_\nu Q_Y(B)$. The function $z \mapsto V_Y(zB)$ has a zero of order at least three. The maximum

principle applied to $V_Y(zB)/z^3$ therefore gives

$$|V_Y(tB)| \le C_\nu \varepsilon e^{-\lambda_V d(Y)} t^3 Q_Y(B), \qquad 0 \le t \le 1. \tag{4.cxxviii}$$

To bound a coordinate derivative, leave a fixed further margin in the radial disc and vary one color coordinate by a complex w with $|w| < c_\nu(1 + |B_b^a|)$. The resulting point is still in the larger box, and $Q_Y(zB + we_{b,a}) \le C_\nu Q_Y(B)$. Coordinate Cauchy gives a bound $C_\nu \varepsilon e^{-\lambda_V d(Y)} Q_Y(B)$ on $B_b^a D_{b,a} V_Y(zB)$, uniformly on a fixed disc of radius greater than one. This last function of z vanishes to order at least two. Applying the same maximum-principle argument and summing the three colors proves

$$|B(b) \cdot D_b V_Y(tB)| \le C_\nu \varepsilon e^{-\lambda_V d(Y)} t^2 Q_Y(B). \tag{4.cxxix}$$

Consequently every summand in the last line of eq. 4.cxxvii is bounded in the original potential norm, uniformly down to $t = 0$, and

$$\sup_b \int_0^1 \|\mathbf{a}_{t,b}\|_{\lambda_V}\, dt \le C_\nu \varepsilon. \tag{4.cxxx}$$

The apparent negative powers of t have been canceled by the actual orders of vanishing.

The independent parameters have a common admitted neighborhood at every $t > 0$. Choose $c_\nu > 0$ smaller if necessary and take $\max_b |t_b - t| < c_\nu t$. Nonnegative shares imply $|T_Y(\mathbf{t}) - t| < c_\nu t$, so $|T_Y(\mathbf{t})| \ge t/2$. The scaled coordinates remain in the larger fluctuation box. Applying the radial argument to $(t_b/t)B(b)$ gives $\|\widetilde{\mathbf{V}}(\mathbf{t})\|_{\lambda_V} \le C_\nu t\varepsilon$. Thus the potential path also stays inside its accepted slot if its initial allowance is chosen small enough. There is no singular parameter domain being asserted at $t = 0$; the integrable diagonal limit is the one just proved.

Each density is zero unless b belongs to its actual domain. Its root therefore survives the actual union filing. Fixed covariant shares introduce neither field dependence nor a new read outside that domain. For Jacobian and older families the unnormalized path $V_Y(tB)$ uses only the coordinate Cauchy bound in eq. 4.cxx; no third-order assumption is needed for its bond derivative.

For a separately prescribed independent-bond convention, write its normalization density as $R_b(Y; B)$. The same proof applies if its exact derivative is $t^{-2}B(b) \cdot D_b V_Y(tB) - 2t^{-3} R_b(Y; tB)$, with $\sum_b R_b = V_Y$, the same support and norm bound, and third-order vanishing of each R_b. Those are concrete finite identities and estimates to verify. They do not follow from the single equality $\sum_b a_{t,b} = \partial_t V_t$: arbitrarily large terms with zero bond sum would leave that equality unchanged. In particular, the construction in eq. 4.cxxvii does not silently identify inherited coefficients, own scalar readouts or operation identities with a different convention.

The moving sharp cutoff has an integrable rooted tail. We next prove the boundary estimate for the actual cutoff leg. The cutoffs act on three real coordinates of each tested free bond, with the Euclidean Lie-algebra norm. A cutoff on a further linear image would require its corresponding uniformly nondegenerate marginal bound; it is not identified with a free coordinate by name. Put

$$\chi_t(B(b)) = \mathbf{1}_{\{t|B(b)|<\mathfrak{b}\}}, \qquad 0 \le t \le 1, \quad \mathfrak{b} \ge 1. \tag{4.cxxxi}$$

At zero the cutoff is one. As a measure derivative for $t > 0$, $-\partial_t \chi_t = |B(b)|\delta(\mathfrak{b} - t|B(b)|)$. For every fixed $B(b)$ away from the final boundary its integral over $0 < t < 1$ is exactly $\mathbf{1}_{\{|B(b)|>\mathfrak{b}\}}$. This is the one-dimensional change of variables $u = t|B(b)|$. It proves the total-variation identity without dividing by a characteristic function.

For use with complex Gaussian matrices we require a uniform majorant before integrating in t. Let D be the local covariance after the auxiliary coordinates have been integrated out as in eq. 4.l. Its real reference and perturbation obey the same uniform gap bounds as there. If $|F(B)| \le F_0 e^{\rho|B|^2}$, define

$$S = \mathrm{Re}(D^{-1}) - 2\rho I, \qquad Z_{\mathrm{abs},\rho} = |\det D|^{-1/2} (\det S)^{-1/2}. \tag{4.cxxxii}$$

For the permitted ρ and perturbation size, $S>0$, both S and S^{-1} have uniform operator bounds, and

$$|d\mu_D(B)|\, e^{\rho|B|^2} = Z_{\mathrm{abs},\rho}\, d\mu_{S^{-1}}(B), \qquad Z_{\mathrm{abs},\rho} \le e^{A_K(\widehat{\varepsilon}+\rho)m}. \tag{4.cxxxiii}$$

This follows by writing the density on the real contour. The bound is the normalized local comparison bound, with the local scalar-coordinate dimension m. No factor depending on the auxiliary dimension has appeared.

Let P be a set of q other distinct failed free-bond tests. For a sufficiently small fixed $\gamma>0$,

$$\prod_{a\in P} \mathbf{1}_{\{|B(a)|\ge \mathfrak{b}\}} \le e^{-\gamma q\mathfrak{b}^2/2} \exp\{\tfrac{\gamma}{2}\sum_{a\in P}|B(a)|^2\}. \tag{4.cxxxiv}$$

Writing Π_P for the orthogonal projection onto their $3q$ real coordinates, the new real precision is $S-\gamma\Pi_P$. Choose $\gamma\|S^{-1}\|\le 1/2$. It is positive, its covariance has uniform upper and lower bounds, and its normalization ratio is at most $e^{C_K\gamma q}$. To verify the last claim, diagonalize $\gamma S^{-1/2}\Pi_P S^{-1/2}$. There are at most $3q$ nonzero eigenvalues, each at most $1/2$, and $-\log(1-u)\le 2u$ on that interval. Thus the logarithm of the ratio is at most $3K'\gamma q$. This cost counts failed coordinates, rather than all coordinates outside the local Gaussian.

The marginal of the root block $B(b)$ in this tilted normalized real Gaussian is three dimensional, even if the full local dimension is large. Its radial density is bounded by $C_K u^2 e^{-c_K u^2}$. Indeed its covariance is a principal block of the full covariance, with the same uniform eigenvalue bounds. The usual three-dimensional Gaussian density is therefore at most $C_K e^{-c_K|x|^2}$; integration over the sphere of radius u gives the assertion. Consequently, uniformly in all admitted complex matrix parameters,

$$\begin{aligned}\Big|\mathcal{J}\Big[|B(b)|\delta(\mathfrak{b}-t|B(b)|)\,F(B)\prod_{a\in P}\mathbf{1}_{\{|B(a)|\ge\mathfrak{b}\}}\Big]\Big| \\ \le C_K F_0 e^{A_K(\widehat{\varepsilon}+\rho)m + C_K\gamma q} e^{-\gamma q\mathfrak{b}^2/2}\mathfrak{b}^3 t^{-4} e^{-c_K\mathfrak{b}^2/t^2}.\end{aligned} \tag{4.cxxxv}$$

This display uses the auxiliary-integrated local functional. For a boundary distribution it follows either by polar coordinates in $B(b)$, or by first using a thin positive shell in that coordinate and taking its limit. The Gaussian density and the free-potential factors are smooth; the remaining cutoffs are bounded Borel functions. Fubini and the displayed integrable majorant justify that limit.

The singular-looking factor is integrable. The substitution $u=\mathfrak{b}/t$ gives

$$\int_0^1 \mathfrak{b}^3 t^{-4} e^{-c_K\mathfrak{b}^2/t^2}\,dt = \int_{\mathfrak{b}}^\infty u^2 e^{-c_K u^2}\,du \le C_K e^{-\gamma\mathfrak{b}^2/2}, \tag{4.cxxxvi}$$

after reducing γ if necessary. For example, bound $u^2e^{-c_Ku^2/2}$ by its finite maximum and integrate the remaining Gaussian tail; with $\mathfrak{b}\ge 1$ the extra polynomial is absorbed by a still smaller fixed exponent. The bound in eq. 4.cxxxv is uniform before the t integration. It therefore also bounds an integral whose integrand is a supremum over the admitted matrix and external parameters. This constructs the boundary envelope with the supremum inside the integral.

We spell out its application to the literal finite expansion. During this leg only the globally defined quadratic free family is present, so its selected interaction domains require no small-field box Y_0. Expand $\prod_b \chi_{t_b}$ into failed tests. Differentiation in a tested bond b selects terms whose failed set contains b, replaces its factor $1-\chi_{t_b}$ by the boundary measure, and leaves every other failed factor at threshold at least $\mathfrak{b}$. Use eq. 4.cxxxv for that root. The independent coupling Schwarz estimates for the selected free-potential Mayer factors, the enlarged coarse-decoupling Cauchy estimates and the coarse collar count are exactly those used in eq. 4.lxxi–eq. 4.lxxxii. The root bond is part of the actual support $Z_0(\mathbf{D},P_0)$. Thus no remote root is created.

For precision, the Schwarz argument is a holomorphic one and never squares the boundary measure. At fixed $t > 0$, insert independent couplings λ_Y in the selected free-potential Mayer factors. The resulting boundary functional is holomorphic on the discs in eq. 4.lxx, with the unsquared boundary factor kept inside that linear functional. Indeed the larger Gaussian-only budget bounds its integrand by $2^{\#\mathbf{D}} e^{CW_0 L^4 N} e^{\rho|B|^2}$; eq. 4.cxxxv gives a common boundary majorant on those discs. Differentiation or a contour integral in the couplings is therefore justified by this same majorant. The functional vanishes when any selected $\lambda_Y = 0$. Apply the scalar Schwarz lemma successively in these variables, and then Cauchy's formula in the coarse parameters. Writing $r = \#\mathbf{D}$, $v = |P_0| \geq 1$, $h = |Z \setminus Z_0^\sharp|$, $p = e^{-\gamma \mathfrak{b}^2/2}$, and $g_{\mathrm{bd}}(t) = \mathfrak{b}^3 t^{-4} e^{-c_K \mathfrak{b}^2/t^2}$, this gives

$$\begin{aligned} |\partial_{t_b} T_{Z,\mathbf{D},P_0}| \leq C_K g_{\mathrm{bd}}(t) e^{C_0 N + C_K \gamma(v-1)} \left(\frac{2a}{W_0}\right)^r \\ \times e^{-(\lambda_V - \lambda_0)\sum_{Y \in \mathbf{D}} d_f(Y)} p^{v-1} (R_s - 1)^{-h}. \end{aligned} \tag{4.cxxxvii}$$

The zero tests and the boundary factor have no coupling derivative and are not subjected to an L^2 Cauchy–Schwarz inequality. The coarse parameters change the Gaussian matrices, not the real boundary coordinate. The formula in eq. 4.cxxxvi integrates g_{bd} to at most $C_K p$, restoring p^v in the unmarked estimate in eq. 4.lxxiv. The factor $e^{C_K \gamma(v-1)}$ costs at most e^{CN}, since $\gamma(LM)^4$ is bounded. Enlarge C_0 by that fixed constant before choosing K_*, Θ and the strict rates in eq. 4.lxxvi–eq. 4.lxxvii. Thus the same literal hull and product sums apply with an integrable root envelope throughout.

Allocate the same strict surplus of spatial and decoupling rates as in the unmarked proof. The normalization cost in eq. 4.cxxxiii is bounded per coarse cube when $(LM)^4(\widehat{\varepsilon} + \rho + \gamma)$ is bounded. The rank-tilt cost $e^{C_K \gamma q}$ is included in this allocation, since $q \leq C(LM)^4 \#Z$. The failed-test position sum has at most $C(LM)^4$ choices per coarse cube. Every selected cutoff term still has its root failure. In place of an unmarked linear amplitude this gives

$$\begin{aligned} p_{\mathrm{cut}} &= C_K (LM)^4 e^{\Theta} e^{-\gamma \mathfrak{b}^2/2}, \\ \int_0^1 \sup_P |\partial_{t_b} H_Z(\mathbf{t}; P)|_{\mathbf{t}=t\mathbf{1}}\, dt &\leq C p_{\mathrm{cut}} e^{-\lambda_2 (d_c(Z)+5)}. \end{aligned} \tag{4.cxxxviii}$$

Here Θ is the rate expenditure of eq. 4.lxxviii–eq. 4.lxxx; all physical smallness conditions include this factor. The supremum includes the local decoupling parameters needed in forming this activity. The estimate follows by the same nonnegative sum over selected domains and failed sites as before, with one site pinned to b. Pinning removes a position sum; any polynomial number of possible roots inside a domain is absorbed by the already retained strict rate gap. An empty choice cannot contribute a root.

Finally differentiate the absolutely convergent cluster series once. In each connected cluster mark the polymer that is differentiated. The rooted tree bound sums all its remaining polymers to at most $e^{a(Z)}$, where a is the size weight of the hard-core criterion. Sum its marked activity with eq. 4.cxxxviii, spending the strict difference between λ_2 and the retained output rate. Positivity of these majorants permits Tonelli in t and in the cluster sum. We obtain

$$\int_0^1 \sup_P |\partial_{t_b} E_X(\mathbf{t}; P)|_{\mathbf{t}=t\mathbf{1}}\, dt \leq C p_{\mathrm{cut}} e^{-\lambda_{\mathrm{out}} d(X)}, \quad \partial_{t_b} E_X = 0 \quad (b^\sharp \not\subset X). \tag{4.cxxxix}$$

At a fixed pair on X, only the hereditary subsystem of polymers contained in X is used. When the union condition is dropped in the positive bound, only the uniform local norm majorants are extended, not actual activity functions outside their declared cores. Its integral is the cutoff-leg density $E_\chi(X, b)$. Summing in b recovers the difference between the all-one and all-zero cutoff endpoints. Midpoint tents preserve its root as in eq. 4.cxxi–eq. 4.cxxiii.

All these estimates are local on their admitted independent-pair cores. The complete sum is identified with the physical cutoff integral only at p_W and its admitted continuation in W. No

global Gaussian on arbitrary independent currents, and no estimate for a history's outer stored-variable integral, has been used.

4.5.4. *Window-first ordinary formation.* The estimate in this section is an ordinary formation estimate. It concerns the actual functions obtained by rewriting old terms on box backgrounds, before their fine-cube bracket localization. The outer potential/current pair may have independent components. This causes no substitution of an arbitrary pair into a theorem about critical backgrounds: the inner window function first constructs its own constrained box background and its own current. The hypotheses below retain the domain and response assertions needed to perform that construction on the whole complex parameter set. We fix the window-first rule below as part of the localization: at one old base point, its near pointed sum is one window member before any fine bracket is applied.

The maps and geometric inputs. Fix a step from level k to level $k+1$. For an old level $j \le k$, put

$$a = k - j, \qquad \sigma_j = L^{-a}, \qquad \rho_j = \max\{1, \alpha_k/\alpha_j\}, \qquad s_k = \delta_k/\alpha_k. \tag{4.cxl}$$

The radii and the ordinary flow satisfy $\rho_j \le C(1+a)^{1/2}$. In particular

$$C_{\mathrm{age}} := \sup_{a\ge 0} C(1+a)^{1/2}L^{-a} < \infty, \qquad \rho_j\sigma_j \le C_{\mathrm{age}}. \tag{4.cxli}$$

Here δ_k is the tested fluctuation amplitude, whereas α_k is the analytic field radius. The ratio in eq. 4.cxl is an ordinary full-radius ratio. No small-field gain is being deduced by replacing a smaller ratio with one.

We spell out the ordinary background and geometry inputs. They must concern the actual assigned maps, not arbitrary functions with similar notation.

First, let P range over the local complex core used to form the new potentials. Let $\mathbf{H}_k(P; s, B')$ be the actual response to the tested free fluctuation coordinates, with the indicated fine-cube parameters. The plain nonlinear iterated block average is denoted $\mathcal{M}^j$. On a window $\square$, with a fixed partition function $\zeta_\square$, the datum used for an inner term is the restriction of

$$\mathcal{V}_{j,\square}(P; s, t, \nu) = M_{\mathbf{B}_j}\Big(e^{\,i\eta_k(t+\nu\zeta_\square)\mathbf{H}_k^{\mathrm{win}}(P;s,B')}\,U_+(P)\Big), \qquad 0 \le t \le 1. \tag{4.cxlii}$$

The notation $U_+(P)$ denotes the exponential representative of the upper box. The response $\mathbf{H}_k^{\mathrm{win}}$ is transported to that same frame. The original node frame is recovered at the two endpoints of each row. The factor η_k converts a potential in level-k units to a bare bond logarithm. The map $M_{\mathbf{B}_j}$ reads the ordinary iterated average at each determining row, at the level of that row. The formula in eq. 4.cxlii uses the nonlinear average. Replacing it by its differential would not give the window identity. The box-background map applied to this datum returns a pair

$$P^{\mathrm{box}}_{j,\square}(P; s, t, \nu) = \big(U^{\mathrm{box}}_{j,\square}(\mathcal{V}_{j,\square}), J^{\mathrm{box}}_{j,\square}(\mathcal{V}_{j,\square})\big) \tag{4.cxliii}$$

in which J^{box} is the current of that constrained critical configuration. The ordinary maps include their prescribed node and gauge representatives.

Second, all these maps are holomorphic on the full independent fine-parameter discs $|s_\Delta| < R = e^{\bar\kappa}$. The unamplified substitutions have a fixed positive amount of datum, chart and core room. If $r_{B,j}$ is the dimensionless datum radius, the background package supplies $\alpha_j/r_{B,j} \le C$. Its response and nonlinear-average estimates bound the change caused by the ν term, in every relevant normalized datum, chart and core norm, by

$$C_R|\nu|\,\delta_k\sigma_j/\alpha_j \le C_R|\nu|s_k\rho_j\sigma_j. \tag{4.cxliv}$$

The constant C_R includes the fixed loss from the enlarged fine-parameter discs. These are estimates for the actual nonlinear average and response on their assigned analytic domains. For example, in a datum norm the estimate follows by the uniform first-response bound, composed with the derivative of the actual average, and integration along the perturbation. For the inner terms it must also hold

for the other core inequalities and the tower substitutions. The outer and removed terms use their own directional estimates below. Existence and holomorphy on the corresponding datum balls are part of the background package.

4.5.4.1. Restriction and the two substitutions. Use the two fixed tower rules on the admitted localization domains, with inward rows removed. Here L is odd, $L \geq 13$, the geometric sizes are powers of L, $R_1 \geq L$, $M_1 \geq R_1\mathfrak{M}$, and $M \geq L^4 M_1$. The localized tower estimates use the separated-region floors and the fixed continuation and averaging radii of the background construction. In particular they use $\rho = L^{-2}R_1\mathfrak{M} \geq \mathfrak{r}^{\mathrm{s}}$, the last-level torus width of at least 6ρ sites, and the floors $\mathfrak{M} \geq \mathfrak{m}_{\mathcal{M}}$ and $R_1\mathfrak{M} \geq \max\{\mathfrak{r}_{\mathcal{M}}, \mathfrak{r}^{\mathrm{prop}}\}$. The corresponding decay rates satisfy

$$\delta_{0,\mathrm{red}} R_1\mathfrak{M} \geq 8(4\log L + \log 2), \qquad \mathring{\delta}_{0,\mathrm{b}} R_1\mathfrak{M} \geq 512 \log L, \qquad \delta_*^{\natural} R_1\mathfrak{M} \geq 18(4\log L + \log 2).$$

For nested localization domains $X \subset Y$ of levels $j-1$ and $j'-1$, set $\lambda = L^{-(j'-j)}$. Restriction from Y to X maps the core at radii (b_0, b_1, c_0) into the old core at radii $(\lambda b_0, \lambda b_1, \lambda^3 c_0)$. In the simple clauses of eq. 2.v, the curvature and the first difference of the potential gain λ^2, the potential gains λ, and the independent current gains λ^3. The tower of any admitted $Z \subset X$ is computed from the same bare product in both presentations. Its curvature and current, read at their own levels as in eq. 2.vii, inherit the ratio λ in the hereditary ceiling. If $j' = k+1$, $m = k+1-j \geq 1$ and $A_i \leq 2\sqrt{1+m}\, a_i$ for $i = 0, 1$, this restriction sends the radii $((1+2\beta_{\mathrm{s}})A_0, (1+2\beta_{\mathrm{s}})A_1, A_0)$ into $(a_0/3, a_1/3, a_0/3)$ for $0 < \beta_{\mathrm{s}} \leq 1/4$. Indeed $(1+2\beta_{\mathrm{s}})2\sqrt{1+m}\, L^{-m} \leq 1/3$.

For the outer substitution in level-j units, take the old triple in $\mathcal{U}_j^{\circ}(X; b_0/2, b_1/2, c_0)$, with $c_0 > 0$, $0 < b_0 \leq b_1$, $b_1^2 \leq c_{\natural} b_0$, $c_{\natural} \geq 1$ and $b_0 + b_1 \leq a^{\sharp}$. Choose $a^{\sharp} < a_T$ and below the fixed ceiling of Prop. 3.132. Take $K_{\mathrm{red}}^{\sharp} \geq K_T$ from Cor. 3.130, enlarged to cover the fixed substitution constants. If the potential shift satisfies

$$\max\{|\mathbf{A}|, |\nabla_{\mathbf{U}}\mathbf{A}|\} < \frac{b_0}{128 K_{\mathrm{red}}^{\sharp}(1+c_{\natural})}$$

on the internal bonds and differences, and $|\mathbf{J}'| < b_0$, the triple of $(e^{i\eta_j \mathbf{A}}\mathbf{U}, \mathbf{J}')$ obtained by eq. 2.ix lies in $\mathcal{U}_j^{\circ}(X; b_0, b_1, b_0)$. In fact, multiply the shift by z with $|z| \leq R = 4K_{\mathrm{red}}^{\sharp}(1+c_{\natural})$. Write $\beta_0 = b_0/32$. The shift and its first difference with transport by $\mathbf{U}$ have size at most β_0 on this disc. Transport by the real base U changes the difference by at most $\beta_0/4$. The local logarithm estimate gives bounds below b_1 for the potential and its first differences. In the plaquette product estimate, the change relative to the old plaquette is bounded by $\eta_j^2(2\beta_0 + 14\beta_0^2 + 4\eta_j\beta_0 b_0)$. Multiplying back by the old plaquette gives a change at most $3\beta_0\eta_j^2$, within the curvature margin. For a tower of level $p \leq j$ put $\lambda_p = L^{-(j-p)}$. Each normalized curvature or current readout of that tower is holomorphic in z and bounded on the disc by $K_{\mathrm{red}}^{\sharp}(1+c_{\natural})\lambda_p b_0$. Its value at zero has size less than $\lambda_p b_0/2$. Schwarz's lemma applied to the difference from its value at zero gives a change at $z = 1$ of at most $\lambda_p b_0/2$. This checks the hereditary clauses for both rules and every truncation. The real base is unchanged and the independent current is tested separately.

The inner window estimate starts with the flat-reference continuation $e^{i\mathsf{a}_0}$ of the upper window datum, in the node frame of the window. For a fluctuation $\mathbf{A}$ in level-k units put

$$\mathsf{a} = \frac{1}{i}\log(e^{iL^{-k}\mathbf{A}}e^{i\mathsf{a}_0}), \qquad B(c) = \frac{1}{i}\log \mathcal{M}^q(e^{i\mathsf{a}})(c), \quad c \in \Gamma_q.$$

Here Γ_q is the level-q row set of the old truncated window tower. The actual nonlinear average is used. If B_0 is the same datum at $\mathbf{A} = 0$, the logarithm bound and holomorphy of the average on its absolute row disc give $|B(c) - B_0(c)| \leq (9/2)C_Q L^{q-k} \sup|\mathbf{A}|$. Indeed the bond logarithm changes by at most $(9/8)L^{-k}|\mathbf{A}|$, and the Schwarz estimate on the line joining the two bond logarithms costs $4C_Q L^q$. The bound holds for complex fluctuations in the admitted ball. This also controls the whole datum with its actual amplitude. Write $d = A_0 + \sup|\mathbf{A}|$, where A_0 is the upper curvature radius on the complete box. The upper comb estimate gives $\|B_V\|_{\infty} \leq C_M A_0$. The restriction

identity and the weighted response of the flat upper background then give $\|B_0\|_\infty \le C_M A_0$ on every row of the old tower. Since $q \le j \le k$, the preceding increment estimate yields

$$\|B\|_\infty \le C_M d, \qquad \|B\|_{\mathrm{central}} \le C_M d L^{j-k}. \tag{4.cxlv}$$

The second bound uses that every central row has level j; its upper background contribution has the stronger factor $L^{j-(k+1)}$. These constants depend on the fixed geometry, not on either depth. The same first bound holds after the cutoff axial change: its comb has $O_M(L^{k-j})$ links of size $O_M(dL^{j-k})$, hence its logarithm has size $O_M(d)$. Its cutoff extension has that same supremum, and the endpoint product on every row stays within $C_M d$ of the identity. Lower rows outside its support retain their original values. For the central axial bound require, in addition, the complete upper field's first-difference bound of size $C_M d$ on the settled layer, as in the window theorem. Its level-j plaquette defects are consequently at most $C_M d L^{2(j-k)}$. An axial link is a product of at most $C_M L^{k-j}$ such plaquette factors, with bounded transports. It is therefore within $C_M d L^{j-k}$ of the identity on the central carrier, where the cutoff equals one and the complete comb rectangles remain in the settled layer. This proves the central bound after the axial change; it uses that first-difference estimate as well as the datum bound. On the outer cutoff transition only the global $C_M d$ bound is asserted here. Thus the remote response has the proportional factor d; the fixed continuation ceiling supplies only its domain. An independent correction B_{err} contributes $C\|B_{\mathrm{err}}\|_\infty$ separately. In particular, the auxiliary correction ball used for Cauchy estimates does not change the amplitude of the actual evaluation, where $B_{\mathrm{err}} = 0$.

The window continuation at the datum $\tau B + B_{\mathrm{err}}$, $0 \le \tau \le 1$, gives the old curvature, potential and current margins $(a_0/4, a_1/2, a_0/4)$ in its normalized core. Use the actual upper input and literal-datum convention of Prop. 3.135. Choose $M_\flat \ge M_0$, $a^\flat < a_I(M)$ and $2B_3^2\mathsf{K} \ge C_I$ from that proposition, and take its increment constants c_2, c_3 or smaller ones. The required bounds are $M \ge M_\flat$, $A_0 + A_1 \le a^\flat$, $a_0 + a_1 \le a^\flat$, $2B_3^2\mathsf{K}Ma_0 < a_1$, and $A_0 \le 2\sqrt{1+m}\, a_0$. Its fluctuation has size below $c_2 A_0$ and the complex correction has raw norm below $c_3 a_0$. These are local input bounds on the entire window. In eq. 4.cxlii, the fluctuation includes $(t + \nu\zeta_\square)\mathbf{H}_k$ in the same node frame. To use the window estimate, identify its upper continuation and determining rows with the ones in that formula. Check the bounds on the transported fluctuation and any correction on the full retained ν-disc and all independent fine-parameter discs. In particular, if the transported response has $\|\mathbf{H}_k\|_\infty \le C_R\delta_k$ on the fine-parameter discs, then the window input on $|\nu| < c_\nu/s_k$ is at most $C_R(s_k + c_\nu\|\zeta_\square\|_\infty)\alpha_k$. When α_k/A_0 is bounded, small s_k and c_ν make this less than $c_2 A_0$. The same row derivative bound on the admitted window gives a datum increment of size $C|\nu|L^{q-k}\delta_k$ relative to $\nu = 0$. This is the datum estimate in eq. 4.cxliv after dividing by the old radius. Its use for the actual maps requires the comparison just described. The other core readouts must also obey their bounds throughout the disc. The outer estimate starts with a shift already bounded in its required norm. The removed substitution likewise requires its own joint background and current bounds.

4.5.4.2. The window at the radii of the run. Let x_i be the inverse couplings and use the running radii $\alpha_\iota(x) = C_\iota x^{-1/2}(\log x)^q$, $\iota = 0, 1$. For $m = k + 1 - j$ set $A_\iota = (1 + \beta_{\mathrm{s}})\alpha_\iota(x_k)$ and $a_\iota = \min\{\alpha_\iota(x_{j-1}), \alpha_\iota(x_j)\}$. The drift bounds are $-c_5 \le x_i - x_k \le \bar{B}(k-i)$. If $x_i \ge x_k$, the logarithmic factor in $\alpha_\iota(x_k)/\alpha_\iota(x_i)$ is at most one, and the remaining factor is at most $\sqrt{1+k-i}$ by $\bar{B}\gamma^2 \le 1$ and $x_k \ge \gamma^{-2}$. If $x_i < x_k$, the logarithmic ratio is at most $1 + c_5\gamma^2$, using $\log x_i \ge 1$. The choice $(1 + c_5\gamma^2)^q \le 1 + \beta_{\mathrm{s}}$ therefore gives $A_\iota \le 2\sqrt{1+m}\, a_\iota$. Both minima are attained at the same index, so $a_1/a_0 = C_1/C_0$. The running ceiling gives $a_1 \le 1$ and both radius sums at most $a^\flat \le a^\sharp$. Thus $a_1^2 \le (C_1/C_0)a_0$, and the choice of C_1/C_0 gives $2B_3^2\mathsf{K}Ma_0 < a_1$.

For the inner substitution take the window of 2^4 level-k cubes with a common vertex and put $\square_0 = \square^{\sim 5}$. Use the rule-$\mathfrak{r}_1$ tower of $\square_0$ to depth $k+1$ and its truncation to depth j, with the same convention on inward rows at both depths. The upper determining data $M_{\mathbf{B}^+}(\mathbf{U})$ on the first tower

have a comb representative V and a node gauge v, with

$$M_{\mathbf{B}^+}(\mathbf{U}) = V^v, \qquad |V-1| < K_\square M \alpha_0^+, \qquad |v|\,|v^{-1}| < e^{K_\square M \alpha_1^+}, \qquad \alpha_\iota^+ = (1+2\beta_{\mathrm{s}})A_\iota.$$

The comb construction uses the upper bare plaquette and potential bounds and the $\mathfrak{r}_1$ tower clause for this box. It also uses the fixed smallness ceiling on $(LM)^4(\alpha_0^+ + \alpha_1^+)$. The representative is holomorphic at fixed real base. Its node gauge extends by the tower's prescribed site rule. The tower at the actual upper datum is the extended gauge transform of the flat-reference continuation at $B_V = i^{-1}\log V$.

4.5.4.3. The ordinary response and its current. At the ordinary step on the constant sequence, the raw source of the response is the corrected fluctuation logarithm at level k. In the free variables of eq. 4.cxcii it is $B' = z - h_W d$. The constant-sequence datum conversion is the identity. On the tested fluctuation box the contraction gives $\|B'\|_\infty \le C\delta_k$. On each admitted local restriction use the same source on the corresponding rows, extended by zero outside its support. For the assigned response settings take $C\delta_k < \varepsilon_{\mathrm{D}} e^{-64\kappa}$.

Write $\mathbf{H}_k$ for the potential of the decoupled response and j_k for its increment of current, both in level-k units. The bounds for the solution on the independent parameter discs give

$$\|\mathbf{H}_k\|_\infty + \|\nabla_{\mathbf{U}}\mathbf{H}_k\|_\infty + \|\mathsf{j}_k\|_\infty \le C_R \|B'\|_\infty.$$

For the current use the difference estimate between B' and zero. At a local layer these are bounds in that layer's units; the assertion here uses the constant sequence. The potential and current maps are holomorphic at fixed real base and have the same restriction law on the interior of active wall components, with their own support collars. Outside the components retain the explicit current of the reduced system. The current estimate is for the current from the decoupled equations. A second difference of a decoupled potential cannot be estimated from the first-difference bound.

The weighted estimate for the current follows in the same fixed pair and tower, with the switches held fixed. For two sources B_1', B_2', let $\mathbf{H}_i$ be their potentials and use the multiplier of eq. 3.mccxviii. Put

$$Z_s = \widehat{Q}^\sharp H_s^\sharp \mathbf{J}, \qquad K_i = (\widehat{Q} + C'_{\mathbf{H}_i})^\sharp \omega_s(\mathbf{H}_i), \qquad R_i = \mathsf{f}(-i\xi\,\mathrm{ad}_{\mathbf{H}_i})^{-1}.$$

The shifted current in Prop. 3.174 is $\mathbf{J}_i^\flat = \mathbf{J} - Z_s + R_i K_i$. Since Z_s is independent of the source, its difference is

$$\mathbf{J}_2^\flat - \mathbf{J}_1^\flat = R_2(K_2 - K_1) + (R_2 - R_1)K_1.$$

The local transpose bound and the multiplier estimate in eq. 3.mccxviii give a bounded unweighted current norm for K_i and the weighted Lipschitz bound for $K_2 - K_1$. Indeed, subtract the two multiplier formulas, use the resolvent identity for $\Psi_{s,\mathbf{H}_i}$, and then the first-difference bounds for $H_s^{\circledast}$ and $C'_{\mathbf{H}}$, as in the proof of eq. 3.mccxix. The inverse factors R_i are bounded on the common bond disc, and their difference costs $C\xi|\mathbf{H}_2 - \mathbf{H}_1|$. Thus the second term, in the current units at a site y, is at most $C\xi_y|\mathbf{H}_2 - \mathbf{H}_1|$, since $\xi \le \xi_y$. This is the weighted potential difference bound with the same spatial weight. Thus a source difference supported away from the full read has the same exponential gain in the current norm as in the potential norm, on the admitted complex switch disc. This applies to the cutoff change within one old box after including the stencils of its converted rows. The weighted Hölder difference of the potential on that same tower follows by using the local first-difference Hölder norm in the propagator estimate of the response theorem. It retains the same source difference and spatial weight. The identification with the physical current is at a real critical point at full switches. Its stencil is the native action's stencil before restriction to the read.

Consider the outer evaluation obtained by shifting the restricted pair by the ordinary response with multiplier λ. In level-j units its potential shift and current are

$$\mathbf{A}_{j,\lambda} = \lambda\sigma_j \mathbf{H}_k|_X, \qquad \mathbf{J}_{j,\lambda} = L^{-3(k+1-j)}\mathbf{J}_+|_X + \lambda\sigma_j^3 \mathsf{j}_k|_X,$$

where $\mathbf{J}_+$ is the input current in level-$(k+1)$ units. The shift in the bare exponential is unchanged because $\eta_j\sigma_j = \eta_k$. The covariant difference of the shift gains σ_j^2 since the transport uses the same bare bond field. If the upper triple is in the upper core used in the two-level restriction, the first current on the right is within $a_0/3$. The potential, its covariant first difference, and the current increment are all bounded by $C_R|\lambda|\sigma_j\delta_k$. On $|\lambda| < c\,a_0/(C_R\sigma_j\delta_k)$, with c chosen below the explicit outer shift ceiling and the remaining current margin, the outer substitution therefore belongs to the old core. The running radius comparison makes this disc contain $|\lambda| < c_\nu/s_k$ for a fixed small c_ν. This checks the outer shift that enters the ordinary bracket of the full response. The extra distance gain in a window derivative, and the two differences of responses in a removed term, require estimates for those distinct shifts on their full carriers.

For real physical data with all fine parameters one, the same response satisfies the exact constraint and slice equations. Its potential produces the critical configuration at the prescribed datum up to the node factors, and its completed current is the actual current of that configuration. Thus the two endpoints of the ordinary interpolation are the physical backgrounds, after the stated node normalization. At intermediate multipliers the pair can be off the critical graph. The current slot in the displayed formula is retained there.

The upper frame on the full window box. Let $\mathbf{B}^+$ be the upper tower of $\square_0$ and $\mathbf{B}_j$ its depth-j truncation, with the same convention on inward bonds. The bracket domain Y contains $\square_0$. The upper input is in the ordinary core at $((1+2\beta_{\mathrm{s}})A_0, (1+2\beta_{\mathrm{s}})A_1, A_0)$; its hereditary clause supplies the tower of $\square_0$ and its truncations used in the comb construction. The window uses the upper tower configuration at its comb datum V^v. Put $B_V = i^{-1}\log V$. The comb estimate gives $\|B_V\|_\infty \le CMA_0$ and $\mathsf{k}(v) \le e^{CMA_1}$ at every node, where $\mathsf{k}(g) = \|g\|\|g^{-1}\|$. Its prescribed extension $\tilde{v}$ has the same bound at every site.

Apply the flat-reference Landau pair to the continuation $\Phi_{\mathbf{B}^+,\mathbf{1}}(B_V)$ on a fixed datum disc inside the continuation and response radii. The identity holds on every inner bare bond of $\square_0$:

$$\Phi_{\mathbf{B}^+,\mathbf{1}}(B_V) = \big(e^{i\eta_{k+1}\mathbf{H}_{k+1}(B_V)}\big)^{u_{B_V}}.$$

The derivative bound in this theorem has one inverse local length ξ_y^{-1} for the potential on the pillar at y. Integrate it on the line from 0 to B_V. Each top is an endpoint of a bounded number of determining rows, and the exponential sum over tops is uniform. Consequently

$$\sup_y \xi_y \sup_{b \text{ over } y} |\mathbf{H}_{k+1}(B_V)(b)| \le C\|B_V\|_\infty.$$

In the ascent-gauge lemma the form $\mathbf{H}_{k+1}$ therefore lies in its weighted small ball, by weak coupling. The gauge factor of the Landau pair equals $h[\mathbf{H}_{k+1}]$ of that lemma. At real data the two factors have the same prescribed values at all tops and both satisfy the ascent identities, which determine their remaining values. The equality continues holomorphically on the datum disc. In particular $\mathsf{k}(u_{B_V}) < 3/2$ on the whole box. Thus the upper tower configuration equals $E^{g_\square}$, where

$$E = e^{i\eta_{k+1}\mathbf{H}_{k+1}(B_V)}, \qquad g_\square = \tilde{v}\,u_{B_V}, \qquad \sup_{\square_0} \mathsf{k}(g_\square) \le C.$$

Only the local-length bound for the background potential is used here. A uniform upper-level bound for that potential on the finest layers is unnecessary.

Use the assigned ordinary decoupled response on its own admitted active region, then restrict it to $\square_0$ using the full response reads. The fine parameters vanish off the active cells. The pivot-completed datum B' is supported at level k, with $\|B'\|_\infty \le C\delta_k$. The constant-sequence bound above uses local lengths one. On an admitted layered response chart the support estimate on the fine-parameter discs gives

$$\xi_y \sup_{b \text{ over } y} |\mathbf{H}_k(P; s, B')(b)| \le C\delta_k e^{-\theta d_{\mathbf{B}}(y,\Sigma_k)}, \qquad \theta = \mathring{\delta}_0/8.$$

Here Σ_k consists of the tops at which the datum is supported. Their local lengths in level-k units are at least L^{-1}, by the geometry of the level-k rows. If there is no such top the response is zero. The scale comparison in the same separated sequence gives $\xi_{y'}/\xi_y \le Le^{(\mathring{\delta}_0/16)d_{\mathbf{B}}(y,y')}$. Take y' in Σ_k at minimum distance. The loss from dividing by ξ_y is therefore paid by the support exponential. This proves $\sup|\mathbf{H}_k(P;s,B')| \le C\delta_k$ in level-k units also on the fine layers of the box. The proof uses the support estimate for the whole datum, without summing the responses over its nonzero sites.

For an assigned shift in the upper tower frame, transport it by $\mathrm{Ad}(g_\square^{-1})$ at the initial site of each bond. Its bound remains $C\delta_k$ in the exponential frame on the whole box. A shift supplied directly in the exponential frame uses the same bound. The window condition $\|\mathbf{A}\|_\infty < c_2A_0$ then has fixed room, since $\delta_k/A_0 \to 0$. This comparison concerns the two representatives of the upper tower. The fluctuation originating at the input pair uses the relative frame below.

The rows in this frame. For $c \in \Gamma_q$ in the truncated tower, every bare bond of its full two-block carrier lies in Ω_{q-1} of the upper tower for $q \ge 1$. The local lengths there are at least $L^{q-1-(k+1)}$ in upper-level units. This is the carrier assertion of the tower lemma, applied to the truncated sequence, whose Ω_{q-1} is the same as in the upper tower. It yields

$$L^q \sup_{b \text{ in carrier}(c)} |\eta_{k+1}\mathbf{H}_{k+1}(b)| \le CLMA_0.$$

For $q = 0$ the corresponding estimate follows directly from the local-length bound at a bare bond. If $\mathbf{A} = (t+\nu\zeta_\square)\mathbf{H}_k^{\mathrm{win}}$, then $L^q \sup|\eta_k\mathbf{A}| \le CL^{q-k}(1+|\nu|\|\zeta_\square\|_\infty)\delta_k$. In particular all the row discs stay within the absolute average radius on $|\nu| < c_\nu/s_k$ for small fixed c_ν. On this disc the transported shift also satisfies $\|\mathbf{A}\|_\infty < c_2A_0$ on the whole box.

These checks identify the row of the actual shifted upper tower with the row of $e^{i\eta_k\mathbf{A}}E$, transformed at its two endpoints by $g_\square$. To check the regular branch, all intermediate row carriers are inside the same two centered blocks. The row estimate keeps their values close to the identity in the exponential frame. Hence every relative contour matrix and every argument of its local mean lies in the prescribed logarithm chart. Conjugating the relative matrices multiplies their distances from the identity by at most the fixed condition number of $g_\square$. The same charts remain valid in the actual frame. In fact for a relative contour diameter d, smallness ensures $\mathsf{k}(g_\square)d < \omega_{\mathrm{c}}$ and $4\mathsf{k}(g_\square)d < \omega_{\mathrm{c}}'$. The transported mean therefore lies in the ball that characterizes the unique normalized mean. The relative logarithm is transported by the same conjugation. Applying this at each intermediate scale gives the claimed endpoint rule on the full carrier, including the outer determining rows. Thus no outer-row datum correction is needed for the unamplified path of this upper box construction.

On the exponential chart write $B(t,\nu)$ for the family of logarithms of these transported row values. The old continuation uses $\tau = 1$ in its datum $\tau B + B_{\mathrm{err}}$. Use $B(t,0)$ and add $B(t,\nu) - B(t,0)$ in the correction slot, which is zero at $\nu = 0$. The bare bond logarithm changes by at most $C|\nu|\eta_k\delta_k$, so the order-q row estimate gives a datum change at most $C|\nu|\delta_kL^{q-k}$. Taking the supremum over all $q \le j$ bounds the correction by $C|\nu|\delta_kL^{j-k}$. Decrease c_ν so that this is less than half the old correction radius c_3a_0 on the common disc, using $\alpha_kL^{j-k}/a_0 \le C$ uniformly in $j \le k$. On an addressed old domain in $\square^{\sim 2}$ the window theorem's normalized core readouts and the two hereditary tower readouts are holomorphic and bounded on that correction disc. Their Cauchy estimate gives eq. 4.cxliv. The independent input current is used by the decoupled response; the output current of the inner box is its constrained current.

At a physical real critical endpoint use the nested restriction on the constant-layer box, or on its truncated sequence. The box rows determine every ambient row affected by extension by the unchanged exterior. Any bond inside the box in a crossing plaquette is a fixed row of level zero. Hence such an extension preserves the ambient constraints and changes only the action of the inner plaquettes. The restricted field is critical, and regular uniqueness identifies its orbit with the box

orbit over its own datum. This applies at the upper and old critical endpoints with their respective towers. At other points the box reading is the prescribed continuation from the row family. The two removed terms use their assigned endpoints, response differences and core estimates.

The lower rows at the edge of the window box. Write $D_q(c)$ for the bare read set of the order-q average at a row $c \in \Gamma_q$. It is contained in the two centered blocks of side L^q with centers at the endpoints of c. Indeed the one-step contour averages, pivot and two block transports use only the double block. At the next finer level each site of those blocks is replaced by its centered block of children. Iterating gives the stated read set. In particular the mask is determined by the actual row, including those on the lower layers of the truncated tower. The second-kind holonomies are read from these rows by the tower rule.

Fix the background input, the node frame, the fine parameters and t as ν varies. A row whose $D_q(c)$ misses the support of the bond direction $\zeta_{\square}\mathbf{H}_k^{\mathrm{win}}$ is constant in ν.

The frame used for the fluctuation. Let E be the chosen representative of the upper box background and let $\mathbf{U}$ be the configuration of the input pair. The relative smoothing construction relates these two configurations. The single-lattice window construction in [B87, (3.24)–(3.29)] instead evaluates the response at the upper box field extended by $\mathbf{U}$ outside and carries the independent current. In that extension use the upper tower in the representative of its prescribed datum. The separation of its first two members leaves a bare rim inside the box. Each bare bond there is a determining row at level zero and hence already has the value of $\mathbf{U}$. Therefore a plaquette crossing the box face uses exactly the original links, including its links on the inner side. The same check applies to a stencil of fixed bare reach inside this rim. If one uses the real tower of the input real factor for the extension's real factor, the two also agree on the rim and the relative bond logarithms there are the original ones.

The same splice preserves every order-q row whose full double block crosses the box face. More generally, write W_i for the members of the inserted tower, with W_0 the box and $W_i = \varnothing$ beyond its depth. Consider rows with their full double blocks in the ambient first member. The average of the splice at a row c is the original one if c is retained in the inserted determining set, or if neither endpoint of c lies in W_{q+1}. For a retained row this follows from the prescribed datum and its full carrier in the box. For the second case, argue by induction over q. At level zero a bond that is not inner to the box is unchanged, and an inner bond of this kind is fixed by the bare datum. At positive level, a row with an endpoint in W_q is an inner retained row, since its endpoints avoid W_{q+1} and the layer gap fits its double block inside W_{q-1}. If both endpoints are outside W_q, their order-q blocks are outside W_q by alignment. Each input row in the one-step average then has no endpoint in W_q, so its value at the preceding level is unchanged. This proves equality on the prescribed nonlinear branch. The same induction works on the admitted complex row charts, because each unchanged read has the same full input. If a double block crosses the box face, an endpoint in W_{q+1} would put that block inside the box by the layer gap. This proves the asserted crossing-row equality.

For an auxiliary hereditary tower use the criterion on every row of its actual truncated determining set, including the rows at its top. If it holds, the full real and complex input data for that tower agree with the original data, so its chosen continuation and its current read are unchanged. This covers, for example, a containing tower of the same depth and the same monotone rule. For an arbitrary straddling tower a lower determining row can be wholly inside an active member of the inserted tower and use a changed average. Such hereditary reads still require admission and estimates. For the relative-frame rule write

$$w_0(x) = E(\Gamma_{y_0,x})^{-1} a_{\square} \mathbf{U}(\Gamma_{y_0,x}), \qquad w = (\mathcal{K}_{E,\mathbf{U}} + 1)^{-1}[(\theta_{\square} + \Delta\theta_{\square})w_0].$$

Here the anchor $a_{\square}$ fixes the frame at the base point, and $\mathcal{K}_{E,\mathbf{U}}$ is the mixed covariant operator on the frame. The inner fluctuation uses $\mathrm{Ad}(w)$ on the support where the frame is invertible. The regularity estimate for this frame concerns the input connection expressed in the box coordinates.

It is this estimate, together with the covariant response bounds, that is needed for the ordinary first-difference Hölder estimate. The comparison of the two representatives of the upper tower above uses the bound on their condition number.

At a real critical reference in the nested geometry, restriction to the box is critical at its own full tower datum. By regular uniqueness, $E = \mathbf{U}^g$ there for a real gauge g, with anchor $a_\square = g(y_0)$. Transport along any comb path then gives $w_0(x) = g(x)$. For the mixed connection $E(x,y)g(y)\mathbf{U}(x,y)^{-1} = g(x)$. It follows that $(\mathcal{K}_{E,\mathbf{U}} + 1)(\theta_\square g) = (\Delta\theta_\square + \theta_\square)g$ with the prescribed cutoff boundary values. Uniqueness of the smoothing equation gives $w = \theta_\square g$. Hence its adjoint action is the one of the physical gauge wherever $\theta_\square \neq 0$. This comparison applies to the whole real path of shifts from that critical reference on those carriers, since the frame is fixed before varying the fluctuation direction.

If a determining row c of level q has its complete backward carrier in that chart, its changed datum is

$$\mathcal{M}^q(\mathbf{U}^g)(c) = g(c_-)\mathcal{M}^q(\mathbf{U})(c)g(c_+)^{-1}.$$

One must use both node factors at every such row, including the lower rows. The old constrained configuration at the transformed full datum is read in its corresponding orbit. Holomorphic continuation of this identity uses normalized frame representatives and the regular logarithm charts on the complete carrier. In particular the real quaternionic normalization of w may be replaced in a complex chart by a local analytic determinant normalization. The adjoint action itself only requires invertibility. The endpoint identity does not supply invertibility where the cutoff is zero.

For complex inputs, keep the operator on the same box and with the same boundary condition as at the real reference. Put $\mathcal{K}_0 = \mathcal{K}_{E_0,\mathbf{U}_0}$, $G_0 = (\mathcal{K}_0+1)^{-1}$, $\Delta\mathcal{K} = \mathcal{K}_{E,\mathbf{U}} - \mathcal{K}_0$, and $F = (\theta_\square + \Delta\theta_\square)w_0$. Subtract the equation for $\theta_\square g$ at the real reference. The identity is

$$w - \theta_\square g = (I + G_0\Delta\mathcal{K})^{-1}G_0\big[F - F_0 - \Delta\mathcal{K}(\theta_\square g)\big].$$

To obtain a uniform complex frame from this identity, one can bound $G_0\Delta\mathcal{K}$ by $1/2$ in the sup operator norm on the box. On a carrier with $\theta_\square \geq \theta_* > 0$, a sup bound $\theta_*/(4\sup\|g^{-1}\|)$ over the whole box for $G_0[F - F_0 - \Delta\mathcal{K}(\theta_\square g)]$ gives $\|(\theta_\square g)^{-1}(w - \theta_\square g)\| \leq 1/2$ there. The inverses in the formula and on the carrier then follow by convergent Neumann series, holomorphically and with a uniform condition number on that carrier. We must prove the operator and residual estimates on the admitted complex input sections, with a matched reference in the perturbation range and bounds uniform in the lattice spacing. The first-difference Hölder estimate also uses the relative-frame regularity in the box connection. Near a vanishing cutoff the assigned outer reads are part of the localization rule.

The cutoff on the baseline field. In the single-lattice formula both the baseline and the extra window direction are cut off. To compare the baseline with the one in eq. 4.cxlii, let $\chi_\square$ be one on $\square^{\sim 3}$ and supported inside the box. With the same fluctuation field in the same box frame, join the two baseline choices by

$$\mathbf{A}_v = \big(t[\chi_\square + v(1-\chi_\square)] + \nu\zeta_\square\big)\mathbf{H}_k^{\mathrm{win}}, \qquad 0 \leq v \leq 1.$$

With fixed room in the sup bound for the window field, this path stays in the inner substitution disc. On a level-q row the derivative of the plain logarithmic datum in v has size at most $C_R\delta_k L^{q-k}$. It vanishes whenever the complete double block lies in the plateau of $\chi_\square$, since there the bare product is independent of v. For an inner read contained in $\square^{\sim 2}$, all remaining source rows are separated from the read by at least cML^{k-j} in the old weighted distance, after reserving the fixed stencil reach. Indeed the distance through the physical margin is at least cML^k in bare units and the old tower uses spacings at most L^j. Integrating the weighted source estimate along the path gives the old potential and its first differences an error bounded by

$$C_R\delta_k L^{j-k}\exp(-cML^{k-j})$$

in old units on the inner read. For the constrained current in this same exponential representative, first pass the plain row difference through the local naturalizer. Its stencil enlarges the source support by a fixed reach and preserves the distance bound with a smaller constant. At the flat reference the current of the reconstructed field is $\mathsf{f}(-i\xi\,\mathrm{ad}_{\mathbf{H}})^{-1}\mathbf{F}^{\flat}$ at full old switches. The reduced first variation $\mathbf{F}^{\flat}$ has the same weighted source estimate as $\mathbf{H}$. Taking the difference of this product, the inverse acts bond by bond and its difference is bounded by the local difference of $\mathbf{H}$. This gives the same bound for the normalized constrained current on the inner read. This argument treats the baseline-cutoff change inside the fixed old box. The window identity retains the removed difference and uses the assigned domain and box pair on each of its other segments.

The change of localization and its sum rule. For an old member F, denote its original domain response along the source interpolation by $P^{\mathrm{dom}}(t,u)$. For a near window the source's two removed segments go from P^{dom} to its prescribed intermediate pair and from that pair to the frame-dependent inner pair P^{in}. Calling the intermediate pair P^{mid}, at fixed path parameter the restoring identity is

$$\partial_u F(P^{\mathrm{dom}}) = \partial_u F(P^{\mathrm{in}}) + \partial_u\big[F(P^{\mathrm{dom}}) - F(P^{\mathrm{mid}})\big] + \partial_u\big[F(P^{\mathrm{mid}}) - F(P^{\mathrm{in}})\big].$$

Use the fundamental theorem of calculus on each removed segment before differentiating at zero. The assigned current is carried as a component of the pair throughout the interpolation. Each removed direction uses its own full carrier and complex disc.

For the common pointed sum, apply this identity to each member and to its own tent, then add before the fine bracket. For the resolver on the prescribed box, include the complete box reads of the frame and the old inner carriers in the base. This uses a fixed number of current cubes. The locality estimate uses this base for the entire relative-frame construction. For the source's local fields, restriction to the wall component of the base gives the same field on that component. Once the whole frame read set is in the base, the hereditary restriction in the source rule therefore gives the same inner function on the smaller ambient domain. The finite resummation of the brackets recovers the physical sum, and the two differences restore its original domain response. This argument permits a common-base grouping of the complete localization and preserves its summed physical action difference.

For eq. 4.cxlii we must use the smoothed frame on the full carriers where it is admitted and the assigned outer-layer readings elsewhere. The cutoff can vanish on outer carriers. The frame, old endpoint data and both removed directions must therefore come from one localization rule on the bracket's actual complex domains. The same choice is required at both depths in the comparison.

It follows from eq. 4.cxli–eq. 4.cxliv and the fixed room that there is a constant $c_\nu > 0$, independent of j,k, such that the admitted inner substitutions have the common disc

$$|\nu| < \mathcal{R}_\nu = c_\nu/s_k. \tag{4.cxlvi}$$

Indeed choose c_ν so that $C_R c_\nu C_{\mathrm{age}}$ is smaller than half of every fixed room. eq. 4.cxliv then keeps each substitution inside its assigned domain. This argument verifies an inclusion using the actual input-domain estimates; it does not extend functions to unions of complex gauge orbits. We take $s_k < c_\nu/2$, so that $\mathcal{R}_\nu > 2$.

Third, the critical box-background maps in eq. 4.cxliii obey the weighted first-response, Hölder and compatible boundary-comparison estimates used in the nonlinear pointed window theorem. The complete fields on eq. 4.cxlvi, including the unperturbed field, have output size at most $C\alpha_k$. The central axial datum is bounded by $C\alpha_k\sigma_j$. Its half-datum-ball condition holds when $C\rho_j\sigma_j$ is sufficiently small, which fails at most at a fixed finite set of young ages by eq. 4.cxli. The remote datum has only an absolute $C_M\alpha_k$ bound. Use the fixed continuation radius and the once-for-all ceiling eq. 4.xxx to put the whole axial datum in its half ball. This ceiling is imposed on the upper input, the transported fluctuation and any raw correction throughout the discs of eq. 4.cxlvi, with the room already required in eq. 4.cxliv. The window stock satisfies it by reducing $a^{\flat} < a_I(M)$

after fixing M; no bound on the number of old levels is used. At the exceptional young ages the actual core memberships and the whole-core bound for a member's own tent action remain available. Finite boxes are treated first; their linearized boundary comparison is uniform in the bare mesh. Periodic or distant tails are retained with their stated exponential lengths.

Finally, assume the actual window identities and elementary localization geometry. The partition $\sum_{\square} \zeta_{\square} = 1$ is inserted along the direction of differentiation. For complete physical pairs the old action difference is the sum over windows of $\int_0^1 \partial_\nu|_0$ of its window evaluations eq. 4.cxlii–eq. 4.cxliii, plus the prescribed outer and removed terms. The same local formulas define their extensions at every local complex core. Equality with a global physical fibre integral is asserted only at complete physical pairs.

An inner window contains at most $C_M \sigma_j^{-4}$ old base points. At a fixed base point the number of old domains of tree length between m and $m+1$ is at most $C_D e^{\kappa_D m}$. Diameters are bounded by $C_M(1+m)$, and the input decay rate has a fixed surplus over κ_D. Thus every fixed polynomial diameter factor is summable. An outer field has the additional decay from its distance to the window, while a removed field has the factor e^{-cM/σ_j}. On the assigned single-lattice charts the bounds in the member's local pair norm on the complete $X^{\sim}$ are

$$C_R \delta_k \sigma_j \begin{cases} e^{-\delta_F \mathrm{d}(X,\square)}, & \text{outer cutoff direction,} \\ (1+|w|)e^{-\delta_F M/\sigma_j}, & \text{each removed segment direction.} \end{cases} \tag{4.cxlvii}$$

Here w is the removed term's direction parameter with $|w|\delta_k$ small. For the directional estimates we use admission in the old core on the respective parameter discs, with a fixed fraction of its radius available along each segment. Long input domains retain their original tree decay: one fraction supplies e^{-c_κ/σ_j}, and the remaining fraction supplies the declared output spatial rate. Here $c_\kappa > 0$ comes from tree length in M-cubes and the allocated input rate. When these long-domain tails are written together with removed-response tails as e^{-cM/σ_j}, the fixed c is allowed to depend on M and the input rate; it is not asserted independent of them. These are geometric and response hypotheses, not bounds on the value of an old member.

Renormalize the critical inner function first. Let an old regular member have norm g_j, be gauge invariant and Euclidean as a pointed total, and have its own coefficient b_j. At every base point remove its vacuum value and $b_j A(h_z, \cdot)$ before bracket interpolation. The pointed Hessian theorem fixes this coefficient by the unit normalization of the same tent action. Site-frozen members may differ at different base points: the argument uses each member's own hypothetical Euclidean family and its own coefficient. No translation invariance of that array is required.

For $j < k$, here is the quantitative window estimate on eq. 4.cxliii. The axial field near a base point has linear constant-curvature part of size $C\alpha_k \sigma_j^2$. The Hölder and nonlinear response errors have sizes $C\alpha_k \sigma_j^{2+\alpha_H}$ and $C r_{B,j}^{-1} \alpha_k^2 \sigma_j^4$, respectively. Cauchy's second and third derivatives of a member cost $C g_j/\alpha_j^2$ and $C g_j/\alpha_j^3$. The linear derivative vanishes by constant-color invariance. The quadratic value on the affine part is canceled on the whole pointed total at that base point by the member's own tent action. No coefficient is assigned to an individual domain X. The individual Taylor remainders have a fixed polynomial in $D = 2 + \mathrm{diam}_j X$ times their original spatial decay; the domain count above sums these polynomials. Multiplying the remaining errors therefore gives, at one base point after this domain sum,

$$C g_j \left[\rho_j^2 \sigma_j^{4+\alpha_H} + \rho_j^3 \sigma_j^6 \right]. \tag{4.cxlviii}$$

This is the local Taylor argument on the constrained critical box pair, with its uniform weighted response sums. When its local Cauchy-size parameter is large, the whole-core bound and the own-action bound give the same estimate after increasing that summable polynomial, since $1+T^2 \le CT^3$ for $T \ge 1$. Any fixed finite set of young ages failing the central half-datum-ball test is handled by the same whole-core bounds; their scale ratios have a fixed positive lower bound. The remote

absolute-domain condition is retained separately. The resulting constant is independent of the number of old levels.

Now sum the $C_M\sigma_j^{-4}$ base points. Because $\rho_j \geq 1$, $0 < \alpha_H \leq 1$, and $\sigma_j \leq 1$, the renormalized inner window function has bound

$$Cg_j\rho_j^3\sigma_j^{\alpha_H}. \tag{4.cxlix}$$

Truncating the pointed total at the enlarged window contributes only the long-domain tail already set aside in the geometry. It does not replace the pointed total by an unnormalized individual term.

A defect or an aged remainder has no coupling counterterm. After its value at the identity is removed, constant-color invariance still eliminates the linear derivative, provided there are no fixed color spectators. The vacuum-only window argument gives at one base point, after the same polynomial domain sum, $Cd_j\rho_j^2\sigma_j^4$, where d_j is that origin's norm. The large local-size case uses $1 \leq CT^2$ for $T \geq 1$. After the base-point sum its inner bound is

$$Cd_j\rho_j^2. \tag{4.cl}$$

Stored-field boundary origins are not included in this statement. Their spectators and their hull geometry need the separate boundary formation estimate.

At $j = k$ no age improvement is needed. The vacuum-normalized old member together with its own action has whole-core norm at most Cg_k, by the coefficient bound $|b_k| \leq Cg_k/\alpha_k^2$ and the core bound on its tent action. The actual fluctuation change has size $C\delta_k$ within a core with fixed analytic room $c\alpha_k$. Cauchy's inequality therefore gives Cs_kg_k, with its original spatial decay. There is no fine-volume age factor at this level. This is the term with weight ω_1; no cancellation between different current-level domains is used for it.

The one small factor and the outer terms. Fix $t \in [0,1]$ and the fine parameters. Subtract the window function's value at $\nu = 0$. It vanishes there and is holomorphic on eq. 4.cxlvi. The bounds in eq. 4.cxlix–eq. 4.cl hold on that whole disc. Schwarz's lemma, or Cauchy's formula for its derivative at zero, therefore supplies precisely one factor $1/\mathcal{R}_\nu \leq Cs_k$. The actual window formula uses that derivative and its integral over t; the interval has length one. Thus an old regular inner term contributes $Cs_kg_j\rho_j^3\sigma_j^{\alpha_H}$, and a vacuum-only origin contributes $Cs_kd_j\rho_j^2$. No second amplification factor is extracted later.

The outer direction and the two removed segments. Use the potential and the reduced current together in the norm for the old member. The unamplified domain field has size $C\sigma_j\delta_k$, and the directions obey eq. 4.cxlvii. These core estimates can omit the Hölder quotient. Use the current specified by the interpolation along each segment.

For the outer direction, at an admitted unperturbed point with fixed old core margin, the normalized shift stays in that margin on an affine multiplier disc of radius $ca_0(\sigma_j\delta_k)^{-1}e^{\delta_F\mathfrak{d}(X,\square)}$. Cauchy's estimate therefore gives the outer smallness and the distance factor together. If the window is near X but X leaves $\square^{\sim 2}$, use the spare old-domain length factor instead. For a removed segment use $|w| \leq 1$. On the admitted core the difference between its endpoint values of a member of size g_j is bounded by

$$Cg_je^{-\kappa d_j(X)}\frac{\sigma_j\delta_k}{a_0}e^{-\delta_F M/\sigma_j}.$$

This follows by integrating the old-field derivative along that segment, with the fixed fraction of the old radius available for Cauchy's inequality. A Cauchy estimate in w on the circle $|w| = 1/2$ gives the same bound for the directional derivative at zero. The two endpoint differences telescope at real physical arguments, with the exact domain and box endpoints of the window identity. The fine-cube brackets use these bounds on the entire parameter discs. This argument needs the bounds on the assigned segment directions and endpoints. The unamplified determining rows use the preceding comparison. After the fine-site count the bound is

$$Cs_kg_j\rho_j\sigma_j^{-3}e^{-cM/\sigma_j}. \tag{4.cli}$$

The same reasoning applies to a vacuum-only origin with g_j replaced by d_j. For $0 < \sigma \le 1$ and $\rho \ge 1$,

$$\rho\sigma^{-3}e^{-cM/\sigma} \le C\rho^3\sigma^{\alpha_H}, \qquad \rho\sigma^{-3}e^{-cM/\sigma} \le C\rho^2. \tag{4.clii}$$

Indeed the suprema of $\sigma^{-3-\alpha_H}e^{-cM/\sigma}$ and $\sigma^{-3}e^{-cM/\sigma}$ are finite. Any fixed additional polynomial from spatial summation is absorbed in the same way, by decreasing the exponential rate once. Long-domain tails are treated with their retained tree decay and the same elementary inequality. This proves the ordinary outer and removed bounds without applying the pointed cancellation to an arbitrary pair (U, J).

The sum of the removals on a capped window. For the native near unit whose own padded box fits the box-read class, one can estimate the two removed terms together. This class has $\nu \ge 3$ and its axial-datum majorant is strictly smaller than the old box radius $\alpha_{3,j}$. Use the same capped determining set at both endpoints. At the inner endpoint use the averages of the cutoff layered field. At the other endpoint splice the inner prescribed row datum with the rows read from the domain response. In the splice the exact nonlinear relative average $Q_\star$ uses both endpoint factors. The cutoff mismatch vanishes on each full double block in the plateau. For the splice itself, the capped and old determining sets agree on the complete row reads wherever the splice weight is nonzero. The old response has its prescribed row datum there, so the two relative logarithms being spliced are equal in the same node frame. Outside the splice the datum is read from the response itself. Thus on the complete capped set the second endpoint is the box restriction of the domain response over its own datum. This identification uses all rows of the splice, with the old current read in the same chart.
